LIGHTING - Yes you do. They require light right up until harvest. It provides direction for growth. In fact, many species such as oysters will turn into a mass of coral without adequate light. Shiitake won't grow at all. Cubes without light will twist around, not knowing which way to grow. Performance will suffer. 12/12 right up until harvest is the proper procedure.

LIGHTING - Even MH is at the 'red' end of the spectrum, just not as red as the old SV or HPS. MH has a color temperature of around 4,000K and HPS is around 2000K, but cool white fluorescent is 5,000K and natural daylight fluorescent is 6500K. Regular household light bulbs are around 3000K. The higher the color temperature in Kelvin, the more 'blue' the light is.

LIGHTING - I've measured many flushes of various species on a day to day basis and found that most mushrooms grow more during the period of darkness than during the period of light. The change in temperature caused by cycling the lights 12/12 is also positive. Mushrooms are not plants, but as said above, light does indeed have a major effect on them.

LIGHTING - The main pinning triggers are full colonization, an increase in fresh air that comes with the decrease in CO_2 levels, and a steady rate of evaporation from the substrate. Once those conditions have been met, light becomes a secondary pinning trigger. A few minutes of light will work, but 12/12 has been shown to produce superior product.

LIGHTING - That's why growers who use a very bright fluorescent light in the higher part of the color spectrum have much better pinsets and yields than those who use ambient room, or worse yet, only a few minutes a day of dim light. The light should be bright enough to penetrate well into the casing layer, which should also be loose and airy.

LIGHTING - Light is only a secondary pinning trigger, not the main one. Full colonization of the substrate, with an increase in air exchange are the two biggies. For best results, all the pinning triggers should be introduced at once. You'll have to say more than 'kit' to get help, and 'dirt' is what you get under your fingernails. Mushrooms don't grow on it.

LIGHTING - Light at the higher end of the spectrum is far superior to light at the low end of the spectrum. Incandescent light bulbs with a color temperature of 3,000 kelvin are considered 'red', and natural daylight fluorescent with a color temperature of 6,500 kelvin are considered 'blue' which is superior. Search the above terms for much more.

LIGHTING - Lots of people are satisified with 'less' light. It's just that if you want the best possible results, go with the best of all possible setups, which means best light, best substrate, best temperature, best humidity, etc. By all means if anyone is satisfied with less, go for it. Many of use raise growing to an artform, but not all. To each his own.

LIGHTING FRUITING - Just use a plain fluorescent bulb, and keep it above the terrarium, not inside it. Heat isn't an issue that way. As said, there's a big difference between short wavelength light(blue spectrum) and a light that makes your walls 'look' blue. However, the whole blue light thing is overrated. Use a full spectrum lamp.

LIGHTING - All you need to do is rotate your tubs every day or two to offset the light from an angle. Even if you don't, it's cool to see them grow towards the light. There's really no reason they need to grow straight up, and growing at an angle actually gives the caps more room to spread out without interferring with each other.

LIGHTING - What you're giving is great. There are no hard and fast rules. Some experienced folks give more light, some less, but all get great pinsets, so don't worry too much about light. A few hours a day is fine, so placing your project near a window where it gets diffused sunlight, but no direct sunlight is ideal.

LIGHTING - You want lights that are high in the color spectrum, thus a color temperature of 6500 to 7000 Kelvin works great. It will look bright white to your eyes. Christmas lights are a poor choice. They do have some full spectrum LED's out now, or you can use 'natural daylight' compact fluorescent lamps.

SMART FRUITING CHAMBER LIGHTING - If a light 'looks' blue to your naked eye, it means the blue has been filtered out of the spectrum. It's counterproductive. The blue light is at the high frequency end of the spectrum. The best source of blue light, if you want to experiment, is a Metal Halide lamp.

LIGHTING - Incandescent is never recommended for mushrooms. Incandescent lamps emit a red light that is at the opposite end of the spectrum from what mycelium prefers for primordia formation. Use fluorescent, preferably 'natural daylight' tubes with a color temperature above 5,000 Kelvin.

LIGHTING FC - Higher intensity light helps deliver a better pinset than lower intensity light. A few hours is cool, but most growers report better success with 12. The darkness time need not be total darkness. Turning on the light to see what you're during your mushies 'night' won't hurt anything.

LIGHTING - They never need total darkness at any time. Ambient light is fine. 'We' don't say mushrooms require only a small amount of light to grow however. Depending on the species, the results on pinset and performance from much brighter lights is well documented.

LIGHTS, IN OR OUT OF FC/MARTHA - The problem is when the lights are turned off, they will draw in moisture as they cool, then will be wet inside next time they're turned on. It's best to keep the lights outside of the terrarium or mini greenhouse unless they're battery operated.

LIGHTING - And natural daylight fluorescent takes it a step higher than cool white. They're the best of all. Warm white=3000K, cool white=5000K, and natural daylight fluorescent=6500K. The higher the light temperature in Kelvin, the higher the frequency, or closer to blue light.

LIGHTING - I use four 4' natural daylight 6500K fluorescent tubes for my mini greenhouse. It works like a charm. The important thing is to keep the humidity to as close to 100% you can get while still allowing plenty of air exchange. All three are important pinning triggers.

LIGHTING - I've found the brighter the better. You might even move the cakes to where they can get some diffused sunlight each day. Even direct sunlight for a few minutes is a good thing. You might try some damp verm on top of the cake too. That seems to help with pinsets.

LIGHTING - 5100K is fine. I think 6,500K to 7,500K is better, but when you compare to incandescent bulbs which burn at 3,000K, they're way better. Definitely, you don't want red. You also don't want any sort of colored cover over the bulb, and that includes blue.

LIGHTING - If it's a 'kitchen and bath' fluorescent, it probably has a color temperature of 3,000 Kelvin, just like incandescent. It will still work, but possibly not as well as 'natural daylight' fluorescent. Put it right up close to the fruiting chamber, but not inside.

LIGHTING - 12/12 is optimum, as is light at the high end of the spectrum. For the best bang for your buck, get natural daylight fluorescent tubes and run them 12/12. Mushrooms grow and hyphal knots form primarily in the period of darkness, so 24/7 is a mistake.

LIGHTING - To repeat, light is a pinning trigger, but it isn't the only one, and it's greatly overrated. For the best pinsets, you have to balance several triggers at once. Screw up on any of them, and pinsets suffer, regardless of what you do with light.

LIGHTING - Light has no effect on colonizing mycelium. The information from twenty to thirty years ago to keep them in the dark is just plain wrong. Light is not a pinning trigger until full colonization and a reduction in ambient CO_2 levels.

LIGHTING - You want bright fluorescent light in the high frequency range. Look for 'natural daylight' tubes or whatever they call them in your country. They should have a color temperature of 6,000 Kelvin to 7,000 Kelvin for best results.

LIGHTING - NEVER use 24 hour light. They grow and form primordia during the period of darkness. Attics are usually horrible places to grow due to wild temperature swings. Light is required for primordia formation as well.

LIGHTING - 12/12 from a high spectrum fluorescent, such as 'natural daylight' tubes with a color temperature of 6,500 Kelvin, will outperform other sources unless you have a bright south window. Avoid direct sun.

LIGHTING - Incandescent is the worst possible light for mushrooms. While it might 'work', you'll get much better performance and pinsets if you'll screw in a compact fluorescent instead of an incandescent light bulb.

LIGHTING - Cool white fluorescent gives the most bang for the buck in my experience. You'll definitely see an increase in pinning activity with metal halides, but they use a lot of energy and produce a lot of heat.

LIGHTING - CFLs use a tiny fraction of the electricity an incandescent bulb uses to produce the same amount of light. If you buy a CFL for mushroom growing, look for one that says 6,500 K on the packaging.

LIGHT - Light has absolutely NOTHING to do with telling the mycelium that it has reached the surface. The increased fresh air, with the corresponding drop in CO_2 levels sends the mycelium that message.

LIGHTING - Lighting is extremely important, and it's important to provide it at the right light temperature and intensity. Look for tubes with a light temperature above 5,000K.

LIGHTING - A 13 watt cfl does not produce 60 watts. It produces the lumens a 60 watt incandescent bulb does, but at a higher frequency, which is better for pin formation.

LIGHTING - I'd check the manufacturer website for that info. You can get a 6500K fluorescent fixture and tube for under twenty dollars at your local home megacenter.

LIGHTING - Diffused sunlight through a window is great. In fact, five to ten minutes of direct sunlight will often get a stubborn substrate to begin pinning.

LIGHTING - Bright light stimulates pinning. The light has to be bright enough to penetrate the casing layer. Dim light will result in poor performance.

LIGHTING - Warm white=3000K, cool white=5000K, and natural daylight fluorescent=6500K. The higher the light temperature in Kelvin, the higher the frequency, or closer to blue light.

LIGHTING - Fluorescent lighting is great. Look for a color temperature in the 5,000K to 7,000K range. UV light is bad for mushrooms.

LIGHTING - For those of you who have a project that 'just won't pin' try switching to natural daylight fluorescent and watch them take off.

LIGHTING - You don't need a light right on the tub. You can have it near a window(recommended), or use just a regular ceiling light.

LIGHTING - That would explain the no pins. You want a light at the other end of the spectrum. I'd suggest fluorescent tubes.

LIGHTING - I use four 4' natural daylight 6500K fluorescent tubes for my mini greenhouse. It works like a charm.

LIGHTING - You don't want blue. You want full spectrum. That means they will look white.

LIGHTING - Light is a secondary pinning trigger, once full colonization has been reached.

LIGHTING - Any cfl would be better than an incandescent light bulb.

LC/AGAR/CLONING/STERILE PROCEDURE/HELP/PROBLEMS/OTHER

AGAR - Put a lid on the jar that has been drilled and fitted with a filter. In other words, if you're using a jar, treat it like a grain jar. I use a whiskey bottle with a filter in the lid for agar because it's easier to pour. Pour the dishes after the agar has cooled, but before it's solidified. I wait until I don't need an insulated glove or pot holder to protect my hands from the heat. This will prevent condensation. Pour the dishes in a vertical stack, and then slip the sleeve back over them as protection while they cool. The agar will settle out until after pressure cooking. Just before pouring the plates, give it a stir. By the way, you can PC any sealed container, except some plastic bags. I routinely PC water in jars and also test tubes of agar that are tightly sealed. They don't blow up. Pressure inside the jar and outside is the same, therefore there is little to no differential between them. Just don't do something stupid like pop the weight off the PC at the end of the cycle and you can seal jars just fine. Agar being sterilized for Petri dishes in a jar or bottle should get a filtered lid, as I said above. You can use jars as Petri dishes, but you'll tire of it quickly. They're much more of a pain in the ass to work with than Petri dishes. Many growers new to agar use their jars, but once they switch to Petri dishes, they don't go back. A simple strain isolation series can easily generate fifty or more dishes working simultaneously, and that's a LOT of jars to keep stacked up.

AGAR - A few years ago, I ran several experiments to prove/disprove stamets' theory that if you clone very young healthy pins, the hormones that stimulate pinning are active, therefore the mycelium that grows from those pins will in turn produce better flushes with abundant primordia and fewer aborts. These pins were not sterile by any means, yet they were layed on the agar and the rapidly expanding mycelium simply overran any bacteria or molds that may have been present. You wouldn't get that same performance from a large fruit that was fully mature. Of course, I would never transfer those sections to grains because of dormant contaminant spores that may be present. Instead, a small piece of mycelium from the leading edge should be transferred to a new dish, which once grown out for a few days can then inoculate up to ten quart jars, or be transferred to LC to grow out the isolated strain for even larger inoculations. It was inconclusive on the hormone thing. This was already an isolated strain and an excellent performer. If anything, it may have pinned a day or two sooner, but there's too many other variables involved to be able to attribute it to just the hormones. Use pins. The pins grow very aggressively to eat for lunch any contaminant spores that might be on them, a large already slowed down fruit will not. I used Gentamicin Sulfate.

AGAR/ISOLATES - The hot agar is a way to isolate away from contaminants. It's mostly used when cloning wild mushroom tissue that is infused with bacteria and molds within the mushroom itself. You pour the piping hot agar over the contaminated culture until it's completely covered with agar, and then watch it carefully over the next few days. The bacteria and molds are 'pasteurized' by the hot agar, but in this case, the mushroom mycelium is more resillient and begins to grow up through the top layer of agar, reaching the surface in 48 hours or so. Shave off the mycelium with a scalpel as it appears on top without taking any of the agar. Do this with each growth that appears on top as soon as you see it, preferably within an hour or two of its appearance. This tek separates healthy mushroom mycelium from the contaminants. After the transfers, each dish is inspected under the microscope to identify perfect vs imperfect fungi. The molds are tossed out and the mushroom mycelium is kept.

AGAR - Do not turn them upside down. As workman said, keep temperature swings to a minimum. Keep the dishes in a vertical stack, and usually only the top one will have any condensation after a few days. It also helps if you wait to pour the Petri dishes until the agar has cooled enough that it starts to thicken. You won't need heat protection for your hands at this point either. This is the best way to avoid condensation. Always colonize agar at normal room temperature. You'll need to transfer away from contaminants as soon as they're noticed. Antibiotic agar will help with bacteria if you're attempting to clone outdoor wild mushrooms, but the antibiotics aren't needed when working with indoor clones or spores.You want to wrap Petri dishes with parafilm. It breathes, yet has a pore size that prevents contaminant spores from entering. Without parafilm, the slightest temperature variation will cause contaminants to be drawn into your dishes, where they might remain dormant until you spawn the agar to grains, at which time you'll wonder where all the green came from. I would imagine micropore tape would work also. Some growers use Glad cling wrap. I use Parafilm.

POURING AGAR - Don't disturb them unnecessarily. Over time, the excess water will replace moisture that evaporates from the dish. The moisture is caused from the inside of the dish being warmer than the outside.
When you pour agar, let it cool until it begins to thicken a bit. You want it to cool in the bottle you sterilize in, not the Petri dishes. When cool enough to pour without heat protection for your hands, fill your Petri dishes, and leave them stacked in a vertical pile. This will equalize the temperatures between the dishes and reduce condensation to a minimum. If you don't have a flowhood, you should slide the plastic cover back over the stack to enclose them as they solidify.
An excellent bottle for agar is a used whisky or other liquor bottle with a long neck and screw on lid. You can use polyfill or a synthetic filter disk cut to size in the lid. Just drill a 1/4" or larger hole in the lid. Cover with foil and PC. The filter will keep the agar from contaminating as the PC cools and until ready to pour. Don't remove the foil until just before you pour the dishes.

AGAR - In a glovebox you can easily get a tiny piece of good mycelium from that dish and move to a fresh one. Get the mycelium from the opposite side of the dish to the contaminant. Once you have the mycelium on a new dish, about two to three days later, you'll see the mycelium crawling off the wedge to the new agar. At this point, transfer a tiny piece of the fresh growth to a new plate. If you make the second transfer before the mold germinates, you now have a clean culture. If not, continue doing transfers until you get ahead of the mold. It's easy to clean up cultures from contamination on agar. You need to wrap your dishes to prevent contaminants getting under the lid. Remember, any time the air temperature in your room changes, the agar expands and contracts, forcing air in and out of the dish. This causes contamination if you don't have a gas permeable wrap around the edges such as parafilm. Some growers use cling wrap with success, but I stick with parafilm. At any rate, get the edges wrapped. Good luck.

AGAR - One swipe of spores on agar will yield hundreds of strains. By selecting a dozen or so of the best rhizomorphic strains and fruiting each one separately, you can find the super performer that will cover every spot of your casing layer with healthy pins. It might take hundreds of multispore grows to find that strain, if ever, because multispore inoculated substrates usually end up with only one or two strains by the time they fruit because they've all combined. (anastomosis). This means the good fruiting and potent strains combine with the poor fruiting and bunk strains. You never know what you're going to get. Isolate on agar, then fruit separately and test each strain. When you find the best one, you can keep master slants in the refrigerator and grow that isolate forever.

AGAR - The reason you don't see rhizomorphs early on is because there's so many substrains active, they cover each other up. It usually takes two or three transfers to begin to see rhizomorphic growth. I'd transfer a tiny piece from each sector to new dishes. I usually make the first transfers as soon as the spores begin to germinate, when the total growth is the size of a dime or less. Repeat the process a few times. Don't try to isolate 'one' rhizomorphic growth. Instead, isolate as many as you can, and then fruit each one. Once you determine the best isolate, you can store it in master culture slants to use for years to come without degradation.

AGAR/TRANSFER - A Petri dish that is fully colonized is not one that I'd use to inoculate grain masters with, even if the dish was wrapped with parafilm. I'd suggest taking a small piece of mycelium from the Petri dishes, and use it to inoculate fresh dishes. Allow that to grow for a few days, and then grab a very tiny piece of mycelium from the leading edge of the new growth. Transfer that fresh mycelium to a third dish and allow to grow 2/3 of the way across the dish. This clean mycelium can then be used to inoculate up to ten 1 quart/liter grain masters, which can each inoculate ten more via grain to grain transfers.

AGAR - You simply lift the lid of the grain jar and drop the agar wedge in. Prior to that, wipe the surfaces of the Petri dish and grain jar with alcohol, flame sterilize the scalpel, wear surgical gloves that have been washed with alcohol, and work as fast as possible, leaving the agar culture exposed for only a few seconds, and the grain jar lid open no more than 2 seconds. It may be stating the obvious, but the use of a glovebox or flowhood should be considered mandatory. Let the mycelium recover from the wedge into the grains for a few days before you shake.

ISOLATING ON AGAR - Sometimes, even with a clean sporeprint, you'll get a bit of contamination on the dish along with the mushroom mycelium. This is easy to transfer away from, by taking a small piece of mushroom mycelium and moving it to a new dish. Always take mycelium from the leading edge of the growth because this is the farthest away from the contaminant. We also transfer individual sectors away from each other so individual strains can grow out to determine the best fruiting ones. When cloning wild mushrooms, there's almost always molds and bacteria present, so it takes several transfers to get a clean culture.

AGAR - It often takes a few transfers from the initial spore swipe for strains to differentiate. Take a series of transfers of pieces of mycelium from the leading edge of the circle of growth and transfer to new plates. As these start to grow out, you'll probably see some sectoring. Transfer each sector to a new dish, and continue until you have single sector isolates, and then fruit each one to find a few stellar performers. Be sure to keep them properly labeled so when you fruit out a great one, you can go back to the original Petri dish that you've stored in the refrigerator, to get an earlier version of it to propagate and store in a culture slant.

AGAR - The purpose of agar is to be able to isolate mycelium away from contaminants, and to be able to isolate strains. By inoculating and leaving, if contaminants are present, they'll germinate and get a head start on the slower growing mycelium. I'd wait until you get back to inoculate. Often, bacteria and molds will be growing along with the mushroom mycelium, and you'll want to be there to make transfers. Agar isn't for expanding mycelium, so don't allow a dish to grow fully out.

AGAR - A single swipe of spores from a print, or a couple drops from a syringe might generate dozens or more sectors. I'd suggest transferring all of them to new dishes. You don't want to just isolate one strain, because it might be a dud. Isolate several promising looking strains and then grow each one out to determine the one(s) you want to keep for perpetuity in master culture slants.

AGAR - Cool the agar until just before it's too thick to pour. In addition, be sure to stack the dishes in a vertical configuration for colonization. Temperature differential causes condensation, so both the hot agar, and also the heat produced by the mycelium will cause condensation. Stacking the dishes helps prevent condensation from the latter by equalizing the temperature.

AGAR - You'll be much more likely to inoculate with molds and bacteria using powdered material. The dry tissue can also be grown out on agar without spores, but it takes a lot of transfers and patience. I'd suggest antibiotic agar. You can use up to 15mg of Gentamycin sulphate per liter of agar to help control bacteria. You'll just have to isolate away from the molds though.

AGAR/LC - Can you get DEXTROSE (straight corn sugar) & LIGHT DRY MALT powder? Both can be had at wine & beer (home brew) places. If so? Level teaspoon of each, into quart water. Simmer on stove to dissolve, filter, pour in jars, PC 5 to 8 minutes & you should end up with a fluid that is a light golden beer color (no chunks or flakes).

AGAR - We don't use agar to expand the mycelium so large dishes are worthless. We use agar to clean up our cultures from contaminants in the two dimensional space of a flat plane. Therefore, smaller dishes are most efficient because you shouldn't leave a culture growing more than ten days or so on a dish before doing something with it.

AGAR - Never use a warming plate with Petri dishes. Leave them in the bag they come in until they are IN your glovebox or in front of a flow hood. Wrap with parafilm, four squares per dish as soon as you inoculate. There is absolutely no reason to worry about keeping Petri dishes in the dark. Light has zero effect on agar or colonizing mycelium.

AGAR/SPORES - Unless the spores were from a cap that just dropped them an hour or two earlier, it takes a bit longer to see growth. You might see something if you put the dish under a microscope, but it takes a few days after germination for them to thicken up enough to see with the naked eye.

AGAR - Always mix the dry ingredients first, then add a small amount of room temperature water and swirl it around until the powder is dissolved. Don't shake, just swirl. Then add the rest of the water and sterilize. Pour the dishes before the agar cools below 100F or it will begin to solidify.

AGAR - If two drops or even three land, it won't kill your plate. One is usually enough though, especially if you're doing strain isolations. Just be sure to put one drop on each of a dozen plates so you can isolate out a LOT of strains to find the best performer(s).

AGAR - Antibiotics such as Gentmycin sulphate will help protect against bacteria, but do nothing to slow down fungi such as trichoderma or the other contaminants of mushroom culture. Sterile technique is the key to avoiding contaminants of all kinds in our art.

AGAR - When working with wild prints, I'll often use antibiotic agar, and mix it with less malt. If you buy pre-mixed agar powder from fp or sporeworks, you can mix it a bit weaker than recommended. This will keep from feeding the mold and bacteria quite so much.

AGAR - Agar is for germinating spores and isolating strains from each other and away from contaminants. You can use agar wedges to inoculate jars, which you then use for grain to grain transfers to expand the mycelium. Agar itself isn't used to expand mycelium.

AGAR TRANSFER - You want the Petri dishes open the least amount of time possible. I follow the 5 second rule. Never allow a Petri dish or jar lid to be open for more than five seconds at any time. Never have more than one Petri dish open at the same time.

WATER, AGAR - Lake water works fine, as does bottled or even tap water. I use regular tap water for everything except mixing agar. The organisms in the lake water won't help as they'll be 86'd by the PC.

AGAR - Fungi is perfect bacteriological agar made from the correct Petri types of agar, has malt/peptone/yeast which is the best combo, and has alot more then those packets you get from those 10 dollar packets.

AGAR - Normally, the term nutrient agar is used to refer to agar that has blood or other ingredients to tune it specifically to bacteria, which is what we are trying to tune against. I recommend MEA.

AGAR - I don't remove it from the pressure cooker until it's below 150F, and I then wait to pour until I don't need any heat protection for my hands. That's about 115F or perhaps less. If you pour it too hot, you'll get a lot of condensation on your Petri dish lids.

AGAR - The moisture on the lid is caused by the temperature differential. Don't store dishes upside down. Inoculate as soon as the agar cools. There is no need to wait.

AGAR - If not the pre-mix, you'd want to get some bacteriological grade, light malt extract, dextrose (optionally) nutritionally yeast, and peptone.

LC/AGAR - I use extra water in the PC when doing agar or LC so the pressure will drop more slowly due to the thermal mass of the extra water.

AGAR - Yes. You can also transfer healthy mycelium away from the contaminant, thus cleaning up the culture.

LC/AGAR - Extra light malt, dextrose, nutritional yeast, gypsum. Makes the strongest growth.

AGAR - One fruit body MAY contain multiple sub-strains of the same original. Look into agar.

AGAR - Gentmycin sulphate makes a great antibiotic because it's autoclavable.

AGAR/PETRI DISHES - Glad cling wrap instead of parafilm.

CLONING - Often, the reason later flushes produce only a few larger fruits is because the pinning surface has been torn up by previous picking, and the few remaining spots to pin from are all that's left...thus larger fruits form. Cloning these does not insure you'll get large fruits next time. That said, large fruits are not desirable. Smaller fruits have more active product per gram than larger ones, so try to produce larger flushes of smaller fruits. When cloning, select a young, rapidly growing fruit for best results. You want a fruit that is rapidly dividing cells, so it will take off quickly on agar. I prefer to clone from clusters, because they'll tend to produce clusters on future flushes, giving the volume desired, but with smaller and more desirable fruits.

CLONING TEK - Just so you take the tissue from the center of the stem after tearing it open with your hands. Use a flame sterilized blade. You can probably skip the alcohol. The air inside the bag should be still. I do similar when cloning wild mushrooms on backpacking trips. I take several Petri dishes sealed up in a baggie, a clear trash bag to use as a glovebox, and a scalpel and alcohol torch. The scalpel is flamed outside the bag, then stuck in while still hot. When it cools, the clone is taken. Don't forget to wear latex gloves.

CLONING - You can pour iodine over the stem to kill live bacteria on it, but it's really not necessary if you rip the stem lengthwise first to expose tissue that has never previously been exposed to air, thus generally free of contaminants. Outdoor mushrooms should be dipped in iodine no matter what before cloning, but with indoor grown ones usually it isn't necessary. Don't use alcohol on mushroom tissue.

CLONING - It won't affect your pinset because that's related to your technique, but it's well known that mycelium cloned from a cluster will produce mushrooms in clusters. That's not just cubes either. Edible growers have noted this for decades. The best oyster strains have been cloned from wild fruits that grew in clusters. In other words, clusters are a genetic trait.

CLONING - You can use iodine, or better yet, just tear the stem lengthwise to expose virgin tissue in the middle, and then cut a tiny piece out from there that has never been exposed to air. Use a flame sterilized needle or scalpel to get the tissue.

IODINE CLONING - I get iodine from a local drug store. It says "10% iodine solution" on the bottle. I like it for cloning because it kills bacteria without stressing out the mycelium the way peroxide does. When you're cloning, you want the mycelium to grow as fast as possible, and peroxide shocks it, and then it has to recover before it grows again. As we all know, molds grow faster than mushroom mycelium, so we don't want to do anything to slow down growth.

CLONING INDOOR FRUITS - I should also mention, when cloning clean indoor fruits, no iodine is needed. Simply split the stem as shown in the video, and scrape a touch of mycelium out of the center where it hasn't been exposed to air. The iodine/betadine is perfect for cloning wild outdoor mushrooms that have all sorts of bacteria and molds growing in conjunction with them.

CLONING STRAIN - Small, rapidly growing fruits make the best candidates for cloning. If the mushroom has already matured, the cells have stopped dividing, thus it's not a good candidate. If you like clusters of fruits, clone from a cluster. If you like individual fruits, clone a loner.

CLONING BLEACH - I've cloned wild mushrooms before by dipping in 10% bleach for up to fifteen minutes to kill bacteria before placing on agar. The bacteria is killed, but not the mushroom OR mold mycelium that might be along for the ride.

CLONING MUSHROOMS - I often dip wild mushrooms, and dry mushroom tissue into a ten percent bleach solution before cloning, to kill off bacteria. The fungi survives just fine, but it kicks the bacteria out.

STRAIN ISOLATION VS CLONING - As for cloning vs strain isolation, they're not related. By the time a substrate fruits, hundreds or perhaps thousands of strains have exchanged DNA, either weakening or strengthening the mass. What you get is a 'heinz 57' that may or may not be that great because the weaker genes and the stronger genes(mycelium) have all combined. An example would be mixed breed dogs. We've all seen good examples and others that are dumber then hell.
Strain isolation on agar begins when the spores first start to germinate. I make the first transfers as soon as I can see mycelium growing from the point of inoculation, long before sectoring can be detected. By doing this, and by continuing to separate each individual growth, you can isolate mycelium prior to the process of anastomosis combining dikaryons into a single mass.
You don't isolate looking for one super rhizomorphic strain. You isolate down to single sectors and then fruit out each one to determine the best performer. When you transfer mycelium to a grain master, the original Petri dish the mycelium was taken from is placed into a clean refrigerator. By doing this, when you find the best performing strain, you then go back to your well marked Petri dishes, thus your original P1 culture. This Petri dish can be used to inoculate a few test tube slants that can be incubated for a week, then placed in cold storage. Whenever you need mycelium, a tiny piece the size of a grain of rice can be taken from the test tube and put on agar to grow out, while the test tube is placed back into the refrigerator. These stored test tube cultures preserve the low P value of your isolated strain for years.
I have a complete video tek on strain isolation and master slant preparation and use already filmed. I'll release it when I get the rest of the teks filmed, and editing completed. Hopefully soon.

ISOLATING STRAINS - Right. You isolate every single strain you can, and then fruit them all. While they're fruiting, the 'master' from each strain is in the refrigerator. After you determine the best performers, you go back to the appropriate masters and get them out. Those are the ones you transfer to culture slants for long term storage. Rhizomorphic mycelium tends to fruit better than cottony mycelium, but a single swipe of spores on agar is likely to generate fifty or more individual sectors(strains), and half or so of those will be rhizomorphic. Those are the ones I keep for fruiting, and discard the cottony sectors.

ISOLATING - Don't wait for the first dish to fully colonize. As soon as it begins to grow, transfer mycelium away from the point of cloning to new dishes. This way, you can isolate healthy mycelium away from contaminants. You won't be doing strain isolation on a clone, so don't bother looking for rhizomorphs. Just get healthy mycelium.

STRAIN ISOLATION - For strain isolations, you can't beat the three section dishes. You're only letting the mycelium grow for a few days before making the next transfer, so you can do three times the amount of work on each dish. The four section dishes are great too. I don't even order the plain dishes anymore.

CLONING/ISOLATING - Cloning a fruit from within a cluster will provide a strain that will produce clusters. It matters not which fruit you choose from within the cluster, but you'll have better success if you'll clone while they're still small and rapidly growing.

STRAIN ISOLATES - It's extremely rare for rhizomorphic isolates to be none fruiting.

LIQUID CULTURE - 1000ML LC a.k.a Liquid Culture
1%=1.92Ts
2%=3.84Ts
3%=5.76Ts
4%=7.68Ts
1%=0.64TB
2%=1.28TB
3%=1.92TB
4%=2.56TB

LIQUID CULTURE - Throwing spores into honey or karo has to be the worst possible way to make a liquid culture and I'll be glad when this current fad passes and folks can get back to established techniques. Just inoculate some grains or brf in the standard way and you'll be miles ahead. For those who wish to make LC for inoculation, here's a way to get 100 syringes full of inoculant in two weeks: 1) Inoculate a quart jar of rye berries or wbs with your spores. Upon full colonization, shake the jar to loosen each individual kernel. Be sure to give it the smell test to make sure it smells like fresh mushrooms. 2) PC a quart of distilled water in a jar with a filter disk or tyvek, etc. In a glovebox or in front of a flowhood, pour 2/3 of the quart jar of sterilized water into your jar of shaken grains. 3) Shake well and then pour the now mycelium rich water back into whatever was left of your jar of sterilized water. Use the jar lid to hold back the grains themselves from pouring out. You now have a full quart of highly concentrated mycelium water that can then be used as is, or diluted two or three times again, and used to fill syringes. Because the grains were shaken first, the mycelium is ripped into shreds and will be sucked through even small needles easily, although larger needles always work better for this. Remember, mycelium grows poorly in water unless under constant stir which oxygenates it. With grains, they colonize in two weeks or less because oxygen is throughout the jar in the spaces between the kernels.

LIQUID CULTURE - A glovebox is not advanced equipment. One can be made free with stuff around the house, so there's no need for people to work in open air or fecal and mold infested bathrooms and kitchens. There is also no way to generate 100 full syringes of liquid mycelium in very small pieces within two weeks from injecting spores into honey or karo. I'm sure if people blindly used the grain method I described above, many would still have problems too, because they're inserting unproved and possibly contaminated spore solution into grains, which also isn't proper mycological technique. However, agar can easily be poured in a glovebox, and the Petri dishes used to isolate healthy mushroom mycelium away from any contaminants in less time than it takes to even know if a karo LC is contaminated or not. That agar wedge can then be used to inoculate the quart(or pint) jar of grains, that can then be turned into at least 100 syringes, or used for g2g transfer to get ten jars the old standard way. In addition, after the water is poured out of the grain jar, it can be placed back on the shelf to re-colonize, and the process can be repeated again. I just strongly feel new growers are doing themselves a disservice when they simply inject spores into honey water and then sit there waiting for something to happen. At the very least, inject directly to grains so you can visually inspect the process. Perhaps Agar's lids with injection ports will help those who have never used grains to get off to a good start.

LIQUID CULTURE - You might want to read more than the last paragraph. I described a method to generate ten times as much LC in a shorter period of time without contamination. I'm not against liquid culture. I use it all the time. I'm simply dead against the idea of squirting a syringe into a bottle of karo/water. I insist on having at least some verification my LC is good before I inject a bunch of jars. The analogy of a new growers greatest fear doesn't hold water. If his pf jars contaminated due to contaminated spores/syringe, it does no good to have even ten gallons of contaminated LC on hand. If they contaminated due to his sloppy procedure, he's likely to have used the same sloppy procedure making an LC. In my posts, I always try to show a way to have the greatest possible success rate, not necessarily the cheapest, easiest or laziest method.

LIQUID CULTURE - Sort of, but if you want liquid culture syringes, all you have to do is grow out a quart jar of rye berries, and then when it's fully colonized, shake it well, and pour nearly a full quart of sterilized water into the jar. Shake well again, and then draw the myceliated water back out into syringes. As an alternative, you can pour the quart of myceliated water into a sterile gallon of water to dilute the solution. You'll then have enough liquid culture to fill a few hundred syringes, and it only takes two to three weeks to get to this point from spores. In addition, after harvesting the mycelium from the surface of the grains as described above, you can then still use the left over grains to inoculate ten to twenty additional jars of grains via grain to grain transfer in the traditional method.

LIQUID CULTURE/COLONIZED SPAWN JAR - You want a fully colonized jar of grains to start with. Add sterilized distilled water to nearly fill up the jar, then shake well, and draw the now myceliated water back out. This is far faster and more dependable than making LC from spores because you can smell the rye jar before using to make sure it isn't contaminated. In addition, a jar of rye colonizes in two weeks, and will make at least 30 syringes. You won't get that performance from karo water.

LIQUID CULTURE - You can harvest liquid mycelium from the rye or wbs several times. After shaking the jar of grains to break them up, you can pour nearly a full pint of sterilized water into the jar, then shake again. Since there are nutrients in the grain juice/mycelium, you only need to pull a small amount of this solution into each syringe. Finish filling the syringe with sterilized water, and the mycelium will grow into it, expanding by several factors within a week.

LIQUID CULTURE - The more air to a liquid culture the better. That's why experienced growers always use a magnetic stirrer running 24/7. This ensures the entire LC is constantly oxygenated. I still don't understand why growers are slowing down their work so much trying to grow liquid cultures in mason jars. You can expand mycelium at least ten times faster in grains than in liquid, AND you'll know if it's contaminated before you use it.

LC CONTAMINANT EYE - If it's snow WHITE. It's right. FOR LC If you don't stir or agitate one every day, myc gets to the top & forms little islands that turn to thick pancakes. As, it has better gas exchange on the surface. How, I test for LC contams, is to STOP stirring one. If anything grows on the surface that isn't snow white. It isn't RIGHT. Most often contams show up as light gray / light blue growing on the surface.

LIQUID CULTURE - In addition, many growers waste valuable time by injecting spores into sugar water. Many times, you don't know you have contaminants present until you use your 'lc' to inoculate grains or brf. By then, you would have long ago discovered the contamination and replaced the contaminated jars, had you been growing on grains or brf directly.

LC JAR - Every tiny exposure to unfiltered air, increases the chance of a contam getting in. After jars are cool. With polyfil in one hole, simply stick syringe needle right through tape on other hole, inject & tape (with sterile tape) over the existing tape. That minimizes external air exposure.

LIQUID CULTURE - I sterilize the water that will be used for the LC syringe. In a separate pan I boil the syringe for at least half an hour. Put a lid on the pot and leave the syringe in the boiling water right up until you're ready to go to work.

STORING LC - You can store G-1 LC in 5, 50 or 100 vials of sterile water (years & years). Any time you want G-1 pull a tube out of the Fridge & go for it. Either start a new LC with it, or go to grains, then G2G.

LC - If you allow LC to go longer than five days post eberbach, the mycelium begins to grow into a solid organism which is not nearly as effective to inoculate with as a few million individual colonies.

LC - 1/2 teaspoon light dry malt, 1/2 teaspoon corn sugar to quart water, simmer, filter, add to jar, add lid w/filter, PC 15 minutes, innoc, store at around 82F.

DON'T USE MARBELS FOR LC - FOR LC...Marbles tend to break glass and not have that swirling tornado twirl when using.

LIQUID CULTURE - In fact, I have liquid mycelium cultures stored in the refrigerator for years that are still viable.

INOCULATING WITH LC WBS - Drain the WBS much longer, if you inoculate with LC. (rids WBS of excessive moisture).

LIQUID CULTURE - People have used bottled fruit juice for LC for years. It requires no sterilization.

LC - LC's are very prone to contamination, if ever exposed to open air.

FLAVOR OF MUSHROOMS - You won't add anything to the substrate to change the flavor. Mushrooms are NOT plants and don't have a circulatory system. Mushrooms grown on straw don't taste like straw and mushrooms grown on a bible don't taste like paper, and mushrooms grown on horse manure don't taste like horse manure...you get the point.

CONTAMINATED NATURE MUSHROOMS - In nature, thousands upon thousands of organisms can inhabit the same square inch of soil, thus each has his own niche and they all work together in harmony like instruments in a band.
Since we have no way to duplicate this indoors, we use sterile culture where the only organism allowed to grow is the mushroom mycelium.
It's a common misunderstanding that a contaminated substrate means a contaminated crop, which is incorrect. By that definition, all outdoor mushrooms would be toxic, yet they are not. If our sterile culture

becomes contaminated, the contamination might kill off our mycelium, but will be of little harm to us. Eating mushrooms from a cake with green mold will NOT hurt anyone.

MUSHROOMS FROM CONTAMINATED SUBSTRATES - Every mushroom that grows in the wild grows in conjunction with molds. In fact, I don't think I've ever picked an oyster mushroom from a log in the forest that didn't also have trichoderma growing on it. That's how common trich is. In fact, trichoderma inhabits nearly every cubic inch of soil on earth except extreme deserts and the arctic. On page one of Paul Stamets 'Mycelium Running', he starts with this sentence: "There are more species of fungi, bacteria, and protozoa in a single scoop of soil than there are plants and vertebrate animals in all of North America". However, we can pick wild boletes, chaneterelles, agaricus, matsutake, etc., etc., from this mold infested soil, and eat them without getting sick. We can pick Cubensis from a nasty pile of maggot infested cow shit and eat it without getting sick. If you put blue cheese salad dressing on your salad, you're eating huge chunks of the penicillium mold, because it's floating in the dressing. It never ceases to amaze me the fear that gets spread on these boards over harmless molds. If your fruits were covered with yellow or brown molds, I'd say toss them, as you would any moldy fruit or other food. Likewise if they were wet and became rotten from bacteria, because bacteria can cause food poisoning. However, as I've said for many years, just because there's a spot of mold on a cake, does not mean the fruits growing from that cake are contaminated. Mushrooms do not have vascular systems like plants, and do not suck up contaminant molds or bacteria from the substrate. If the fruit is fine and healthy, munch away. And, for those of you who don't know, please stop spreading myths and fear.

SPENT MUSHROOM MYCELIUM - Once your mushrooms have fruited a few times, the substrate is used up. You can't replace it with more fertilizer, because mushrooms are not plants that uptake water and nutrients to create energy in the leaves. Mushroom mycelium, which lives in the soil, eats its food, therefore after a few flushes, the food is gone. If you have a straw and dung loving species, you can bury the spent substrate into some horse or cow manure in a shady spot outdoors. Keep it slightly moist, and in a month or two, you'll probably see a nice flush. If you have a wood decomposing species, do the above, but with hardwood chips and sawdust.

COOKING WITH MUSHROOMS - Next time you have a bunch of fresh cubes, cut off the stems and set them aside for another day. Take the caps and rub a little blue cheese or ranch salad dressing into the gills. Rub olive oil on the outside of the cap. Add salt and pepper to taste, then grill outside on the bbq until done(gill side up), usually only a few minutes, when the dressing in the gills starts to boil, it's done. It's hard to beat cubes for good taste when cooked. When raw, they're nasty as hell, just like any raw mushroom. The heat will degrade them slightly, but not much. Cook up about 50 grams of fresh caps and you'll be happy.

MUSHROOMS FROM CONTAMINATED SOURCE - Mushrooms from a contaminated cake are safe to eat. They don't 'absorb' contaminants from the substrate or all wild mushrooms would be unsafe to eat. If the mold or bacteria is on the fruit itself of course, don't eat it. It's common in the commercial industry to harvest fruits from contaminated substrates and send them to market. There are no health regulations against it because it's not a risk factor.

EATING MUSHROOMS - Getting nausea and the shits from eating raw mushrooms is not a sign that they were contaminated. It's very hard for our systems to digest raw mushrooms, thus it's normal for the body to want to puke them out. Raw mushrooms are not digested, thus you excrete them in much the same form as you swallow them. Therefore, getting the shits a day after tripping is also common.

MUSHROOM SUBSTRATE NEED - What do mushroom nutriment needs? SUBSTRATE: carbon / nitrogen ratio <17:1, nitrogen 2.6%, phosphorus 0.2-0.5%, potassium 1.5-2.5%, calcium 1.5-2.5%, available boron <2 ppm, available ammonium <10 ppm, soluble salts 3.0-5.0 dS/m. This suffices from spawning to cropping.

SPENT MYCELIUM - The reason is it's probably not out of food. It's old. You can't take some 100 year old dude and if you keep feeding him, he'll keep on living. It doesn't work that way. Things live for a given time, then die. It's nature.

KEEPING MUSHROOMS FRESH - I've used a combination of CO_2, Argon, and Nitrogen gasses, and they still rot. You need to dry them though.

CONTAMINATED MUSHROOMS - Molds would be visible, and bacteria needs water to survive. If they were cracker dry, they're fine.

MUSHROOMS CAN'T SUCK UP SHIT LIKE PLANTS - Mushrooms DO NOT HAVE circulatory/vascular systems.

MUSHROOM GENETICS - Mushroom genetics are far different than plant genetics. With mj, one can plant seeds that will generally produce a crop similar to the parents. Such is not the case with mushrooms. Each mushroom produces millions, if not billions of spores. Each spore has a set of genetics unlike any other spore. 'Think fingerprints'. Now, another analogy. Humans breed fairly true because a male and female produce offspring, thus the child is a 50-50 cross. Following that analogy, understand that mushrooms can have 20,000 or more 'sexes' represented in those billion or so individually unique spores. Thus, the chances of a collection of mushroom spores breeding true to the parents is very low.

MUSHROOMS - It's not just nutrients, because mushrooms aren't plants. Mushrooms eat their food just like humans and produce body heat as they metabolise the food, just like humans. They also release the carbon in their food as CO_2 just like humans. Therefore, they need solid food, not just nutrients. Their preferred food in artificial cultivation seems to be grains, such as rye and rice. You can expand your harvest by using large amounts of less nutritious foods for the mycelium such as manure and coir. You won't find a 'nutrient' that you can add to the solid food that will enhance the crop much, if any at all.

MUSHROOMS - Nitrogen is for plants. Mushrooms eat their food. I speculate in a few years, you won't ever even hear the term 'nitrogen' in relation to fungi. Potency isn't related to substrate, so you can add all the junk you want and it won't make them more potent. You'll want to isolate for a strain on agar that is more potent, and then save it in master slants.

MUSHROOMS - You are correct. Mycelium doesn't have a vascular system. It's composed of long cells, stacked end to end to form a network. It doesn't take a circulatory system for heavy metals to be absorbed. Other substances are metabolized by the mycelium. That's why mushrooms can grow on manure, but we don't get e coli from eating mushrooms. However, according to stamets, if there's lead or mercury in the soil, they will absorb it. I've never personally tested for such.

MUSHROOMS - Mycelium does NOT absorb myco-toxins from other species such as molds and transmit them to the fruits! This is very well known in mycology. Every wild mushroom grows in conjunction with hundreds of other fungi, yeasts, and bacteria, yet who has ever been poisoned by wild morels, chanterelles, cubensis, etc?? However, it's best not to use them because the contaminant molds have already eaten some of the substrate that you want your mushroom mycelium to eat.

MUSHROOMS - Mushroom mycelium consumes oxygen and releases the carbon in its food as CO_2, just like humans. Plants do the opposite. Mushroom mycelium produces heat as it metabolizes its food, just like humans. Plants get energy from the sun, but mushroom mycelium gets energy from its food source, just like humans.

MUSHROOM SPORES - Mushrooms can have up to 23,000 'sexes', and millions of spores on a print, so it's always a crap shoot. If you want a particular set of genetics, you need to isolate strains down to single sectors, then keep master slants. Single sector isolates can be crossed with other single sector isolates by dikaryotic mating on agar as well.

MUSHROOMS - I haven't grown cubes in years. I grow legal edibles. We also harvest several hundred pounds per year of wild reishi. For those who are not aware, reishi brings $1,000 per kilo on the legal market. That takes a lot of drying space. Cubensis are a great way to learn the mushroom life cycle, but it only takes a few months to grow a lifetime supply. That's why most growers move on to other species, or lose interest in the hobby. I suggest to all to stop in at the gourmet and medicinal forum to exchange tips and ideas on legal edibles. Mushroom growing is great fun, and if you play your cards right, there's a lot of money to be made.

MUSHROOMS AND PLANTS - All fungi help to break down material in the soil, which in turn makes the nutrients more available to plant roots. In fact, our nemesis trichoderma is a very beneficial organism in the soil for that reason. I've noticed also that burying spent and/or contaminated cakes into houseplants or the garden benefits the plants. They always green up and look much better a month or two later.

ANASTOMOSIS MYCELIUM MUSHROOMS - Anastomosis is the pairing of dikaryotic mycelium with other dikaryotic mycelium. In other words, combining strains, but not species. For example, Penis Envy could combine with cambodian cubensis via anastomosis, but neither could combine with oyster, shiitake, or mold.

MUSHROOM MYCELIUMS LIFE - The mycelium runs out of food and/or it reaches the end of it's natural cell division life cycle. Both often occur at about the same time. Adding nutrients or more manure will be of little benefit, just as giving a steak dinner to a 100 year old man isn't going to make him 20 again.

MUSHROOMS/PLANTS - As for helping with the CO_2/O_2, forget it. The mycelium produces way more CO_2 than plants can metabolize, and the amount of plants that would fit in a mini-greenhouse won't do squat as far as helping with O_2 for the mushrooms.

LIFESPAN MYCELIUM - It's worse than a g2g because once a mycelial network flushes a few times, the natural cycle is to die back like a spawned out salmon. To get maximum growth, it's best to always use fresh spawn when going to bulk.

MUSHROOMS - Mushrooms depend on a LOSS of moisture from the substrate to fruit. If you saturate them, or keep a steady moisture level, they fruit poorly if at all. Mushrooms are not plants, which benefit from steady moisture levels.

MUSHROOMS - Mushrooms EAT their food, not drink it from blue water. Fungi is much more closely related to mammals than plants(fact). You wouldn't put miracle gro into your kids baby bottle would you?

MYCELIUM - I once saw a chanterelle lift a rock that weighed at least ten pounds out of it's way as if it wasn't even there. It's amazing how much hydraulic pressure mycelium can build when it needs to.

MUSHROOMS - Growing mushrooms is as much about water as 'nutrients'. In other words, a jar of brown rice won't fruit nearly as well as a jar with 1/3 rice flour and 2/3 verm. That's a fact.

MUSHROOM LIFE CYCLE - Hyphal knots are the very first stage of pinning. They're the size of the head of a pin. They develop into primordia, which then grow into pins.

MUSHROOMS - Growing mushrooms is part art, and part science, but it's not magic. Follow proper procedures, and you'll have success. Good luck.

MYCELIUM - Nice. Fungi in the soil helps to break down the manure, making it more available to the plants as well. Both species benefit.

MUSHROOMS - Mushrooms EAT their food, so you want to provide solid food. Don't use the liquid left over from soaking straw.

MUSHROOMS - Molds are fungi. I don't think there's an organism that can tell perfect from imperfect fungi.

MUSHROOMS - Plants and fungi rarely compete with each other, but often each benefits from the other.

MUSHROOMS - They're part and parcel of the same cell lines that colonize the substrate.

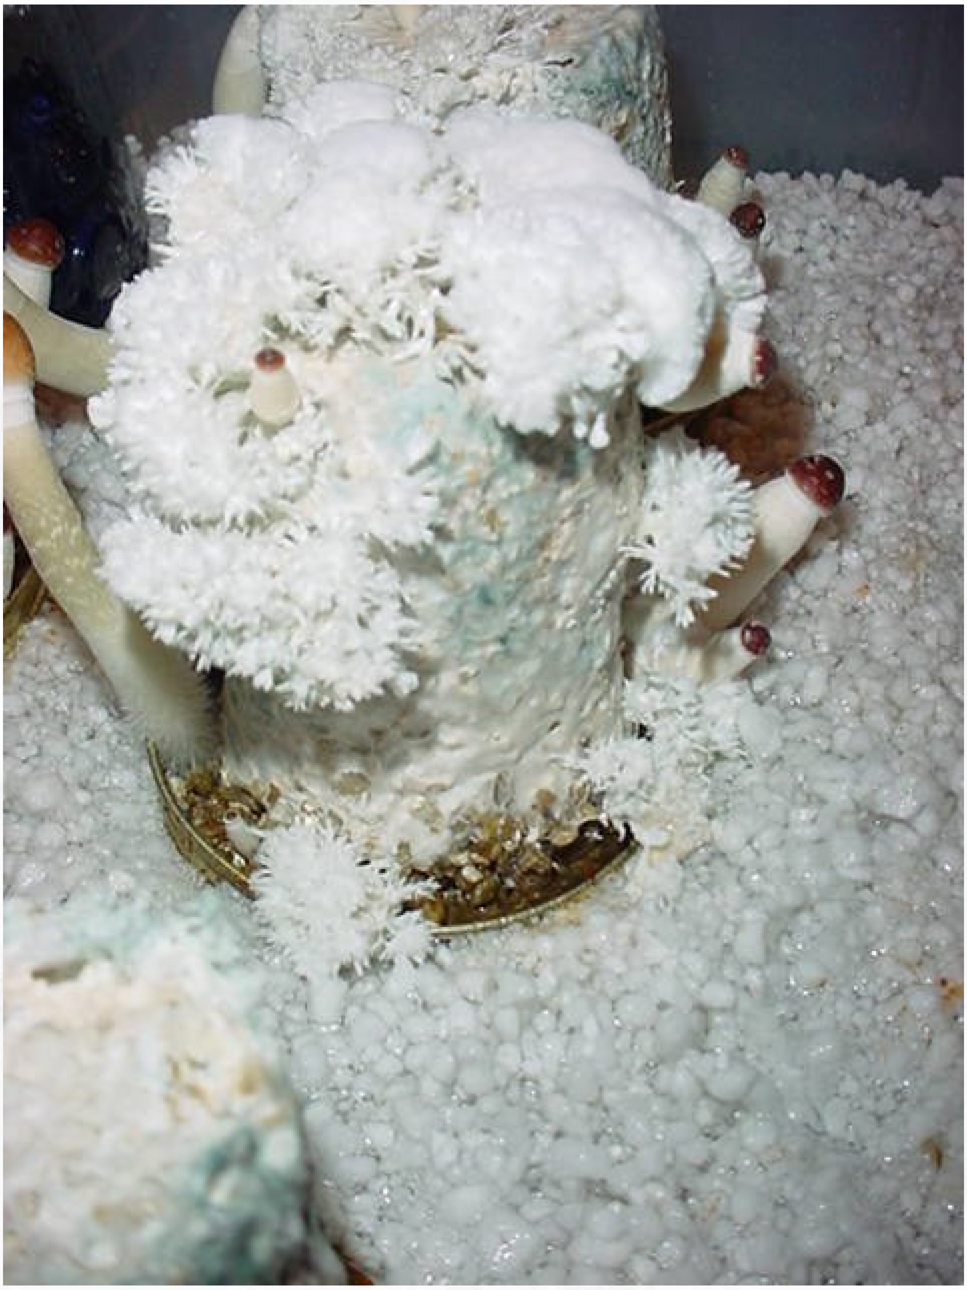
MUSHROOMS - Mushrooms don't 'suck up' toxins from a moldy substrate.

MUSHROOM - A Mushroom Viel is Made Of Tertiary Mycelium.

MYCELIUM - Mycelium is the vegetative part of a fungus consisting of a mass of branching threadlike hyphae that exists below the ground or within another substrate. It is through the mycelium that a fungus absorbs nutrients from its environment. It does this in a two stage process. Firstly the hyphae secrete enzymes onto the food source which breaks down polymers into monomers. These monomers are then absorbed into the mycelium by facilitated diffusion and active transport. Mycelium is also a vital component in many ecosystems in that it helps increase the efficiency of water and nutrient absorption of many plants and also is vital to the decomposition and breaking-up of plant material to form the organic part of soil and to release carbon dioxide back into the atmosphere.

MUSHROOMS/MYCELIUM - Mycelium grows by cell division. Primordia grows by cell division. Once they're fully formed mushrooms(ie pins), they grow by cell expansion, but not entirely. Basidia are single cells that produce spores at the ends of tube-like projections called sterigmata, and they're located on the gills. A larger cap will have more basidia, thus more spores. In other words, you'll get far more spores from a large cap than a small one. When we say mushrooms grow by cell expansion, it doesn't mean that no new cells are produced. It means these additional cells do not directly contribute to growth.

MYCELIUM - Aerial rhizomorphs, usually because they're searching for moisture from the air. You can tell from Road's pic above [see below] the cake is dry from the bluing. That's caused by the standing water in the perlite, which renders the perlite useless. Mycelium can be quite creative in finding ways to survive.



MYCELIUM - Fungi, including molds, grow mycelium. Most mycelium looks similar. With few exceptions, one can't tell what kind of mycelium it is by looking. An experienced cultivator on the other hand, can recognize the fragrance signature of different mycelia. Shiitake has a distinct smell, as does oysters. Ditto for morels. Cubensis has a distinct mushroomy scent. Trichoderma has a 'dirt' type smell to it. If I have an outbreak of trich, I can smell it when I open the greenhouse door, a few days before it's visible as a green spot when it sporulates.

MYCELIUM STORAGE - One last thing you might want to try is to take a piece of mycelium from the agar and drop it into a jar of sterilized distilled water. Be sure to cover the jar with a filtered lid. Sometimes, dry mycelium will recover in pure distilled water. Don't add any nutrients to the water that might also feed molds or bacteria. If the mycelium begins to grow that way, simply suck it up with a syringe and transfer to agar.

MYCELIUM - Mushrooms do not have roots OR root like structures. The mushroom fruiting body is mycelium, and it's genetically identical to the mycelium that is colonizing the substrate. No comparison can be made to plants/roots when discussing mycology. In fact, mycelium is a closer relative to humans and other mammals than it is to plants. That's a scientific fact.

MYCELIUM - Mycelium is much more closely related to humans than plants and that's a fact. Mycelium consumes O_2 and releases CO_2 as a waste product. Mycelium also produces body heat the way we do. I've often compared artificially increasing CO_2 levels to putting a bag over your head and trying to run a foot race. You'd run out of air, as will your mycelium.

MYCELIUM SMELL - If a jar smells sweet, sour, like vinegar, the kitchen garbage or stinky feet, toss it. All those are caused by various bacteria.

MYCELIUM - Hyphae from two compatible spores can exchange genetic information and become dikaryotic, thus able to fruit.

MYCELIUM - 'Fuzz' on the stems, contrary to popular myth is NOT a problem, and is NOT caused by high humidity.

MUSHROOM MYCELIUM - Most mushroom mycelium once 'mated' holds two nuclei in each cell.

MYCELIUM - Mycelium will suffocate and stall or die with no gas exchange, so I'd say it's very important.

MYCELIUM - I've generally found strains that poke spiky mycelium out end up being good fruiters.

MYCELIUM - The most aggressive mycelium I've worked with would be Morel.

MYCELIUM - Rhizomorphic mycelium is the type that forms primordia, so that's a good sign.

MYCELIUM - Mycelium has very little actives to extract.

ALCOHOL - First things first. 96% alcohol is a terrible sanitizer, but a pretty good fuel. For a cell to be destroyed by alcohol, the alcohol must be admitted into the cell via osmosis. However, cells are very good at keeping out substances that would kill them. That's why we mix water with the alcohol. The water 'tricks' the cell wall into admitting the alcohol, and then it kills the cell when it evaporates back out again. Use 70% alcohol for best results. However, alcohol will do nothing against the contaminants that are INside the needle, so you'd be injecting them right into your substrate. Use flame sterilization, and there is no need to wait for the needle to cool. It will cool enough on the way from the flame to the jar, and the first drop or two of solution will finish cooling the needle so that the rest can flow cleanly.

ALCOHOL - It's an explosion hazzard, a fire hazzard, and worthless against airborne contaminants because it settles out of the air too fast. The only way alcohol kills cells is when it penetrates the cell wall, and then evaporates back out. Alcohol by itself, if it doesn't penetrate the cell wall isn't toxic. That's why 70% alcohol works better than pure alcohol. The water 'tricks' the cell wall into admitting it, and then the alcohol evaporates back out from the inside, destroying the cell. Cells admit moisture by osmosis, and therefore exclude toxins such as alcohol unless water is mixed in with it.

ALCOHOL - No. Pure alcohol kills little. That's why it's mixed with water. The reason is that alcohol kills when it evaporates away from whatever it is in. Cells, including bacteria cells admit water through osmosis, but reject toxins. By mixing water into the alcohol, the cell is tricked into admitting it, then when the alcohol evaporates away, it kills the organism. Bacterial endospores are in grains, but we PC for those. The use of 70%

alcohol is great for tables, gloves, needles, etc.

ALCOHOL - 70% is preferred, but it has nothing to do with rate of evaporation. Cells admit water through their cell walls via osmosis. Cell walls are particularly good at preventing the entry of toxins, so by mixing water with the alcohol, it 'tricks' the cell wall into admitting the mixture, which then kills the cell as the alcohol evaporates back out. I'm sure one of our resident chemists can put it in more scientific terms, but that's the jest of it.

ALCOHOL - 99% alcohol is a poor sanitizer. The whole idea of using alcohol is to kill bacteria and mold spores. Cells don't admit substances without water. That's why up to 30% water is added to alcohol used to sanitize skin or other surfaces. It tricks the cell walls into admitting it, and then as the alcohol evaporates back out, it kills the cell.

ALCOHOL - Actually, the reason 70% is more effective is because living cells admit water through the cell membrane by way of osmosis. If there is water mixed in with the alcohol, it's admitted into the interior of the cell where it does the most damage. 99% alcohol can't penetrate the cell wall as effectively, therefore it's less effective.

DENATURED ALCOHOL - Use denatured alcohol from the paint department in your local hardware store. It doesn't create soot. Flame, then use while still hot. Don't cool the needle first. The first few drops of solution will cool the needle, allowing the rest to flow cleanly. Repeat between jars to avoid cross contamination.

ALCOHOL - Personally, I use 80% because it has enough water to penetrate cell walls of organisms, but not so much water it doesn't evaporate completely. The 70% takes too long to dry off my gloves or table when I wash them with it. I mix equal amounts of 91% and 70%. Works like a charm.

ALCOHOL - Just a note here too: 70% alcohol will do a better job of killing off contaminants than 90% or 99% alcohol. The reason is that the cell wall is tricked by the water in the alcohol into admitting it into the interior of the cell, where the cell is then destroyed as the alcohol evaporates back out.

WATER/ALCOHOL - The higher water content is what allows alcohol to penetrate the cells walls by imitating H_2O.

ALCOHOL - Alcohol is not a sterilizer. It is a sanitizer. Big difference.

BLEACH - Actually, bleach is approved for use in organic mushroom farms. I doubt seriously that the running water washed away the trich. It's possible it spread it even more, but only time will tell. Bleach also doesn't kill most fungi, including trichoderma. Good luck with that grow. I hope it works out. The trich sure won't impact your product or harvest, so if your second flush comes quickly, you'll be fine.

BLEACH - Bleach is not toxic to fungi, only spores. It's fine to clean out a glovebox or table if you mix it at ten percent, or also mixed at ten percent it can be used to disinfect a mini-greenhouse to kill flies and fly larvae between crop cycles. 30% bleach is too strong though. Don't go over ten percent or it isn't as effective.

BLEACH - Bleach doesn't harm mycelium much. I've soaked tissue for cloning for several minutes in a ten percent bleach solution. The bacteria is killed off, but the mycelium survives. Bleach seems to harm mycelium far less than peroxide.

DISINFECTANT - Alcohol is the recommended surface disinfectant. Some use lysol, but remember lysol is 80% alcohol and perhaps ten times the price of buying alcohol at the local drug store. To clean your table, just pour it out of the bottle, then wipe with a paper towel. Save the expensive windex for windows.

DISINFECTANT - Use alcohol for your surfaces and ozium for the air.

IODINE - You shouldn't need to do anything but clean the surface if you're using that tek. In fact, skip all the cleaners and just peel off a strip of mycelium like a banana peel, and then stick the needle into the freshly exposed flesh. Iodine is fine for cleaning the outside of the tissue, but use it at no more than ten percent.

LYSOL MUTATIONS - I want to scream every time I hear that. It's wrong. Lysol doesn't cause mutations. I can only catch it so many times, and this Lysol/mutant myth is spreading like a damn virus. Your new homework assignment is to spray Lysol near(not on) one of your fruiting cakes and report the results. Lysol is mostly alcohol and isn't good for mushrooms, but using it in the room isn't going to cause mutations. I spray the face of my flowhood with Lysol prior to transfers, so it's always blowing on something.

PEROXIDE - To avoid confusion, people should mention the percentage of hydrogen peroxide they USE. If you have 30 count peroxide such as it is measured in Europe, it is at ten percent. If you dilute it three to one, you have 3.33% peroxide. If you purchase it at a drug or grocery store in the US, it comes in 3% concentration. If you dilute it ten to one, you have roughly .3% after mixing. As I said above, peroxide is toxic to mycelium, all mycelium, therefore it is hated by mushrooms and mold alike. If you have an outbreak of Dactylium, you can spray the casing layer with it to wipe out the cobweb. This doesn't hurt the mushroom mycelium because Dactylium rarely colonizes over the top of mushroom colonized casing layers. I've found it's a mistake to use as a preventative measure because it sets the mushroom mycelium back and makes it less aggressive, then the faster recovering molds get the upper hand. Sterile technique will prevent molds in spawn, and fresh air exchange will prevent most molds in the growing environment, so go with that for best results.

PEROXIDE - The problem with peroxide on agar is it stunts the mycelium, and then oxidizes away to nothing, leaving the mycelium weak, but having no further effect on bacteria. For cloning, you can have far better results by dipping tissue into iodine before placing on agar. Gentamicin sulphate added to the agar will help prevent bacteria from growing, while not slowing down the mushroom mycelium at all. In all cases, strict attention to sterile procedure will outperform peroxide. I suppose that's what I meant to say, even if I was a bit harsh on ol' Rush.

PEROXIDE - Don't use peroxide on grains. Also, don't use tools to make the transfer. Peroxide will not sterilize spoons, forks, etc. Bang the unopened jar against a tire to break up the grains, and then pour the grains from the master jar to the receiving jars without touching them with anything.

PEROXIDE - Peroxide is toxic to fungi, all fungi. Personally, I no longer use peroxide in the humidifier, but I can assure you that isn't the problem. Peroxide in the humidifier only serves to help control molds within the humidifier itself.

PEROXIDE - Don't use peroxide in the mist water. Peroxide injures mycelium, so to use it for a preventative against contaminants might cause the very problem you're trying to avoid by stressing the mycelium, weakening it.

PEROXIDE - Peroxide does stress mycelium a great deal. We all know that. That doesn't mean it can't survive limited exposure, but it causes damage at the cellular level and that's a fact.

PEROXIDE - Don't use peroxide on your cakes for anything but cobweb control. Peroxide is highly toxic to mushroom mycelium and shocks it, allowing the faster growing trichoderma to take over.

PEROXIDE - Peroxide is no substitute for sterile procedure. Peroxide will wipe out cobweb mold on a casing layer, but it has little other use, imho of course.

PEROXIDE - Peroxide attacks mushroom mycelium too, so dunking in it can weaken the mycelium, making it more likely contaminants can get a foothold after the dunk while the mycelium is still weakened.

PEROXIDE - Don't assault your mycelium with peroxide. That's like throwing acid in your girlfriends face just to see if it sizzles.

PEROXIDE - Peroxide is toxic to fungi, all fungi. Some can tolerate it better than others, but none 'like it'.

OZIUM - Ozium air sanitizer is the best way to keep the air in your home or work space clean and smelling fresh. Ozium does not cover up the odors associated with sewer, pets, cooking and smoking - it eliminates them! . Ozium, the original air purifier, is a chemical agent that actually eliminates smoke and unpleasant odors and reduces airborne bacteria. Ozium actually cleanses the air through glycolized action. The Ozium glycolized formula acts directly on odor causing particles in the air. Ozium is distinguished from other products that simply mask odors. Ozium is an EPA registered air sanitizer and is safe to use residentially or commercially in homes, rental property, hospitals, nursing homes, hotels, veterinary clinics, restaurants, bars, laundry rooms, cars, mobil homes, offices, and just about anywhere there might be an odor problem. Do Not Breathe It Though!

MULTI SPORE INOCULATION - Every time you do multispore inoculation you mix hundreds, if not thousands of strains in the same jar. It makes absolutely NO difference if the spores come from the same print or from prints from halfway around the world. The definition of a strain is NOT the name some vendor put on a print he mailed out. The definition of a strain is two compatible hyphae 'mating' to form dikaryotic mycelium. Hyphae from a PR print are just as capable of mating with each other as with hyphae from a Tex or any other print. It's the same species so they're all compatible. There is NO competition between strains of the same species. Once they become dikaryotic, they continue to fuse by a process known as anastomosis, again with NO competition. Hybridization between 'strains' occurs in every single multispore project.

MULTISPORE - Every hyphal pairing makes a new 'strain' thus every grow is different and will have a different feel because there's millions of spores on each print and each spore has a unique genetic code. That's why there's far more variation in trip quality and macroscopic appearance from each crop from even the same print than there is difference between siblings of the same human or animal family for example. The 'cube is a cube' means just that. They have the same growth and nutritional/environmental requirements. Every trip will be different, so it matters little which named strain one chooses. You won't have the same trip twice, even from the same strain. In fact, you're very unlikely to have the same trip twice, even from fruits from the same substrate tray.

MULTISPORE - Multispore inoculation from a sporeprint is a roll of the dice. You can do ten grows from the same print and have ten crops that hardly resemble each other, other than being the same species. A fruit grown from multispore inoculation may or may not be an isolated strain. This is well known in the edible field. More than one substrain can be present in a single fruit. That's why clones from mushrooms grown from multispore inoculation do not always form single sector isolates on agar. I've seen this many times. However, if you isolate down to single sectors on agar, fruits from each single sector isolate will be genetically identical. However, if you fruit these and take sporeprints, you're back to square one.

MULTISPORE - What you're seeing is the effects of multi-spore inoculation. Often, several strains develop that are not compatible with each other, thus they don't form into a single organism via anastomosis. Therefore, more than one strain is fruiting on the same substrate. If you clone that big ol' choad, future flushes will have all choads, but whether you'll get enough of them to matter remains to be seen. I'd clone it, and then after you eat the thing, you'll know if it's a strain you want to keep or not.

MULTI-SPORE - When you grow from multispore inoculation, it matters little what the name on the syringe was. A cube is a cube and that's a fact. What this means is every grow will be different. When you buy a Cadillac, you can expect a luxury ride. When you buy a Ferrari, you can expect a fast car. When you buy a pickup truck, you can expect it to haul things. No such guarantees exist with cubes. Every multispore inoculation will be different, thus we say, "A cube is a cube".

MULTI SPORE - If you want to mix strains, do so. You can have multiple strains in the same terrarium, or for grins and giggles, you can inoculate a cake with four different strains, one strain per hole. You'll probably not notice anything different from any other multispore grow. This has all been covered hundreds of times, and the information is right here for searching. Strains of the same species are generally compatible.

MULTISPORE SYRINGE - Whoever made that syringe had no idea what he or she was doing. It's way too dark. Dark is bad. Fewer spores are better. That is a fact. A large number of spores is also going to have a large number of contaminants attached. Using too many spores is counter productive. That was known over twenty years ago when Paul Stamets wrote 'The Mushroom Cultivator' because he made that clear in the book.

MULTISPORE - Very often with multispore inoculation, what you have is many different types of mycelium growing together and one on top of the others. What is often mistaken for one type of mycelium is actually this pile of various types, or even the same type. If your cakes are in the FC and fuzzing up, they're good to go.

MULTISPORE - Sometimes with multispore inoculation you even end up with a non-fruiting strain. Other times, you end up with a poorly fruiting strain. Often, you end up with an awesome fruiting strain. It's all a dice roll.

MULTISPORE - If using multispores culture on both, you will have a different results no matter what and each sub-strain will have different properties/levels of chemicals within them..

MULTISPORE - The silly name on the syringe means nothing. Every grow from multispore inoculation is going to be different, just like every child born is different. It's all the same species.

MULTISPORE - In a spore print MULTISPORE = Millions of diff sub strains, within the strain you are using... Spores are like sperm, other then they mate with eachother

MULTISPORE - Multispore will produce different results everytime, because theres millions of genetics.

SPORE MIXING - Since multispore inoculation from a single print creates hundreds of strains, mixing two different prints would behave no differently. As has been said many times, a 'strain' is two compatible hyphae coming together to exchange genetic information, so it makes little difference how many prints go into making the multispore 'tea'. The mycelium doesn't give a darn what silly name somebody put on the print or syringe, it's only concerned with A and B mating types, and since all the cube 'strains' are the same species, hyphae from one spore will exchange information readily with hyphae from another compatible spore. Nobody can answer what the offspring will look like because nobody can say that mushrooms from GT will always be 'such and such' but PR's will always be 'this or that'. I've studied all types of spores under the microscope and I'm here to tell you, these so-called strains floating around with all the fancy names can't be identified either microscopically, or macroscopically from each other. That's why we stickied the strain thread up on top. It was to keep worthless discussion about 'strain' confined up there so it didn't litter the board with wasted bandwidth.

DARKER SYRINGES/SPORES - Darker syringes will result in more contamination problems. There is always going to be a certain percentage of contaminant spores on any print. Therefore, if you use more spores, you get more contaminants. In addition, when you use a massive spore inoculation, you force the mycelium to spend a lot of time and energy combining all the genetics into a common network. Many growers think that more spores results in faster colonization. What it results in is the substrate turning 'white' faster, but there is no evidence at all the project will actually fruit sooner. I'm a firm believer in using the minimum amount of spores necessary to achieve a crop. Clear(to the naked eye) syringes perform better than dark syringes. Nobody can see individual spores with their eyeballs. What you see is clusters of a few thousand that are stuck together. The spores in the center of these clusters are locked out of the moisture in the jars, so they rarely even get a chance to germinate.

VIABLE SPORES - I've ran several tests with the microscopes to determine spore viability. A brand new print will give about 1 spore in 100 that will germinate. After two weeks, that drops to about 1 spore in 500. At one month since taking the print, less than 1 spore in 1000 will germinate, and after one year, you're doing good to get 1 spore in 10,000 that is still viable and it drops even faster after one year. The thing to remember is take clean prints and store them properly. An old print will still work, but remember that you'll need to use many more spores to get the few that will germinate. Remember, when you use more spores, you also risk using more contaminant spores that may be hitch hiking along for the ride. Thus, fresh prints are better.

SPORES - Using more spores is counterproductive. I agree they will 'colonize' faster by using more spores, but the problem is that not all strains are going to be compatible, therefore by using an excess of spores, an excess of strains are going to be created, some of which won't unite to form a common whole. The result is you have several separate mycelial networks, none of which has access to the total amount of food(BRF) in the cake. The best fruiting results from multispore inoculation comes from using minimum spores. Even better, a single sector strain you've isolated on agar in a Petri dish.

SPORE INOCULATION - Using more spores to inoculate a grain or brf jar will result in faster colonization, but that's not always a good thing. You'll be left with many strains in the same substrate because not all are compatible enough to combine into a single organism by anastomosis. Therefore, each 'strain' will have a small piece of the substrate rather than being a single organism in control of the whole substrate, which is better for performance. That's why we practice strain isolation on agar prior to inoculating our grains.

SPORE LIFE PRINT - Actually, the life of spores on a print is three to five years, and less if the print was taken on acidic paper. In a syringe they last longer, provided the syringe was made properly. I have prints going back nearly 20 years, and even the ones I made four to five years ago won't germinate and grow anymore with very few exceptions. Good luck and check out "The Mushroom Cultivator" by Paul Stamets. You can get it from fungi.com or amazon.com.

SPORES - With multispore inoculation, it's common for two or more strains to make it to fruiting. They usually combine into a whole via the process of anastomosis, but some strains are incompatible and remain separate. They don't fight, being that they're the same species. Fruiting is not impaired either as you can see. The same often happens when someone injects one side of a cake with one strain, and another side of the cake with a different strain.

SPORES - I've been saying for many years, and Paul Stamets has been sayin for over 20 years(it's in TMC) not to use an excessive amount of spores. It's counter productive. Since no print is 100% clean, the more spores you use, the more contaminats you inject as well. Since molds and bacteria grow faster than mushroom mycelium, dark syringes give the advantage to contaminants over the mushrooms.

STORING MYC/SPORES - For live mycelium, I inoculate a test tube slant of agar. When the mycelium has colonized the agar in the test tube, I pour a small amount of distilled water over the top of the mycelium, then place the test tube in the refrigerator for long term storage. Once per year, take out the test tube and transfer the mycelium to a new test tube and repeat the process.

SPORES GERMINATING - With a powerful magnifying glass, you can sometimes see it on the second day. Using a microscope, I've observed fresh spores germinating within 20 minutes of swiping on wet agar. That blew me away. I never thought they'd germinate that fast. It can take four days to two weeks to be visible to the naked eye, with closer to four days the norm.

SPORES DROPPING - Spores drop due to internal pressures within the basidia that literally explode the spore away with force. Once dry, the process stops totally. To get more spores, put a drop of water on the cap so it stays wet longer. Nothing will speed it up, but lots of things can slow it down. You should have a readable print in three to four hours.

SPORES - It's genetics, and something else I've discovered, is there are often basidia on the gills producing clear spores. Check your prints under a microscope. You might have good prints, but just can't see them. The clear spores have a far lower germination ratio, but many still do germinate and grow, if used fresh.

SPORES DROPPING - There is some evidence that a heavy spore drop will inhibit future flushes. In addition, it makes a terrible mess, and furthermore it makes the fruits taste even worse than they normally would. Pick just before, or just after the veil breaks for best quality.

SPORES - Spores drop spores when the pressure in the basdidia reaches a crucial point, and then the spores are blown into the air with considerable force. You make a print by setting a freshly cut cap on paper, glass, foil, etc., and waiting for nature to do its thing.

STORING SPORE PRINTS - I think prints will definitely last longer on glass or aluminum foil. Refrigeration might help, but I'd make sure it's a dedicated lab frige. There's too much mold and bacteria in the kitchen refrigerator.

SAVING SPORES IN FREEZER..IF - Spores can be frozen without significant loss of viability by suspending in a 10% aqueous solution of sterilized glycerol (glycerin U.S.P.; available at most pharmacies).

SPORES - The spores will be fine since the water in the syringes didn't freeze solid. Freezing would likely destroy the cell walls of the spores, but just being very cold is fine.

STORING SPORES - Distilled water is the best method for storing spores or live mycelium. Spores stroked in distilled water don't dry out the way they do on a print.

SPORE PRINTS - After a year, they're down to less than one spore in a thousand that will germinate. It gets worse from there. Prints are best used when fresh.

FRESH SPORES - If done in a clean environment, spores can be scraped directly into grains or agar. They need not be re-hydrated first.

SPORES - Many minerals in tap water, and especially well water do effect the survival rate of spores in a syringe.

DROPPING SPORES - The big deal is it makes a horrible mess and makes the mushrooms taste even worse.

SPORE SOLUTION - That was enough for 4 jars. 2ml per jar is plenty.

SPORE PRINTING - I quit taking prints on paper. There's a lot of lime and other chemicals used in pulp production and papermaking. I don't know if that's the cause or not, but I've found prints taken on foil last MUCH longer than prints taken on paper. You can use the same methods, just with foil instead of paper. I'd tear a foot or so off the roll first, and save it for the kitchen, then use the clean foil beyond that point for your prints. I prefer to cover the printing cap with a tyvek sheet. I buy tyvek coveralls at the hardware store, and unzip them and do the printing on foil inside the torso area, then I zip it back up. You can tie knots in the arms and legs, and hood, so it totally seals your printing area up, yet still can breathe so bacteria is reduced. Heavy duty foil. It's several times the thickness of the cheap stuff. For immediate syringe making, you can use the non-stick foil. Spores slide right off it. They will slide right off the foil and into a shotglass still in the shape of the print.

SPORE PRINTING - If you're going to be streaking the spores onto agar, there's no need to be sterile in taking the print. I don't even put a glass or bowl over the cap. Just lay it on a piece of typing paper, and set a coffee filter over the top. After you streak the agar dish, watch it daily, and when the spores germinate and grow half a cm or so, take a small piece of mycelium from the FARTHEST away from the point of germination, and transfer it to a new Petri dish. Discard the original. This allows the mycelium to outrun the contams, and you can get clean cultures this way. Of course, doing it this way, you'd just drop the agar wedges into your grain, as opposed to making syringes. One Petri dish can innoc 10 quarts of rye or corn. Much faster/safer, imo.

SPORE PRINTING - If they're for printing, let the caps begin to drop spores prior to picking. Don't let the caps flatten all the way out because that wastes your spores and makes a mess all over your grow chamber. If they're for eating, pick just prior to veil tear for best overall quality. I agree that paper is a poor printing medium. Its porous surface attracts and holds contaminants, and the lime and acids used in production gives paper a wildly varied pH, which doesn't do much for the spores longevity. I use foil.

SPORE PRINTING - For printing, wait until the cap begins to flatten out, and you'll see spores on the stipe above the veil remnants as well. I disagree with the technique of printing under a glass. I'd suggest laying a sheet of tyvek over the printing caps. All you want is to keep dust off and restrict drafts. A glass can tend to keep the caps too wet, and bacteria may bloom.

SPORE PRINTING - Agreed, you don't need light. Personally, I don't let caps sit for more than 12 hours during printing because I don't want bacteria to be able to form in the stale air beneath the cap as it prints. The good news this way is you can get two prints from each cap. Although they will be lighter prints, they will work just fine.

SPORE PRINTS - Dark prints equal more spores, and since no print is completely clean, it also means more contaminant spores, which germinate and grow faster than mushroom spores.

SPORE PRINTING - After five years, especially if the print is on paper, there's little chance of success. It's not impossible, but less than one spore out of perhaps a million will still be viable.

SPORE SYRINGE GERMINATING - It doesn't make them germinate one second sooner. It just causes such a mass of mycelium you SEE it sooner. It's a horrible idea by the way because your mycelium spends needless energy combining cells(anastomosis) in order to become a single organism. You're much better off using a minimum of spores. Dark syringes or the over use of spores is also a good way to get contaminants. Remember, more mushroom spores also means more contaminant spores that hitch hike along for the ride. Since it takes longer for all those strains that germinate to combine, it gives the contaminants a better chance of getting the upper hand.

DARK SPORE SYRINGES - It becomes much worse when people make their own syringes and make them very dark. Some strains are not compatible, so when someone uses multispore inoculation, it's common to still have two or three strains active at fruiting. Each strain carves out its niche and holds it. Most strains combine into a single organism through the process of anastomosis, but the non-compatible ones don't, therefore you'll have several different substrains growing in the same tray.

SPORE SYRINGES - Having thousands of strains in the same jar may turn it white sooner, but in no way increases performance or yield. Time is spent combining all those pairings into a coherent whole. Fewer spores is much better, and in fact the clearest spore syringes often give the most massive flushes. The reason is that many strains are incompatible, so when you start off with a black syringe, there may be hundreds of incompatible strains at the end, greatly reducing harvest.

INOCULATING - 2CC's is plenty for quarts of grain. Shoot over to the side of the glass so the spore solution can run down. Don't shake until 20% or so colonized with mycelium.

INOCULATING - A torch lighter will leave the needle sterilized. Just make sure you get the needle to glow red hot. No need to wipe with alcohol afterward.

SPORE SYRINGE - A print should make up to ten or even more syringes, depending on size and darkness of the print.

SEX LUBE SPORE SYRINGES - Astroglide or Jet Dry.

INOCULATION - 'Inoculation' is the process of introducing spores to your substrate. 'Colonization' is the phase where the mushroom mycelium is working its way through the substrate, 'colonizing' it. 'Fruiting' is the stage you're at now.

STRAINS - Strains of the same species do NOT compete for nutrients and they do NOT fight it out. That's absolutely silly. Do the genes of a lady from Florida and a man from Texas fight it out when they make a baby? Of course not. Squirt as many different strains into the same jar or substrate as you want. It's no different than multispore inoculation from one print. It's all the same species. Everybody who's done it has reported the same results. A normal flush that looks just like any multispore inoculated flush. Most of the named 'strains' were simply named after the geographical location the print was collected from, as if a man made line in the sand changes the genetics of biological creatures. If a guy collects a print in Florida and names it treasure coast, and another guy collects a print in Georgia and names it hillbilly, are they really different? Both grew in the same region, under the same weather conditions, and spores from both mix freely in the wind. It's the same with all the SE Asia 'strains' in circulation. Lines on a map drawn by the British 50 years ago do not cause the mycelium that's been evolving for millions of years to suddenly morph into new strains, marketing considerations aside. They're all Cubensis. There are distinct strains such as Penis Envy, various albinos and fruits that drop slightly different spore coloring, but the rest is marketing, not mycology and they all mix and match easily. My point was that putting spores from several named 'strains' in the same substrate does not result in a hybrid, since there's no verifiable difference between them.

MIXING DIFFERENT STRAIN SPORES - Different strains do not fight it out. They do not compete for 'nutes', they don't make small fruits, they don't disrupt each others networks, and they don't get cut off from their own network. I speak from experience. Use the search feature and you'll see this issue comes up every couple of months at least, and this same disinformation gets repeated over and over again by those who have never done it. Here's a post I made in a similar thread several months ago with a picture showing two different strains fusing by anastomosis to create a third strain on a Petri dish.
http://www.shroomery.org/forums/showflat.php/Number/5545843#Post5545843Cubensis is easy to cross. Some

mycologists use the term hybrid, but I prefer 'cross', instead using the term hybrid to refer to cross-species matings. Every single multispore inoculation results in hundreds of 'strains'. Where is this fighting? Remember, a strain is born when two compatible hyphae exchange genetic information to become dikaryotic. It doesn't matter one whit whether the spores those hyphae came from originated from the same sporeprint, or sporeprints from the opposite sides of the world. Vendor named strains are just that-names. If the species is cubensis, they will combine normally. That is a fact.

STRAIN - Strain is irrelevant in mushrooms, unlike in mj cultivation where it's everything. A cube IS a cube. The long-time growers know this, thus the disreputable spore sellers constantly invent new names to stamp on the same old strains that have been around for years. Pick a strain from a shroomery vendor for your microscopy study. Sporeprints easily slide into a regular mail envelope. Cubes are cubes, and no named strain produces faster, more rhizomorphic, more potent, blah, blah, than any other on a continuing basis. Strain questions need to be in the strain thread at the top of the page please.

MIXING STRAINS - They may or may not share genetics(cross), but either way there is little to no harm in mixing vendor named strains because they're all the same species anyway. The chances are very high that they will combine into a single organism via anastomosis by the time fruiting comes. Search the posts. This has been asked and answered dozens of times in the last year or two. There's several grow logs in that forum where guys have mixed 'strains' in the same tray with no problems.

STRAINS - People, for the millionth time, the 'named strain' crap is completely irrelevant to growing. Cubes are a SPECIES, and they all grow under the same conditions in the same substrates, under the same temperatures, moisture contents, etc. It seems that everyone who makes a print these days gives it a name and calls it a new strain, which is total bullshit. As far as growing parameters are concerned, cubes are cubes, period.

WHAT IS A STRAIN? - Remember, a strain by definition is a pairing of two compatible hyphae into dikaryotic mycelium. The location the original print was taken from has no more to do with the size and shape of the fruits than being a human from New York or New Jersey or England has to do with how tall or how smart you are. Remember, cubes are all the same species, just like we humans are all the same species.

MUSHROOM STRAINS - Some strains just don't attach well to the substrate, therefore they tend to pick themselves by falling over. Other strains are so well attached they leave a huge divot when you pick them. Multispore inoculation will give one strain one time and the opposite the next. It's just the luck of the draw. It's not related to anything you're doing, except handling them. They prefer to be left alone.

MIXING STRAINS - Most likely, you'll end up with cubes. It matters little the name on the print. If it's a cube, it will grow cubes. If you mix spores from more than one print, you'll still grow cubes. Compare it to a human from Canada having a baby with a human from Mexico. The child will still be human. As long as they're the same species, the genes usually mix freely.

CROSSING STRAINS - Crossing one cube strain with another is quite easy actually. Dikaryotic mycelium readily exchanges genetic information with other dikaryotic mycelium. However, such is not a hybrid. It's a cross. This site operator has a long history and is not a vendor here for a reason. I won't repeat the whole step story here. Click.

SPORELESS STRAINS - I've had a few sporeless strains pop over the years. If they have the other qualities desired, it's a great trait since there's no mess if you wait until after work to harvest a flush. Sometimes, they're only half sterile, and you get zebra stripes on the gills,

STRAIN - PE is definitely slower to pin than other strains. Correct, the PE6 is a PE/Tx hybrid. Hope you guys enjoy it.

PRESSURE COOK TIMES - For larger jars or substrate bags, I've got a little different technique to know how long.
The bacterial endospores in grains need about 30 minutes @ 15 psi, at sea level, to ensure they're killed off. That does not mean 30 minutes from the time your PC reaches pressure, but 30 minutes from the time the interior of the jar or bag of grains reaches full temperature. The way to achieve this is to always use the

minimum stove setting that will hold 15 psi. If your PC rattles at 15, then use 14 so it doesn't rattle at all. Now, you'll notice after pressure is reached, for about 1/2 an hour or so, you'll have to constantly turn down the stove in order to prevent the weight rattling. Once you reach the point where you don't need to reduce the stove burner anymore, your substrate is fully heated all the way through. At this point, allow 1/2 hour to ensure the bacterial endospores in the very center of the substrate bag are killed off. If you're above 5,000 feet elevation, double the above time to one hour.

STERILIZATION JARS - Total sterilization would take at least 24 hours in the PC and your grains would come out as a sticky mush. The one to two hours we use for 'sterilization' gives us a window of opportunity to get the jars colonized before the contaminants that survived the pressure cooker can get a foothold. Don't wait three days. Instead, if you're having contamination problems, simply cook up a few extra jars and always keep a blank or two at each step that you don't inoculate. If you do a grain to grain transfer, keep one jar back that you don't use for g2g. If you experience contaminants and your blanks are contaminant free, the problem was in your sterile technique. If both the blank and the inoculated jar contaminate, the problem was in your sterilization process. By using blanks at every step, you can always narrow down the problem to exactly the step you went haywire on. Once you get your procedures down pat, you won't need to use blanks.

PRESSURE COOKING - You can remove the jars when the pressure cooker returns to zero pressure, but I'd still wait a little while. If you remove the jars while they're too hot, they can loose some of their moisture content to evaporation. Overnight is not necessary, but if you're going to let them sit anyway, the PC is a fine place to leave them. If you need to cook another batch, then there's no harm in removing them. Allow to cool to near room temp before inoculating.

PRESSURE COOKER - The biggest cause I see of dry jars is lifting the weight or relief valve to let pressure out faster at the end. That causes the grains that are at a temperature above the boiling point of water due to pressure, to suddenly loose all their moisture because the pressure that was holding the moisture in place disappears. Let the PC cool naturally until you can handle it without gloves or a pot holder before opening.

STERILIZATION - Sterilization is never complete because that would take overnight in the PC, which would turn the grains to mush. The hour or two we PC gives a window of opportunity for the mycelium to colonize and get a grip on the grains, but it's only a window.

PRESSURE COOKER - I use 90 minutes for quart jars at 15 psi. At 10 psi, go for two hours. I wouldn't attempt corn at ten psi. Corn sucks anyway as a spawn. Just use rye or wbs.

PC. TRICHODERMA - Trichoderma is killed at temperatures far below boiling, so there's no way it survived the

PASTERUIZATION - I can pasterize in a Crock Pot IF I can watch and control the temp!

PASTEURIZING - We pasteurize bulk substrates because molds are killed at very low temperatures that are below pasteurization temps, but some of the bacteria survive. Bacteria in manageable quantities are not a contaminant in bulk growing, but molds are. A sterilized substrate is a prime breeding ground for whatever lands on it, thus if you sterilize bulk substrates, you'll have a higher rate of contamination.

CLEAN MEANS - Sanitize means to reduce the number of contaminants to a safe or relatively safe level as may be judged by public health requirements.
Disinfect means elimination of all recognized pathogenic microorganism but not necessarily all microbial forms.
Sterilize means the destruction of all microbical life by use of chemical or physical procedure.

HOSPITAL SANITATION - Clean clothes & work-place, along with good sanitary procedures. AND Hair covering (net/cap), face mask, exam gloves & Lysol/Oust. ARE YOUR BEST FRIENDS. These are common-place inexpensive items, found at most local drug/pharmacy stores. Using these will cut down on contamination. I am amazed, why many don't use them. Then wonder why their jars/bags, syringes, prints or whatever get contaminated.

THE OVEN TEK - The oven will increase contaminants by stirring up turbulence that swirls contaminants around. The oven tek is bogus. You'd be better off in a still room in open air than using the oven. An air temp of 150 won't do squat to a contam spore in the two seconds it takes to swirl into your jar.

AIR SANITIZER - Lysol is a surface sanitizer. Get some Oust for the air. When you spray oust, it completely fogs up the room. I do about 30 seconds with a can in each hand, which really leaves a thick fog that kills airborne bacteria

OPEN AIR INOCULATION - Anyone who recommends open air inoculations can be compared to a drunk who recommends drinking and driving.

STERILE AIR - If you want sterile(relatively) air, get a laminar flow hood.

CONTAMINANTS BY HUMANS - Growers must realize that WE are the biggest source of contamination. I'll add to the above not to talk or sing, etc., while inoculating jars or doing other clean work. Your breath leaving your mouth is traveling faster even than a flow hood can blow it back. It's also perhaps the largest source of bacteria in our jars. The bests surgical masks will stop 99% of the bacteria leaving your mouth, but think about that 1% of several billion that gets through. That's a lot of bacteria even with a good medical, not dust mask. I hold my breath anytime a jar or Petri dish is open. Gloves are mandatory for consistent success. A box of them is less than the price of a single spore syringe. They'll save a lot of failures.

WASHING HANDS - Soap lifts the oil and bacteria skin cells and washes away with water. There is no true "anti-bacterial" soap that will kill it all (THIS IS A MYTH). Even soap/sanitizer can't even kill it all though. Skin is constantly shedding bacterial cells, You want the beneficial bacteria on your hands. True anti-bacterial soaps need to be left on for a couple minutes too.

FUNGICIDE IN CASING - They use Banrot 40WP. I ran several experiments with this fungicide a couple of years ago. It is so powerful you can soak rye grain in it, then PC, then leave the lid off the jar for 24 hours in an open room, and the grains won't contaminate. It can also be applied to casing material, and I guarantee that no trich or cobweb will grow on it.
It works by preventing spore germination, so it has to be inoculated with live mycelium, as nothing will happen if you try to inoculate with a spore syringe.
After determining that the Banrot 40WP works, I stopped the experiments because I see no reason to use chemicals to replace proper clean room procedure. A properly pasteurized, NOT sterilized casing layer will have no trouble surviving two flushes, which delivers 90% of the fruits you're going to get anyway. After two flushes, I recommend tossing the tray into your outdoor garden and replacing it with a fresh tray for the most effecient use of your growroom space. Thiophanate-methyl is approved by the FDA for use on mushroom crops and I ran some tests on it a few years ago. It's the active ingredient in Banrot 40WP. Banrot 40WP is so powerful you can put it in a jar of grains prior to sterilization, then leave it sitting out with the lid off in a dirty room and it won't grow mold, but if you put live mycelium into the jar it will grow unaffected. However, it's a chemical cure for laziness so I don't recommend it. Just use proper procedure, then toss out contaminated projects. It seems I used 1 tablespoon of Banrot per the several gallons I soaked the 10 cups of rye berries in overnight prior to PC'ing. It's been awhile, so you might search some more and find the posts that I wrote when my memory was still fresh on it.

FUNGICIDES - If fungicides have been used, they only effect spore germination. As long as you inoculate with live mycelium, there won't be a problem. You'll just have to do a test run.

RHODODENDRON LEAVES - Dried Rhododendron leaves are nearly as effective if someone is really having trouble with trich or cobweb. Simply dry them, then grind up in your hands and mix with the casing material at the rate of ten percent. Pasteurize and use. Fungus spores won't germinate in the presence of Rhododendron leaves.

BUG PROBLEM SOLVERS - You can also suck them out with a vacuum cleaner hose, which is kind of fun. They normally bread in your houseplant soil then fly out of your mycelium to feed. They can be killed off in the houseplant soil by soaking the entire pot from the soil line below in the sink for 24 hours. This drowns the adults and larvae. I use sticky paper. Works like a charm. Place it near the entrances to your grow area, and also on the inside. They're likely breeding in your houseplants too. A good cure for both houseplants and casings with fruit flies is dunking. A 24 hour dunk will drown them and their larvae. If you'll cut a lemon or lime in half and leave one of the halves near your grow, they'll congregate on the lemon rather than your mycelium. It's easy then to get them with the vacuum cleaner hose. Shot glass 1/4 full of wine are good traps. Glass with coco cola in it, they drown from the sticky ness. Fly Straps, they work great. I'm not talking about little pest strips, but 2' x 4' mats. You might try some DE to see if it works, but it only works when dry, and it won't stay dry for long on a substrate. Disposal is probably the best option. You could bury them into manure or compost in a shady spot outside to get a crop. They looooove stale beer and wine. Leave a half full bottle of either lying around for a couple of days, not more, and they'll crawl in and drown in the stuff. change the bottle every couple of days. You can use the yellow duct tape, but put a layer of vaseline on it so they stick to it. That's what a lot of the farms around these parts do. DE will help if it's dry. You can even sprinkle it around the shelves, or try baiting them with a bit of honey on a piece of wax paper, surrounded by DE. One needs to be careful handling nematodes and growing mushrooms. Many species are death to fungi, while other types of fungi can trap and kill the harmful nematodes.

GNATS - My favorite method is to cut a lemon in half and leave it near the grow area. The gnats are attracted to the lemon much more than to the mushroom mycelium. You'll see the lemon covered in gnats, and then you sneak up with the vacuum cleaner hose and suck them all up. Works like a charm.

GNATS - They avoid turbulence, but it's also likely to dry out your substrates. Try this if gnats are a problem. Cut a lemon in half and drop it into the bottom of a quart jar. Keep the lid next to the jar. The gnats will be attracted to the citrus, and when there's a bunch in the jar, quickly put the lid on before they can get away, and dispose of them.

BUG PROBLEM - Get a bag of DE from the garden center and sprinkle a thin layer on top of your casing. Completely cover the casing layer. The DE is extremely sharp to insects and will rip them to shreds when they crawl across it. DE is only effective until it gets wet, so you'll have to reapply it after misting. It's non toxic.

FRUIT FLIES BUG PROBLEM - They're attracted by the smell of mycelium for a snack. I've never seen them set up home and breed in a cake or other project. While an irritation to see in our FC's, they're for the most part harmless. I chase them down with the vacuum cleaner hose if their numbers get too large.

ANTS ATTACK - Another tip for ants is to put a bit of borax into a jar lid of honey or karo. The ants suck up the karo with the borax in it, then take it back to the nest to mix into the feed. Within two weeks, the entire colony including the queens is wiped out.

BUG PROBLEM? - Dung/straw based substrate draw gnats (fruit flies). Your infested - already...Get electric bug zapper.

FRUIT FLIES - Normally, they breed in your houseplant soil and then fly out to your mycelium to feed. They can be killed off in the houseplant soil by soaking the entire pot from the soil line below in the sink for 24 hours. This drowns the adults and larvae.

BUG PROBLEM - You can also get a bottle of red wine and drink all but the last inch in the bottom. Leave the bottle in the fruiting chamber as a trap. They're attracted to the wine, then can't get out of the bottle and drown.

KNAT PROBLEMS - Use 'Knock Out Knats' Bacillus Thuringiensis Thuricide to destroy gnats in your grow room.

UV LIGHT CANCER - Skin, or eye exposure to hard UV light is KNOWN to cause cancer. I have used then in air sterilization. But, they were enclosed in 16 gauge sheet metal duct work. Which, the air was forced through in a hepa filter housing. Just be careful, malignant melanoma skin cancer is NO FUN.

SURGICAL MASKS - The standard they're testing is how the mask protects the wearer, which we don't have a concern for. Our projects are not going to give us a fatal disease. Respirators are tight fitting around the cheeks, to prevent you from inhaling air from the edges that doesn't get filtered. This is important if you need protection from airborne pathogens. Surgical masks are open at the cheeks purposely to allow a low pressure route of escape for your exhaled bacteria(breath). What passes through the mask generally has 99% of the bacteria filtered out, depending on brand. Hospital operating rooms have HEPA filters in the ceiling that draw the room currents up and away from the patient. By having the doctor's breath leave in the direction of the ceiling, thus the filters, the patient is protected. This is our scenario as well. When the FDA says they don't test surgical masks, it means THEY don't test surgical masks. It doesn't mean they don't get tested. A surgical mask with the N95 rating is going to do our job just fine. However, a cheapie surgical mask works very well too. It's all I've used for years. The thing NOT to use is a construction type dust mask.

SURGICAL MASKS - Neither of the above. Go to a drug store and get surgical masks. They're designed to filter 99% of your exhaled bacteria. One of those above is only good for 97%, and the other one isn't even rated. You can do much better locally.

STERILE - Kitchens are the worst possible place to work. There is more fecal bacteria floating around a kitchen than in the bathroom right after you take a dump.
I've noticed the new growers that are saying it's ok to be nasty are also buying syringes from vendors so have their sterile lab work already done by someone else. That isn't mycology folks. When you learn to harvest a crop, take prints, germinate spores on agar, isolate strains, and produce a killer fruiting strain that blows you away with its potency, you'll understand what I mean.
Lab work isn't supposed to be clean. It's supposed to be laboratory sterile. No cut corners. When it comes to spawning a bulk substrate, who gives a shit if you pick your nose while working? It doesn't matter. If the grains were properly prepared and colonized in sterile conditions to full colonization, you can spawn to bulk outdoors if you want to. When you go to the Stamets seminars, you'll see Paul build a straw log or other project outside in the open air and it works fine. However, you can bet your ass the spawn wasn't produced outdoors in the open air.
Learn to be sterile where sterility is called for, and be clean where being clean is called for and you'll be fine. I live in a 40 year old condo building in a very damp climate and my entire building is infested with black mold, and it has wall to wall carpeting. It's unhealthy for us and we're trying to sell the damn thing so we can move, but every project I've done has been done in this mold infested place, yet I can grow successfully by following the advice given above, and even filmed my video DVD here, doing lab work and growing a dozen or more species from spores to the fruiting/harvest stage. Several of my terrariums sit within 18" of a wall that has black mold growing on it, yet it NEVER grows on my cakes.
For sterile work, surgical gloves are a must, surgical mask is a must(dust masks are for carpenters, not surgeons), a still air glovebox or laminar flow hood is a must. A closed, draft free room is a must especially if you're using a flowhood, and spray the air with oust at least two or three times before starting the flowhood. I let the flowhood run for at least an hour in that closed and oust sprayed room before beginning work, which gives me time to shower, wash my hair and brush my teeth, use mouthwash, etc.
Once your spawn jars are fully colonized, you can scratch your butt while you inoculate the coir if you want. Bacteria isn't a contaminant of bulk substrates. The important thing is to learn when it's important to be sterile. If someone else is doing your sterile work for you, then don't brag about how dirty you can be and get away with it. Anybody can be dirty and get away with it under those conditions.

STERILE AIR - There are up to 600,000 contaminants per cubic foot of air in a normal room. That's a lot of little nasties to stick to your needle or the top of your jar where it will get pushed into the substrate when you inject. A room also has normal circulation and all those nasties are moving around. You can see this on a bright day when the sun is shining in through a window. You'll see the larger of these dust particles, but there are hundreds of times that many smaller ones that you can't see. A still air box stops the movement of these particles, greatly reducing the chances they'll get on your jar lid or needle. You can also improve your chances by washing the glovebox and leaving the sides and bottom wet. The moisture will attract the dust/contaminants and then they'll stick, leaving the air within, not only still, but with much less contaminants floating. You don't want a filter and fan on a glovebox. The only suitable filters for mycology are several inches thick and require a plenum behind them to build static pressure, which gives the laminar flow. If you used a filter/fan in a glovebox, the turbulence would defeat the purpose. Where a glovebox really shines is when doing agar work or grain to grain transfers. They're not as good as a laminar flow hood by any means, but they're far better than open, turbulent air. Water or peroxide. A wet surface will make the contaminants adhere to it and stick, rather than floating into your jars.

STERILE - Opinions are like something else every one has, so unless somebody wishes to quote some scientific texts to back up claims, let's not be spreading flames over our opinions. I can easily see how water

10,000 feet below the surface of the earth can heat to well over 100C without boiling. After all, think of the weight(pressure) a 10,000 feet deep well of water will exert on the water at the bottom. That's a lot more pressure then the walls of our PC's can contain. However, I doubt seriously the walls of an oven bag can exert that much pressure. There's no way to get every molecule of air out of a bag of coir or manure, even if it soaks in water for a month. In addition, even if it did, you'd be handling a bomb when you open the microwave. My background is engineering, not chemistry, so we should wait for one of the member chemists to chime in. The overall point is mute though, because sterilized substrates are much more likely to contaminate than pasteurized substrates. One shouldn't heat substrate or casing material above about 170F, or the chances of contamination are increased rather than decreased.

STERILE SYRINGES - Flaming needles is to prevent cross contamination between jars. Syringes should always be boiled before re-use. This isn't a tek, it's simply stating what has been said over and over again for years. There is also no need or reason to PC a syringe. Plastic doesn't harbor bacterial endospores, so anything that might be on a syringe will be killed off by simply boiling. You still need to flame the needle between jars. As hyphae pointed out, you certainly don't need a separate syringe for each jar.

STERILE PROCEDURE - Nobody should ever recommend inoculations in open air, especially new growers that got started in the hobby during the winter when natural contaminant counts are low. In addition, the breath of the cultivator is the biggest source of bacterial contamination, and dust masks stop zero exhaled bacteria from reaching the work area. Dust masks are intended to stop the individual from inhaling large particles such as dust and dirt when mowing the lawn, but surgical masks are called for when doing mycology work. A surgical mask is designed to protect a patient from the surgeons exhaled bacteria, which is what we want to accomplish when doing sterile work.

STERILIZING - Actually, that's a terrible idea and I cringe everytime I see it repeated. 'Sterilization' is never complete, but only gives a window of opportunity to get the grains colonized. Wait until the jars return to room temperature, and then inoculate. Glass is an insulator, so if they were even slightly warm on the outside of the glass, your spores are probably cooked and doomed. It never pays to be in a hurry in this hobby. Waiting twelve hours to inoculate is the proper thing to do, and you don't gain anything by doing it sooner.

BOILING/STERILIZING SYRINGES - Boiling water IS enough to sterilize a syringe. Plastic does not harbor bacterial endospores, and fungi like trichoderma and cobweb are killed by temperatures far below boiling. I fill a pot with water and drop the syringe in. After the water has boiled for ten minutes, pull the syringe out and suck in the boiling water, swish it around and squirt it out. Do this a few times. The syringe will be sterile enough for mycology, I assure you. I've done it this way for years.

STERILE - I'd suggest an alcohol lamp to sterilize so you won't be anywhere near your kitchen during inoculations. Kitchens are full of molds and mold producing/carrying foods such as bread and cheese, vegetables, fruits, etc., not to mention all the bacteria that lives and breeds in the sink drain and in all those hard to reach to clean spaces. There's no need to wipe with alcohol after flaming the syringe. Wait two or three seconds and inject. Work in a glovebox of course.

STERILE INOCULATION - Swabbing the needle with alcohol does nothing for the contaminants that have become lodged in the interior of the needle. In addition, look at a needle under a microscope. There's many little holes and imperfections on the surface that alcohol is very likely to miss and thus the contaminant molds or bacteria survive. Always flame before first use, and flame again between each jar to prevent cross-contamination.

STERILIZING NEEDLE FOR INOCULATION - A bic lighter is fine. A butane type lighter is hotter and won't leave carbon on the needle, but as long as you get it red hot it's fine. Allow to cool for 2 seconds and use. The needle will still be hot, but not red hot, and the first half drop of solution will cool it off safely, allowing the rest to flow cleanly. Use a glovebox.

NEEDLE STERILIZATION - The problem is the alcohol doesn't penetrate to the inside of the needle. I suggest flaming the needle red hot, then using the first couple of drops from the syringe to cool it down. That way, you know the inside and outside of the needle are sterile. In other words, heat it red hot, then allow to cool for only a few seconds and use.

STERILIZING NEEDLE - If you flame sterilize, anything you do afterward will only make the needle 'dirtier'. Why not just flame and use? Forget the alcohol after flaming. There is no need to cool down the needle. Just use hot and let the first drop or two of solution cool the needle, so the rest can flow contaminant free.

STERILE - Alcohol does NOTHING to prevent the contaminants that are inside the needle being injected into the grains. The size of the interior of a needle to a contaminant is comparative to the size of a human in a subway tunnel. Needles should always be flame sterilized.

STERILE - Spraying Lysol into the air is a waste of a good surface disinfectant. It does no good whatsoever. Use Oust to clean the air, Lysol or plain iso alcohol to clean tabletops. Other than that, it should be OK. Keep your cotton filter dry at all times or it will mold.

STERILE - If you fail to flame between jars, you can easily cross-contaminate between them. Flame between each and every jar. Alcohol is good for the surface of the jars and tabletops, but flaming is the way to sterilize a needle or scalpel, inoculating loop, etc.

STERILIZING NEEDLE - 70% is more effective at killing organisms than 91%, but in my opinion, syringe needles should be flame sterilized. Alcohol on a cotton wad will do nothing for contaminants on the inside of the needle.

STERILIZATION - Sterilization kills all life forms. After sterilization, you need to keep the substrate under sterile conditions until fully colonized or it will contaminate. That's why we use filter patch bags or jars with filters.

STERILE PRINTS - There is always going to be a few contaminant spores on every print. There's no way to avoid them unless we grew on sterilized substrates in a hyperbaric chamber.

STERILE PROCEDURE - If you're not gloved up, wash like a surgeon with good soap, preferably something with exfoliant properties, and use hand sanitizer.

STERILE PROCEDURE - Alcohol your gloves and tyvek wrist sleeves, spawn jars, flame and alcohol transfer tools, scalpels, etc.

FLAMING SYRINGE NEEDLE - If you flame between each jar, you eliminate the possibility of cross contamination.

PASTEURIZATION - Pasteurization should not be longer than 90 minutes or too many of the beneficial organisms will be killed off, thus leaving the substrate open for contaminants later. Water is a much better conductor of heat than air, thus water or steam pasteurization the preferred method. Water or steam will conduct heat into the substrate fastest, thus allowing you to more precisely control the total amount of time at pasteurization temperature.

PASTEURIZATION DISCUSSION - Pasteurization of substrates doesn't take a few seconds. It takes an hour. The idea is to kill all of the mold spores, and some of the bacteria. The surviving bacteria keep the substrate 'alive', thus reducing the chances of molds forming. A few bacteria in a substrate will also improve fruiting, and some species simply will not fruit on a sterile substrate.

PASTERUIZATION - You'll want to get your material to the proper moisture content before loading into bags or jars. Let the substrate sit for half an hour, and then re-adjust to field capacity. Oven bags are for cooking turkeys in the oven. They're not suitable for stovetop pasteurization, so use jars or filter patch bags, which don't need to be sealed first.

PASTEURIZATION - Pasteurization only kills fungal spores, leaving the beneficial bacteria intact. After pasteurization, the substrate need not be kept sterile, so it's suitable for bulk substrates such as straw and manure that are too big for filtered jars.

PASTERUIZATION - You'd have an easier time if you divided it up into several smaller bags or jars rather than one large one. You want to maintain 140F to 160F in the center of the bag for one hour for pasturization.

PASTEURIZING - You should pasteurize the coir. Some, including me have used it unpasteurized with success, but additives such as compost and/or manure definitely need to be pasteurized, so just do it.

PASTERUIZATION - Open water pasteurization sucks, at least put it in a quart jar. Reason being, because it loses nutrients and the screws up the water content.

PASTERUIZATION - I can pasterize in a Crock Pot IF I can watch and control the temp!

PRESSURE COOKER - POINT OF A PRESSURE COOKER....IN GENERAL: Canning and cooking foods faster/ with less nutrition loss.....MYCOLOGY: Makes it so you don't lose juices and all in roasts and stuff too. Steam steralization at temps higher then boiling water can exhibit.

BEST PC BULK - If you are going to give it a SERIOUS go. All American PC is BEST PC EVER. Bigger the better. Build (at least) a GLOVE BOX. Better yet a HEPA FILTERED FLOW HOOD. FIND HORSE MANURE. Learn WBS & G2G. Learn PH of casing is important.

LEAVING JARS AFTER STERILIZATION - Leaving unsterilized grains in a closed jar is a breeding ground for contaminants. The more contaminants you have in a jar, the more are likely to survive the 'sterilization' process.

GLOVEBOX STILL AIR BOX - You rarely see the old hands using any sort of 'positve pressure' box. A glove box need not be sterile or have sterile air. There is absolutely no way that a dust mask or even a vacuum cleaner hepa filter on a sterlite container with a computer fan is going to deliver better performance than a simple container with two holes cut for your arms, but otherwise closed up.
What you want in a glove box is to have zero air movement. You can lightly mist the inside air of the box with plain water, and this will attract whatever contaminants are floating around in the box to the water droplets, where they will fall by gravity to the bottom of your glovebox. After that, simply do your work wearing latex gloves. I use tyvek sleeves on my wrists, pulled down over the surgical gloves. Wash the gloves with alcohol before working. I have nothing at all attached to the glovebox. Just two 4" holes for my arms to stick through. The loose fitting sleeves seal around the holes well enough, and allows me to pull my hands in and out with ease to use my alcohol torch. (I don't like to use the flame inside the box due to excessive heat) My success rate with the glovebox described above is equal to that of my laminar flow hood. I prefer the flowhood because it's easier to work in front of and you have more room to move around.
The problem with having a fan on your glovebox is it will cause turbulence inside the box, which will keep any contaminants in suspension where they are actually more likely to land on your project than without a fan. Best of luck.
A fan is the worst possible thing you can do to a glovebox. There is also no need to spray lysol or oust in a GB. Wipe it with a damp cloth and go to work. There is nothing sterile about a glovebox. STILL air is what you want.

STERILE TECHNIQUE GLOVEBOX - You can also cut the holes so they're fairly snug around your arms, then just wear latex gloves. Be sure to wash your hands and arms first, then put on a freshly laundered long sleeve shirt to cover the skin on your arms.(dead skin cells flake off all the time and they'll have bacteria) Remember, a glovebox does not have to be totally airtight or sterile. It only serves as a place for you to open or inoculate jars or Petri dishes in a draft free environment. I haven't used attached gloves in years because they're such a pain in the butt to work in. Latex gloves give you really good control. Of course, do your glovebox work in a very clean room with no fans or air conditioners etc running.

GLOVEBOX/STILL AIR BOX - If your box is draft free, then you can skip the mask and hairnet. Most of us use simple rubbermaid totes for gloveboxes, so breathing near the lid could get bacteria inside, so watch for that and either tape the seal or use a surgical mask. The air in the room doesn't need to be sterile by any means. As long as the glovebox has still air and you've sprayed inside with water, you'll be fine. Don't use flammable stuff in your glovebox. You can mist it with your regular mister with plain water, and whatever contaminants land on the floor or back and side walls, will stick there due to adhesion.

GLOVEBOX/STILL AIR BOX - The problem working bare armed is that several thousand dead skin cells per hour fall off each arm. That is a fact of human metabolism. In fact, the overwhelming majority of 'dust' in a house or on the furniture is actually dead skin cells. If you work bare armed, those skin cells that flake off your arms now have a chance to fall by simple gravity into a jar or Petri dish. With a freshly laundered long sleeved shirt, the shirt will catch the majority of those dead skin cells, thus protecting your project. The shirt does NOT need to be sterile, so please stop confusing the subject with this silly arguing.

GLOVEBOX VS AIR FILTER - A glovebox can never rival a flowhood, although one can certainly screw up a glovebox by placing fans and filters on it.
A still air glovebox can be used with the same success rate as a laminar flow hood, but is much more cramped to work in. A flowhood gives you a sterile work space that is big enough for your elbows to move around in.

GLOVEBOX - This is why I recommend soap and water only to clean a glovebox. Lysol and alcohol are both surface disinfectants, and you don't dump spores or mycelium on the floor of the glovebox anyway so they are of no use. Since all a glovebox does is prevent drafts that would blow contamination into your work, soap and water is all that is required to clean them.

GLOVEBOX - Glovebox Hands down beats oven box, too many contaminants in your oven also theres moving air coming in and out of it because it can't be closed unless you can fit inside it :p.

GLOVEBOX - Gloveboxes need not be sterile, and I never use lysol, etc., in mine. Fruiting chambers also need not be sterile.

STILL AIR BOX - I just use soap and water to clean the inside.

TIMERS - Cheap timers won't have the switching capacity to run an air conditioner. You'll need to get an intermatic timer in the metal box from an electrical supply. Sometimes you can get them at lowes or home depot, but make sure they have the 'amp' rating that matches or exceeds the nameplate 'amps' on your AC.

BOOKS - The Journal of Medicinal Mushrooms has as it's editor in chief, Mr. Solomon Wasser, and on the editorial board, another 'lay' person, Mr. Gaston Guzman. Perhaps you've heard of those two?
The issue I'm holding in my hand has articles from such 'lay persons and hobbyists' as Paul Stamets, Christopher Hobbs, John Holliday, Gaston Guzman, Toshihiro Hashimoto, Soloman Wasser, Gregory Plontnikoff, Daniel Winkler and others too numorous to mention.
I feel strongly on a board focused on mycology we should concentrate on mycology and not vulgarity, however, feel free to call it whatever you wish.

BOOKS - I'd recommend both of Paul's cultivation books. The Mushroom Cultivator for a good basic mycology course, and Growing Gourmet and Medicinal Mushrooms for some more advanced tips, correction of a few mistakes in TMC, and detailed descriptions and pictures of common contaminants. These are mushroom growing books, not specifically psilocybe growing books. Those I've seen that only show how to grow cubes are lame and inaccurate at best.

DAMAGED FRUITS - Anytime a spot forms on a cap from damage, it's there forever. It won't 'heal'. The fuzz on the stem is fine, and doesn't mean humidity is too high. It seems to happen with some strains/substrains. Look closely at what you see. Think about when you hit your own body on something and it bruises. The color you see is your actual skin color. That's bruising. Now think about when you get a bad scrape or cut and if forms a scab. The scab sits above your skin as a separate layer. A scab on your body corresponds to mold on your substrate. The mold will be a layer above the substrate.

DISTILLED WATER - Everybody knows about the pure distilled water in a clean, smooth container being able to be superheated slightly above 100C and remain liquid. There's dozens of demonstrations on youtube and others. However, coir or anything else mixed with water can NOT be heated above 100C without the water changing state to a gas. It doesn't matter if there's any air above the water or not.

EXPERIENCE - I found this "dust" of *Bacillus thuringiensis* for begetables. It was not labeled for fungus gnats, and it was not the substrate of this species indicated for controlling fungus gnats. It was really for chewing caterpillars, etc. It's called "Dipel 150 Dust." Five bucks for a pound. The values for treating soil are absurd (too low for me to apply to a casing) so I took a tea-straining teaspoon (one of those latch-and-strain teaspoons) and put it down in the container the bacillus dust and clipped it shut against the side of the container (while still inside) then brought it out and shook it over my casings. There was a layer of this dust that sort of looked like a fine, white snow. I applied this once, then a couple of days later again, then about a week later again. I applied it 3 or 4 times, and, as the bacillus thuringiensis propagated and interfered with the life cycle of the fungus gnats, the adult population began to wane. Over the course of around a month, I've gone from gnat-body-littered stickytape traps changed once a week or so, to, no visible adult gnats in the terrarium. It appears this particular product, though it takes a few weeks, will effectively disrupt and wipe out the fungus gnat life cycles on casings.

EXPERIENCE OF ROGERRABBIT - 36 years. In 1971, I brought home a cow pie that had cubes growing on it because I could see 'mushroom roots' covering the whole bottom of the patty. I mixed it into my compost pile and forgot all about it until the fall rains came when I found hundreds of cubes all around the base of the compost pile. I've been hooked ever since. It actually took me well over a year to learn that mushrooms don't have roots. There were no books on cultivation at the time, and of course no internet. The Dallas, Texas public library was my only source of information. I finally found Alexander Smith's field guide to western mushrooms in the mid 70's, and learned a lot about mushrooms from that, even though it's not a cultivation book.

FIRE FANG - Actinomycetis. It will also grow on coffee grinds if you store them for any length of time.

GNATS/FLIES INFO - They love the fruit bowls and anything else sweet. They're attracted to the smell of the mycelium, but they don't usually breed in our projects. They rarely cause much problem unless they're there by the thousands. I've never had a single contaminant that I could blame on them and I live in fruit fly/gnat heaven. Normally, they breed in your houseplant soil and then fly out to your mycelium to feed. Fruit flies have about a 20 to 30 day life span. They go from egg to larva to adult flies. The adult stage is about 7 to 10 days of the span & in that time, 1 adult can lay about 700 to 800 eggs. The flies do not lay eggs at temperatures below 54 F (12 C) or above 91 F (33 C).

HALF GALLON - Half gallon jars often go anaerobic in the centers. It's also harder for the CO_2 to escape the larger jars. Personally, I don't use anything larger than quarts, even though I have five or six cases of half gallon jars in storage. Try leaving the jars laying on their sides. Next grow, I'd suggest quarts for grains. In addition, the larger the container, the drier you make the grains. You'll use about 20% less water(per measure of grain) with half gallons than you'd use with quarts.

LAUNDRY BASKET TEK DISCUSSION - By Visions method if I remember correctly, you're not supposed to mist the sides. Let them dry out, and the dry straw serves as the contamination barrier. He poured water down from the top. I do it a bit different by placing in a bag or large tote with holes cut into it for gas exchange. This keeps the CO_2 levels higher during colonization, which actually prevents the mycelium from turning as much of the substrate carbon into CO_2, which reduces the size of the substrate greatly. About a week after full colonization, I introduce to the normal fruiting conditions of high humidity and lots of air exchange. I don't fruit them in open air unless it's the rainy season outdoors, in which case I set them on the back porch to fruit. You can see a short, low resolution preview video of the way I do it on my website.

LABELING - My system is to list the date first, parent species second, then strain third, and then each transfer beginning with the letter 'A' and going through the alphabet. Assume the species is Reishi, and the strain is my 'sheriff' (sherrif strain got its name because a dumbass sheriff gave me a bogus ticket the day I cloned it, but that's another story). A swipe of spores made today on agar would be labeled 042607RS. Assuming three days from now I make a series of transfers of the first mycelium to germinate from spores, they would be labeled 042907RS A1, B1, C1, D1, etc. As the strains differentiate, the next series of transfers would be labeled (date)RS-A1-A, (date)RS-A1-B, etc. From the second original dish, the second set of transfers would be (date)RS-B1-A, (date)RS-B1-B, etc and right on down the list. It's important to be consistant with your system all the way to fruiting because when you find that awesome fruiting strain three months from now, you want to be able to go back to the original dish in the refrigerator that corresponds to the fruiting tray, pull it out and make a master culture slant from it. That way, you preserve the genetics of a great strain from a very early time in its life before many cell divisions have occured.

LEARNING - Agreed. My bitch is that when people move to edibles/medicinals they have to un-learn all their bad habits, essentially starting the learning curve all over again. With cubes, they'll fruit on just about anything, regardless of how you prepare the substrate, so they're like learning to ride a bike with training wheels. However, if you don't learn to ride without those training wheels, you'll look awfully silly someday when you grow up and have to bolt them on your harley. That's why I suggest pasteurization of bulk substrates and casing material. However, this has all been covered before, so do a few searches and you'll find all you ever wanted to know from both sides of this coin.

LOOKING FOR A MICROSCOPE - If you want good pics, get ready to spend some bucks. I've got a few cheapies that just sit on the shelf, and never get used anymore. You won't get quality for less than $1,000 and that's the low end. A decent C-mount microscope camera is going to cost $2,000 just for the camera. In fact, the camera will cost more than the scope. You can pick up a pretty good scope for $1,000 whether you want zoom or light microscope. I actually use my zoom more than the light in mycology. The zoom microscope is great for looking at mycelium on Petri dishes, gills on mushrooms, and other stuff like that. If you want to see on the cellular level, you'll need a light microscope and a box of slides and covers. I had a whole section on microscopy filmed for my video, but had to cut it out because there just wasn't enough room on the 2 dvd set for it. Perhaps it will fit into one of the future releases. I'm already working on the next one. Stereo microscopes are for looking at something from the top. The lens and the light are on the same side of the object you're viewing. Stereo microscopes are for looking at gems, coins, bugs, and mycelium on a Petri dish to examine for contaminants, etc. A zoom microscope is a stereo microscope with an adjustment to vary the magnification without changing lenses. Maximum magnification with stereo-zoom and zoom microscopes is usually around 20X to 30X. I have a pretty high end zoom microscope that goes to 50X, but the field of view at that magnification is pretty darn small, defeating the purpose of using a stereo microscope in the first place. A light microscope has the light on the opposite side of the lens from the object you're viewing, thus you see the light that shines through the object. Laboratory and medical microscopes are the light type. If you want to examine the internal structure of spores, or view mycelium to look for the number of nuclei in each cell or to look for clamp connections, you'll want a light microscope. If you order a stereo microscope, be sure to get LED lights, even if they're more expensive. Coin collectors and jewelers can use the cheaper halogen that seems to be standard on stereo microscopes, but the heat will cook your mycelium, and if you look at something inside a Petri dish, the dish fogs up in three or four seconds from the heat, blocking your view. There's some pictures taken with a light microscope on my website on the introduction to mycology page http://www.mushroomvideos.com/1811640.html along with the mushroom gill shots which were taken with a zoom microscope, and the basidia pictures at the bottom of the page were taken with a scanning electron microscope. The pictures of verm and perlite in this thread:
http://www.shroomery.org/forums/showflat.php/Number/6610766#Post6610766 were taken with a stereo zoom microscope.

MUSHROOM FARMER - I know the owners of several local mushroom farms in my area and every single one of them got their start with growing magic mushrooms, then went into the legal business. They're business people and hard workers, but far from prudes. Just put down that you have experience and cautiously decline to talk about species during the interview and they'll get the point, but at the same time know you're being discrete. None of them will hire someone who brags about psilocybes because that could bring heat on them. That said, most of the jobs at mushroom farms are just labor. There's lots of compost to turn, trucks and tractors/forklifts to drive and floors to sweep and high pressure wash. Unless you get a job in the 'lab' it isn't going to be much to do with mushrooms unless you're a picker, and in that case you have to learn to work very fast, which is darned hard work, and stops being fun after the first fifteen minutes.

MUSHROOMS FALLING OVER - It's substrain related. Very good tendency in my opinion, because little damage is done to the casing layer when they fall over or are picked.

MYTH - Early mushroom growers followed on the agaricus farmers knowledge and grew their mycelium in the dark and had good results. Therefore, the wrote that mycelium should be 'incubated in total darkness' and that myth is being repeated thirty years later, even though it is just plain wrong.

MYTHS - Myth: If you can see the tray, it has enough light.
Reality: Bullshit. Bright, high frequency light is much better. Natural daylight fluorescent or metal halide will give the best pinsets.
Myth: You only need a few minutes of light per day.
Reality: Bullshit. 12/12 has been proved for years and years to be many times better.
You don't find the experienced growers making those silly statements. Fluorescent light.

NOOB SPEACH - Sure, you can half-ass the light and still get a crop. You can half-ass a substrate and still get a crop. You can half-ass a fruiting chamber and still get a crop. You can half-ass on air exchange and still get a crop. You can half-ass on humidity and still get a crop. However, if you skimp on all of them, you get nothing. If you work hard on every aspect of growing, you'll get spectacular results. That's why those of us who know try to advise on the best ways to get the results most of us are looking for.

NITROGEN - Don't use urea. If you feel you need a nitrogen boost, use chicken manure, but at no more than 5% of the total bulk substrate. Make sure the chicken manure has cured in the sun for at least a week or two and has zero smell. Otherwise, spread it out on cardboard in the sun until it's dry and odor free.

NITROGEN ONLY WHEN COMPOSTED - Don't use blood meal because it doesn't do much good unless it's been composted in a pile. Fish emulsion does no good at all. Remember, mushrooms are not plants and need to eat their food to get energy. They don't get energy from the sun, so fertilizers are useless.

NEMATODES - One needs to be careful handling nematodes and growing mushrooms. Many species are death to fungi, while other types of fungi can trap and kill the harmful nematodes.

PAN CYANS - Grow them exactly like cubes, except use a thinner substrate of horse or cow manure no more than 2 inches thick, and a 1/4" peat based casing layer. Other than that, don't do anything different. They're not as cold temperature tolerant as cubes, so try to keep fruiting conditions in the 75F to 85F range. They usually take a few days to a week longer to pin than cubes as well. Shotgun terrarium will work fine. I don't like them anymore. The trip always seemed a bit on the dark side, not pleasant at all in my experience. Good luck.

PENIS ENVY - PE's don't pin well unless you do strain isolations and find a really good fruiting isolate. What you have is about average pinset for multispore inoculation.

POPCORN - Colonizing twice as fast isn't necessarily a good thing. If the mycelium is starving, it will search for food. Since the vermiculite is inert, it won't find it. We see the same thing when people use popcorn for spawn. The jars colonize twice as fast as rye, but have only half or less as much mycelium per jar. There is no advantage.

PSILO - As we know, when mushrooms grow, they don't grow by cell division. The cells expand as they engorge with water. A small pin has all the cells it will have as a large mushroom. That's why a small fruit has nearly as much actives as a much larger fruit. The larger fruit is engorged with water, thus it's less potent by weight. That's a fact. Five grams of small mushrooms are far more potent than a single five gram fruit. That's also a fact. The picture of fahtsters above is in the pinning stage. Only a few of the caps have started to tear the veils. The picture from 24 hours later is on my video, and they're quite a bit larger. All bs aside, you don't compare the size of fruits from a four to six inch deep substrate to fruits from a half pint cake. This argument will be going on long after we're all dead and buried. I just won't have people trashing teks because they're unable to pull off grows with them. Ask any long-time grower who has used all methods, and most will tell you for large amounts of fruits, go with bulk substrates such as manure or coir. However, most of us aren't into selling mushrooms, and a few cakes are more than enough for personal use. There is no difference in potency between mushrooms from cakes and from bulk substrates, unless one lets the fruits from the bulk substrate get very large, at which time they're considerably weaker. Think of it like a balloon. If you blow it up bigger, you don't increase the amount of rubber in it.

SCLEROTIA - Sclerotia is a much better experience, and the taste doesn't gag you at all. I've found mexicana to be much more like acid than mushrooms. It's a cleaner trip, without the body numbing that makes it hard to move or communicate with cubensis. I've also found sclerotia to be a much more spiritual trip than cubes. In addition, it's shorter lasting, so it's not out of the question to do on a weeknight, when you have to be at work the next day. They're my favorite, along with ps cyans. I use rye berries, but they're simple as pie to clean up. Simply take a stone in your hands and rub the grains off with your fingers. The texture is similar to nuts, and the mushroom taste is mild and not unpleasant at all.

SPEACH - You want your grain master to be fully colonized, then bang it a few times against a fully inflated tire to separate the kernels. With the kernels separated, you can carefully pour the loosened grains from the

master to the receiving jar. Be sure your receiving jars have been prepared no more than 2/3 full, so that you can pour a tablespoon or two worth of grains from the master without overfilling the receiving jar. No jar should be filled more than 3/4 full after the g2g transfer, because you need room to shake it later.
Hopefully, you have a flow hood, but whether you're using a flowhood or glove box, try to get the transfer done within just a few seconds to limit the amount of time the lid is off each receiving jar. With time and practice you'll develop a technique where you twist the master jar as you pour so the grains will flow out smoothly.
Don't be distracted by the pictures of Paul doing g2g with bare hands. I cringe everytime I see those. Wear latex gloves and wipe them down with alcohol after putting them on. Also, wipe down the exterior of the master and receiving jars with alcohol before the transfer to limit the chances of contaminants from the exterior finding a way inside.

SPIDERS - Don't kill the spiders. They eat fungus gnats that WILL cause you problems. A grow chamber need not be sealed up, nor sterile. You want air exchange to prevent trich and cobweb, so naturally the gnats will get in, and so will the spiders. Spiders are our friends.

STORING REFRIGERATOR - Often, a grower puts a tray in the refrigerator, and a few days later gets pins. Thus, the connection is made that the drop in temperatures caused the pinning. It makes sense right? However, what if he had a tray that he exposed to a ten degree temperature rise and a few days later he got pins? Could he not make the same case that the increase in temperature caused the pinning? In fact, this is what happens in nature. A summer rain(thunderstorm) comes, which 'dunks' the substrate, and then when the sun comes out, the mushrooms pop up very fast, often in 80's and 90's degree temperature. One could make a very good case that in nature, it's the increase in temperature that stimulates the pinset. It's a survival mechanism. They need to spread spores before the mycelium dries out again. I've done both of the above scenarios dozens, if not hundreds of times to get to the bottom of this. That's the reason I say what I do that temperature drop does not play a part in the pinning strategy of tropical species. In fact, some of the best pinsets came when fruiting conditions were five degrees or more warmer than colonization temperature. Cold shocking is the signal that fall fruiting mycelium needs to begin producing fruits. Shiitake, P. cyanescens, P. nameko, etc., to name a few require a cold shock to fruit. Cubensis, H. ulmarium, Pan Cyanescens, etc., do not require a cold shock. The above is not to discourage experimenting in any way. However, get your ducks in a row, and have many duplicate projects made exactly the same way, and spawned, colonized, cased, etc., exactly the same way, and then cold shock some, and increase temps on others. Keep controls that fruit in exactly the temperature they colonize in. From my experience, if you do the above, your results will vary. Sometimes the cold shocked tray will fruit sooner, but other times later, often much later. Ditto for the other parameters. This is what has led me to my conclusions. The other pinning triggers of full colonization, increased air exchange, and near 100% humidity far outweigh temperature considerations. Good luck to all. Experimenting is how we learn. I store master slants in the refrigerator for years at a time. I've never had one single invitro mushroom from a tropical species ever form in a slant. Cause and effect can be tricky sometimes. For example, if you get drunk as snot and drive, you're more likely to get in a car accident. However, what if you have a cup of coffee in the morning and then get in an accident while sober? Did the coffee cause the accident, or was it just 'your time'? My experience says a tray that fruits after being put in the refrigerator was about to fruit anyway. The fridge probably delayed it by a day or so in fact. There used to be a mindset that mycelium could compare to weed, where (in the case of weed) changing the photo period would signal a change from vegetative growth to flowering. It was thought that a temp drop would change mycelium from vegetative growth to fruiting. However, after many side-by-side tests, I've personally ruled out such a phenomena, so I pass that info along. Feel free to experiment to either prove or disprove the above. In no way do I consider my experiences the last word on the subject. Mushroom cultivation, especially when compared to crop farming, is in its infancy and we're still learning.

STORAGE MYCOLOGY - Or, spend $99 and buy a dorm type refrigerator brand new, and never put anything but mycology projects and unopened cans/bottles of beer in it.

STIR BARS - Latex tubing can be used over magnetic bars in order to lower the noise of the magnet.

SUGARS - Dextrose and Karo are pretty much the same thing, Glucose.

TEMPERATURE - Water boils at 212F/100C. You can't boil at 300F without a LOT of pressure. It doesn't matter how hot your stove is or how rapidly the water is boiling, it will be at 212F/100C.

TERRA SORB WATER CRYSTALS - Terra-Sorb Terra-Sorb is a "water crystal" made from a synthetic polymer related to super glue. This brand is made from potassium and there are others made from sodium. The crystals can absorb 400 times their weight in water, and then release it slowly back into their surroundings. They have been tested and shown to be non-toxic and environmentally benign. They have been used in mushroom cultivation and shown to not incorporate themselves into the fruit at all. Over time they will just break down to carbon dioxide and water. They drastically reduce the need for misting a casing and in some instances will eliminate the need all together depending on the fruiting chamber. Just looking for anyone's experience first hand with this product. It is not a secret that it works or exists and given it's ability I would think many others before me would have tried it.

THE WAY IN - Mutlispore innoc, day six.
5 squirts, 1 each corner, 1 down center, about 2.5 cc per jar.
agar is GREAT, because you can tell if any culture is contam'ed - or not.
Liquid Culture (LC)is fastest - I ever had.
Matter of fact, once tried LC straight into pasturized compost substrate, supplemented with 25% PC'ed bulk WBS.
Worked GREAT (but, must have very aseptic enviro to incubate in).

TROPICAL SPECIES - It's well known that cold damages tropical species and thus they should never be 'cold shocked'.

BETTER, FASTER, CHEAPER......TRUE STORY - You cannot get

VOCABULARY - Spawn: Noun form: Grains, brf, etc., fully colonized with mushroom mycelium.
Spawn: Verb form: To mix the above defined colonized grains into a substrate.
Substrate: Manure, compost, coir, coffee grinds, etc. Substrate is the food the mushroom mycelium eats. In the case of brf cakes, the brf is both the spawn and the substrate.
Casing: The non-nutritious, moisture-holding layer we place on top of a substrate as a water reservoir to supply the substrate with the extra moisture it needs to support the developing flush of mushrooms.
Patching: Applying a small amount of casing material over the mycelium that is poking through the casing layer. This allows that mycelium to continue growing, while waiting for more mycelium to reach the surface of the non-patched areas. This results in a more even pinset.

WHAT IS - A pf jar for example is a substrate when fruited directly from the cake. However, a pf jar is spawn when used to inoculate manure or straw, etc.
Rye is a spawn when used to inoculate manure or straw, etc., but is a substrate when cased with peat-verm or verm-coir, although coir is better suited as a substrate than a casing material. If you mix the rye in as an inoculant, it's spawn, but if you lay it in a tray and apply a casing layer over the top of it, the rye becomes the substrate.
A bulk substrate is a large amount of material that supports mushroom growth that you spawn your mycelium into. Bulk substrates can be manure, straw, coir, worm castings, coffee grinds, etc. Grains can spawn to a bulk substrate, or serve as the substrate, but are never considered a 'bulk' substrate.

WHAT IS SPAWN - Spawn as a noun is the grains or other material such as brf cakes that are fully colonized with mushroom mycelium.
Spawn as a verb is the act of placing those fully colonized grains into another uncolonized substrate for the purposes of expanding mycelium mass.
Spawn as an adjective is used to qualify a noun. Thus when used as "the spawned substrate", substrate is the noun and spawned is the adjective form of the word spawn.

HARVESTING

HARVESTING - When harvesting your trying to get good food grade. Fruiting in the low 70's is perfect which benefits by giving better fruit quality. Harvesting your mushrooms should be easy on the casing and gentle. Gentle twist & pull is best. Object is to MINIMIZE casing cover damage. But, getting out clumps of shrooms, often leaves divots. Which you patch. Try not to leave any broken stem. Because that exposed tissue invites contaminates & rot. Better to have a divot in casing, which can be patched. Rather than leave torn stem tissue exposed. Good practice to pick those big fuckers, they take the uumph out of the rest of the flush. With practice, you'll develop a technique for twisting and pulling the mature fruits off that does very little damage. You can even hold a fork or spoon on the casing layer next to fruits you're picking to help hold the casing in place. Food quality is best just prior to the veil tearing. They just seem to go down easier, without that 'make you puke' horrible taste. When Picking A Flush: Remove the aborts, but leave any healthy looking pins. They'll start growing when you pick the present flush. You pick the fruits as they're ready. There is no reason to pick them all at once. You don't pick pins/primordia because they're required for the next flush. Air Dry! Then Put In Dehydrator They'll shrink a lot and let you put more into the dehydrator.

HARVESTING - Food quality is important. If you gag on every bite, then sit during your come-up time trying not to puke, it's no fun. There is no increase in the number of cells in a mushroom after the veil tears, therefore no new active compounds are made. The cells that are already there simply fill up with water. That means the actives that are in a freshly opened cap are the same actives that are in a huge, umbrella shaped, black spore covered cap, but you have to eat more to get them. When we say there is little to no loss of potency, that's what we mean. None was lost, but none was gained either. Only mass was gained, thus you gag more for the same amount. That's what I mean by poor food quality. As for developing allergies, mine have all come in the last few years as I've researched many species. I often have a few hundred jars and up to several hundred spawn bags going at any one time. This has been my full time job since I've been working on my dvd. I quit my job over a year ago, so I've been exposed to a lot of mushroom spores in that time. All of them legal edibles, by the way. The worst for causing allergic reactions is Hypsizygus ulmarium, but cubensis spores will clog up a humidifier filter in no time, and ruin the motor bushings as well. Cube spores will also foul hygrometers, and if you have a computer in the room with your grow, it will destroy the cooling fans, and if they get into the hard drive, will destroy it as well.

HARVESTING - Removing large chunks of substrate is from carelessness. You can easily back up the substrate with two fingers of one hand while twisting and pulling with the other. If the fruits are very well attached, simply do what the commercial farms do and cut the base off with a knife, then remove the stump later. Cut the stem off right at the substrate level and leave the stump there. Remember, mushroom tissue is mycelium. Anything below the substrate level doesn't need to be removed anyway. The strength of the mushroom/substrate connection is strain related, not casing/no-casing related. I have an isolated strain that the fruits fall over and unhook themselves from the substrate just as the veil tears, whether cased or not. That quality comes in really handy when I'm on an outside job working long hours.

AFTER A FLUSH HARVESTING - After picking a flush, allow the substrate to 'rest' for several days to a week. Let it dry out somewhat during this time. A substrate will not flush again right away. After the 'rest period', give it an overnight soak to bring the moisture content back up and place into fruiting conditions. Dunking right away is counterproductive because the mycelium is dormant for a few days and the dunk only supplies moisture to the contaminant molds that might be present, then it dries out before that moisture is actually needed for the next flush. Never leave a substrate that is flushing without air exchange. It will suffocate and die.

AFTER HARVEST - After harvest, it's a good idea to fill any divots created by picking with fresh casing material. Don't wait for it to colonize, because it rarely will. Don't re-case. Trays can be soaked for a few hours under running water. Just let the faucet fill up the tray and gently run over the sides and down the drain. Use jars of water or rocks to hold the substrate from floating. After four or five hours, most substrates will be re-hydrated. I like to wait up to a week after picking a flush before doing the above. During this rest time, allow the substrate to dry out a bit, and then soak as above and return to fruiting conditions.

DRYING - If you choose to use desiccant, it's best to fan or air dry for a couple of days first. When you use desiccant, be sure to have the desiccant lifted off the floor of the tupperware or other container, so that moisture that drips from the fruits can run through the desiccant to the bottom of the container to collect. This will prevent the premature saturation of your desiccant layer.If the fruits are for use within a few days or so, just leave them in front of a fan until then. Dehydrators and desiccant are mainly for when you wish to package them up for later and need to make sure they're especially dry to prevent molding.

HARVESTING - Pick all the mushroom tissue when you pick a flush. Don't leave pieces behind. You can fill the divots with fresh casing material but don't recase the whole thing because it won't colonize anyway. Your mycelium has already gone from colonization mode into fruiting mode. I like to let a cased substrate sit for a week after picking to 'rest'. The reason is that they rarely flush right away anyway, so by letting it sit for a few days to a week, then watering heavily or dunking, you get an immediate second flush. If you water it heavily right after picking, it just sits there wet, which can encourage molds.

HARVESTING - Do NOT pick all the pins from the casing layer. Often, pins for the first two or three flushes are set at time of first flush. Picking them ruins future flushes. You can't pick individual fruits from a cluster without using a knife. Simply grab and gently twist the whole cluster, and it will come off as one piece. Be careful that you don't also pull up a large chunk of your casing layer.

HARVESTING - Mushrooms that are picked small and immature will be more potent by weight than they would be if allowed to fully mature, and that's a fact. As the cells engorge with water, there's no evidence that they increase in potency as well. The 'veil tearing' is just a signpost along the way that indicates a good time to pick. It has nothing in and of itself to do with potency.

AFTER FLUSH - After picking a flush, it's a good idea to let the substrate sit idle for a week, and even to allow it to dry out a bit. After a week, soak it for six to twelve hours under water to re-hydrate. We refer to this as 'dunking'. After the soak, place it back into fruiting conditions, and the second flush usually pops fairly quick, provided the substrate has no contamination.

AFTER HARVEST - Nothing is set in stone, it's just something I've observed with lots of species. Most don't flush again for several days anyway, so during the time, let the substrate rest, and then give a soak to rehydrate and set back into fruiting. It more closely simulates natural the environment they evolved in, and helps to send out a stronger flush.

STORING - Cracker dry, then stored in vacuum sealed bags with oxygen absorber and food grade silica gel packets in each one. They'll keep for many years without degradation that way. I recently opened some from 1996, and there was NO degradation that could be detected after ten years of room temperature storage.

CASING AFTER HARVEST - Patching the divots is the right move, but the new casing material will not colonize, so don't wait for it to. After picking, I suggest letting the substrate sit untouched and dry for a week to recover, and then soaking for a few hours to rehydrate, then return to fruiting conditions.

HARVEST - You can pick individual mature fruits from a cluster by cutting them off just above the base with a sharp knife. Don't wiggle or otherwise stress the rest of the cluster. The aborts will sit there just fine until the remainder of the cluster is ready to harvest.

HARVESTING - The most bang for the buck comes from small fruits, prior to veil tearing. Even pins are great, and that's why you hear about aborts being so good. It's not because they aborted, but because they're at peak potency/gram at the pinning stage.

HARVESTING - With practice, you'll develop a technique for twisting and pulling the mature fruits off that does very little damage. You can even hold a fork or spoon on the casing layer next to fruits you're picking to help hold the casing in place.

DRYING FRUITS - I've never used a dehydrator. Lay your fruits on a piece of cardboard and put a large box fan in front of them. When dry, transfer to Tupperware with desiccant for 24 hours to finish up, and then seal in vacuum pac bags.

AFTER HARVEST/CASING - Fill in the divots with fresh casing material. Don't scratch or re-case the whole thing. The mycelium is in fruiting mode so won't colonize any casing material you add now.

HARVESTING - You pick the fruits as they're ready. There is no reason to pick them all at once. You don't pick pins/primordia because they're required for the next flush.

HARVESTING - When Picking A Flush: Remove the aborts, but leave any healthy looking pins. They'll start growing when you pick the present flush.

HARVEST - I prefer to pick just prior to the veil tearing. They just seem to go down easier, without that 'make you puke' horrible taste.

HARVESTING - Air Dry! Then Put In Dehydrator They'll shrink a lot and let you put more into the dehydrator.

HARVESTING - Good practice to pick those big fuckers, they take the uumph out of the rest of the flush.

DONE! I WANT THIS TO DISPUTE ANY BAD CULT ADVICE EVEN THOUGH THEIR ARE SOME MISINFORMATION OF SENTENCES AND OUTDATED INFO SO CHOOSE WISELY. PLEASE NO RATINGS. THIS IS SOMETHING I DID AND TOOK 3 MONTHS IN THE PROCESS.

Psilocybin Magic Mushrooms Growers Guide

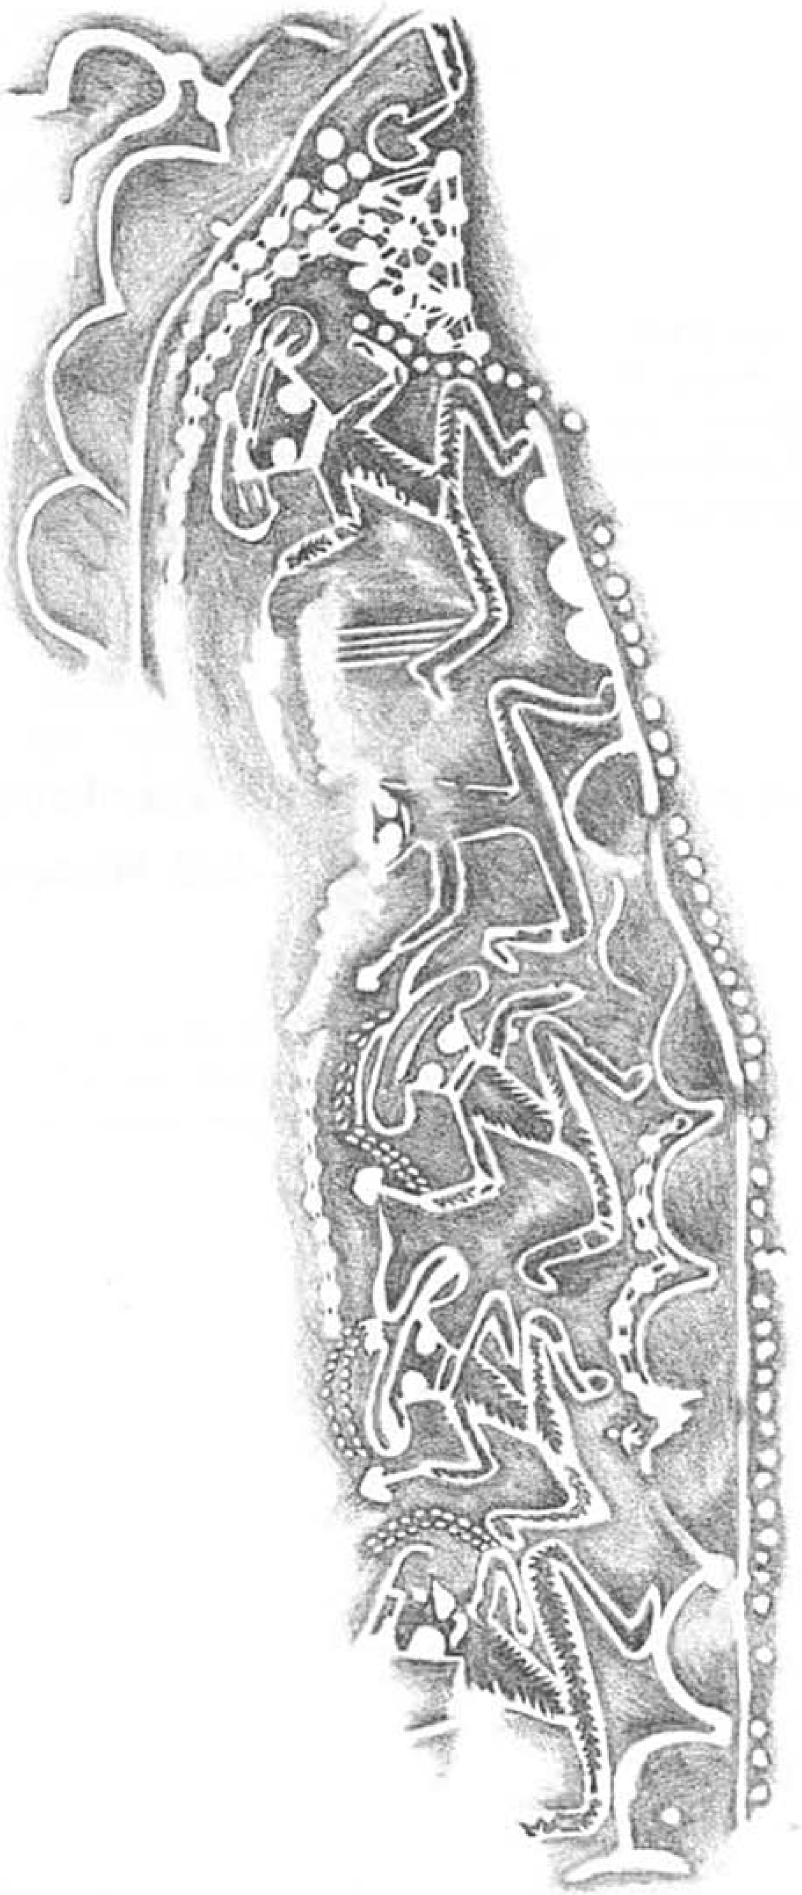
Magic Mushroom Grower's Guide

O.T. Oss & O.N. Oeric
Foreword by Terence McKenna



Rock painting from Tassili Plateau, Southern Algeria, circa 3500 B.C.

DEDICATION

This book is respectfully dedicated to R. Gordon Wasson
and Albert Hofmann, whose investigations of the botany
and chemistry of the
magic mushroom brought psilocybin to the world.

"At last you know what the ineffable is, and what ecstasy means."
R.G. Wasson, 1972

Preface to the Revised Edition

It is not often that something as fragile and culture-bound as a religious mystery can rise from the ashes of near extinction. Even the natural life of a religious mystery ends finally in erosion of connection to the mysterious driving power of some archetype. But few religious mysteries exist long enough to experience this decadence. Most are suppressed by dominant orthodoxies already in place or recently imported through conquest. This latter situation is an apt description of the status of the mushroom religion of Meso-America at the time of the Spanish Conquest.

In the case of Meso-American mushroom use, an ancient shamanic religion - of which we know next to nothing - confronted a Spanish Catholicism whose relatively advanced technology meant complete subjugation of the people, complete breakdown of the ancient gnosis. Practitioners of the mushroom cult were burned as heretics. The Indians' insistence on the mushroom as the "flesh of the gods" must have particularly excited the heretic-hunters and perhaps left them not a little uneasy as they went about their bloody business. After all, "flesh of the gods" is a claim explicitly made for the Christian Eucharist, yet it is not nearly so effective a visionary vehicle as the persecuted mushroom.

The use of the mushroom retreated to the remote mountainous peripheries of Spanish Mexico. The ritual itself was all but lost under a layer of Christianized associations. The mushrooms were called "Jesus" or "St. Peter" - their old names, names of the planetary gods of the Mayans, forgotten.

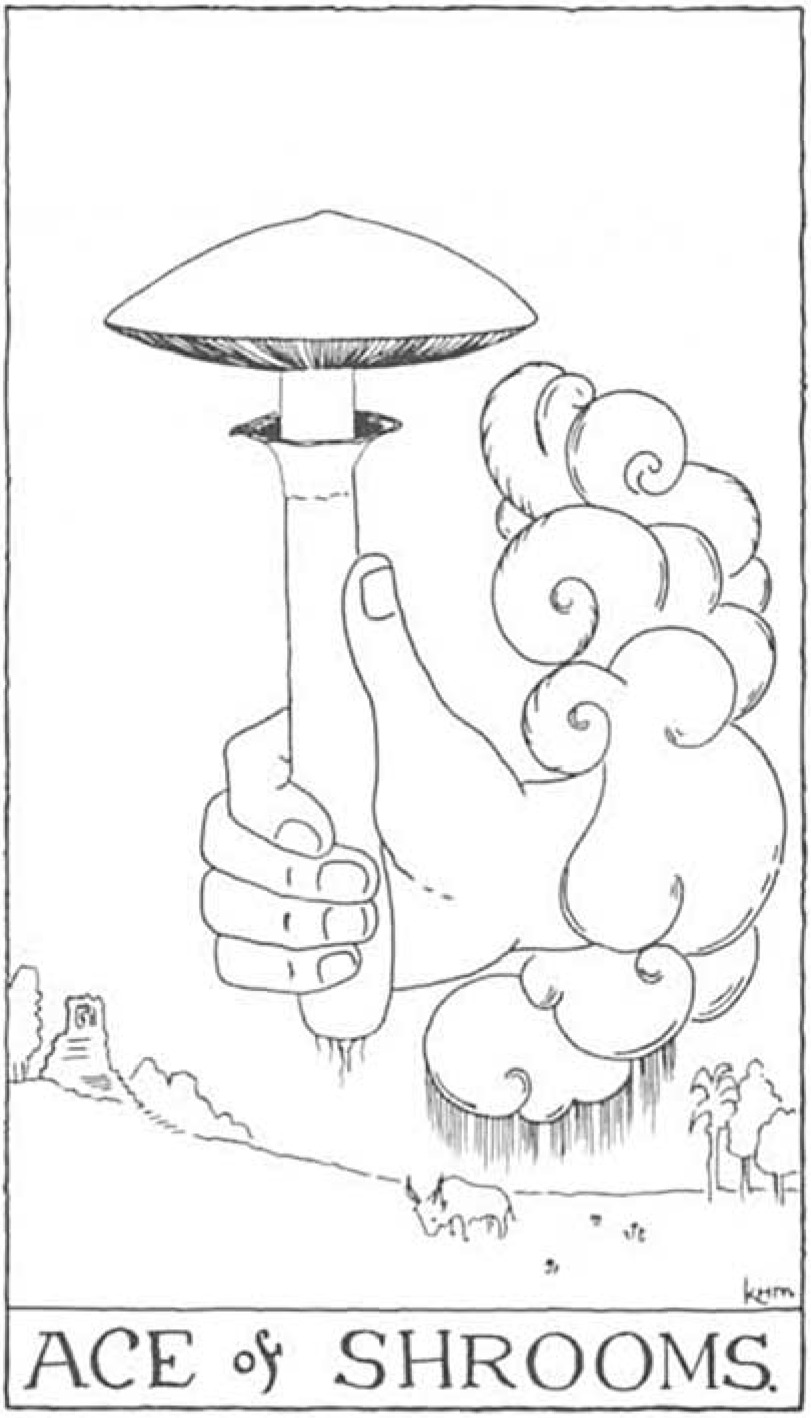
Thus the matter stood for centuries. In the 1950s Wasson made the initial discovery of the slumbering mystery, and more than two decades of mostly academic "ethnomycological" study followed. This book, first published in 1976, opened a new phase in the rebirth of the mushroom religion by placing the knowledge of cultivation into the body of publicly available information. More than a hundred thousand copies of this hook have been sold, it has spawned several imitations, and it continues to sell well. This means that there are now many thousands of mushroom cultivators in the world. It is reasonable to suppose that more people are now actively involved in a religious quest using psilocybin than ever before in history. This is a complete rebirth of a religious mystery and it has taken place in less than a decade! What are the implications of this emergence of a pagan mystery into the banal world of modernity? What are its implications for those closest to this decisive, historical shift, those who, by cultivating and teaching others how to cultivate, are making the change happen?

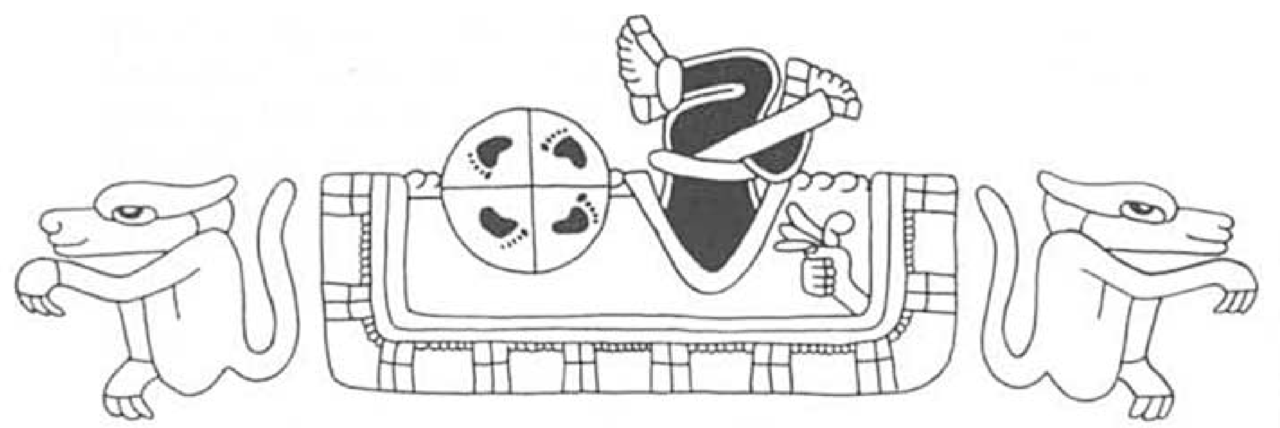
It is clear that pharmacology intends to provide the future with an ever-expanding repertoire of psychoactive chemicals. But I wonder whether what is needed are new drugs or the courage to shamanically apply the botanical hallucinogens already sanctioned by millenia of folk usage. Few of the productions of the laboratory will be found to be as somatically benign as psilocybin or to be so structurally analogous to those compounds naturally occurring in the human brain and responsible for "normal" consciousness.

Once one has actually grown the mushroom, it becomes obvious that the mushroom uses the same strategy whether it is enveloping a Petri dish or a society. A tiny part breaks away from the main body, it becomes a new center of radiative growth that expands until it reaches a critical limit, then it too spawns break-away particles with a life of their own. By this process - normally involving spores, but in cultivation involving propagation of mycelial strains, and on another level involving the teaching of cultivation techniques by one person to another - the mushroom makes its way in the world.

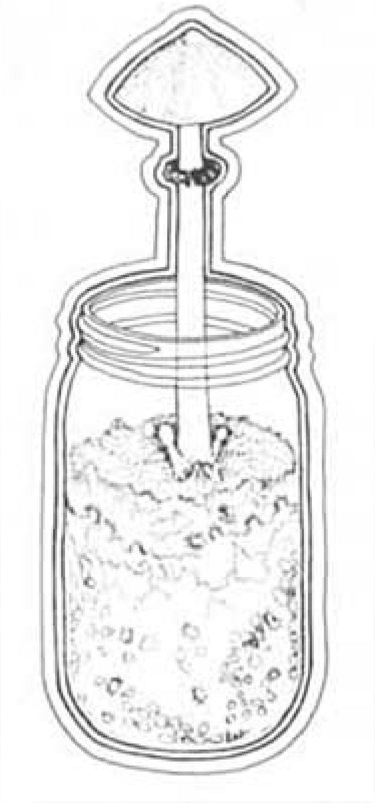
This implies an analogy: That knowledge of how to cultivate is spreading through society in the same way that the mycelium spreads through rye in a jar or a bed of compost. There is an apocalyptic corollary: When the technique is ubiquitous in society, "fruiting" will occur, meaning the real power and import of humanity's relationship to the mushroom will be suddenly revealed.

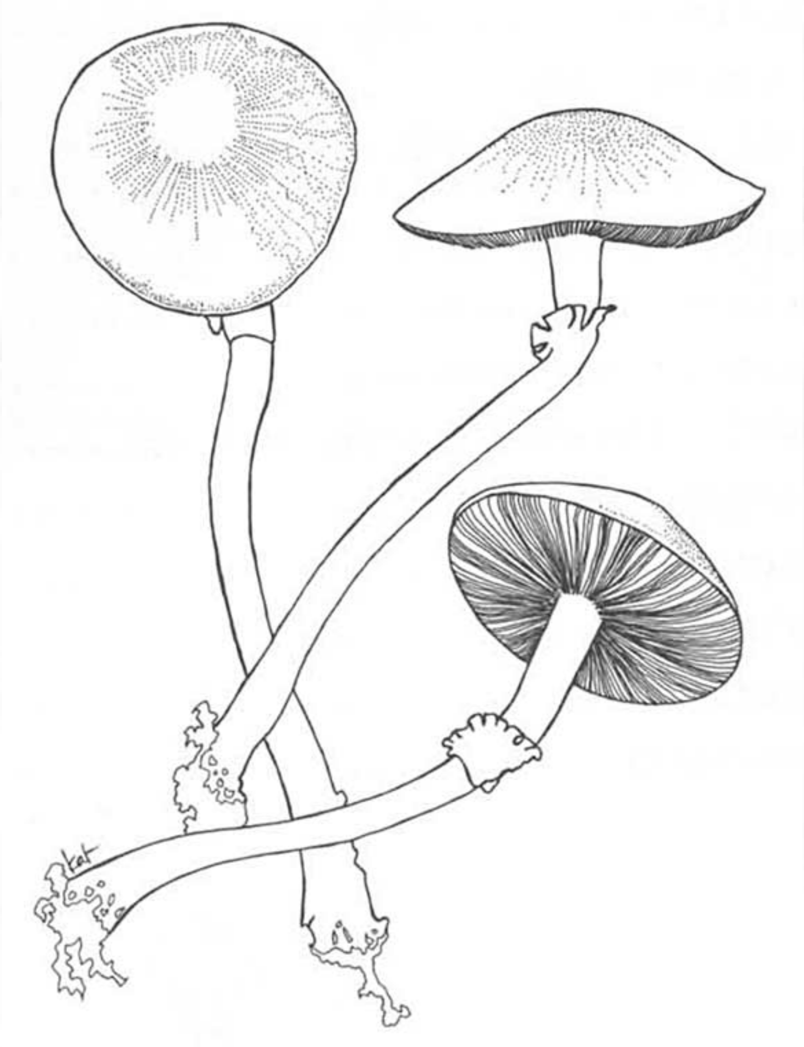
Terence McKenna, August 1985





The Mixtec representation of the psychedelic experience, from the *Codex Vindobonensis Mexicanus 1*.





FOREWORD - by Terence McKenna

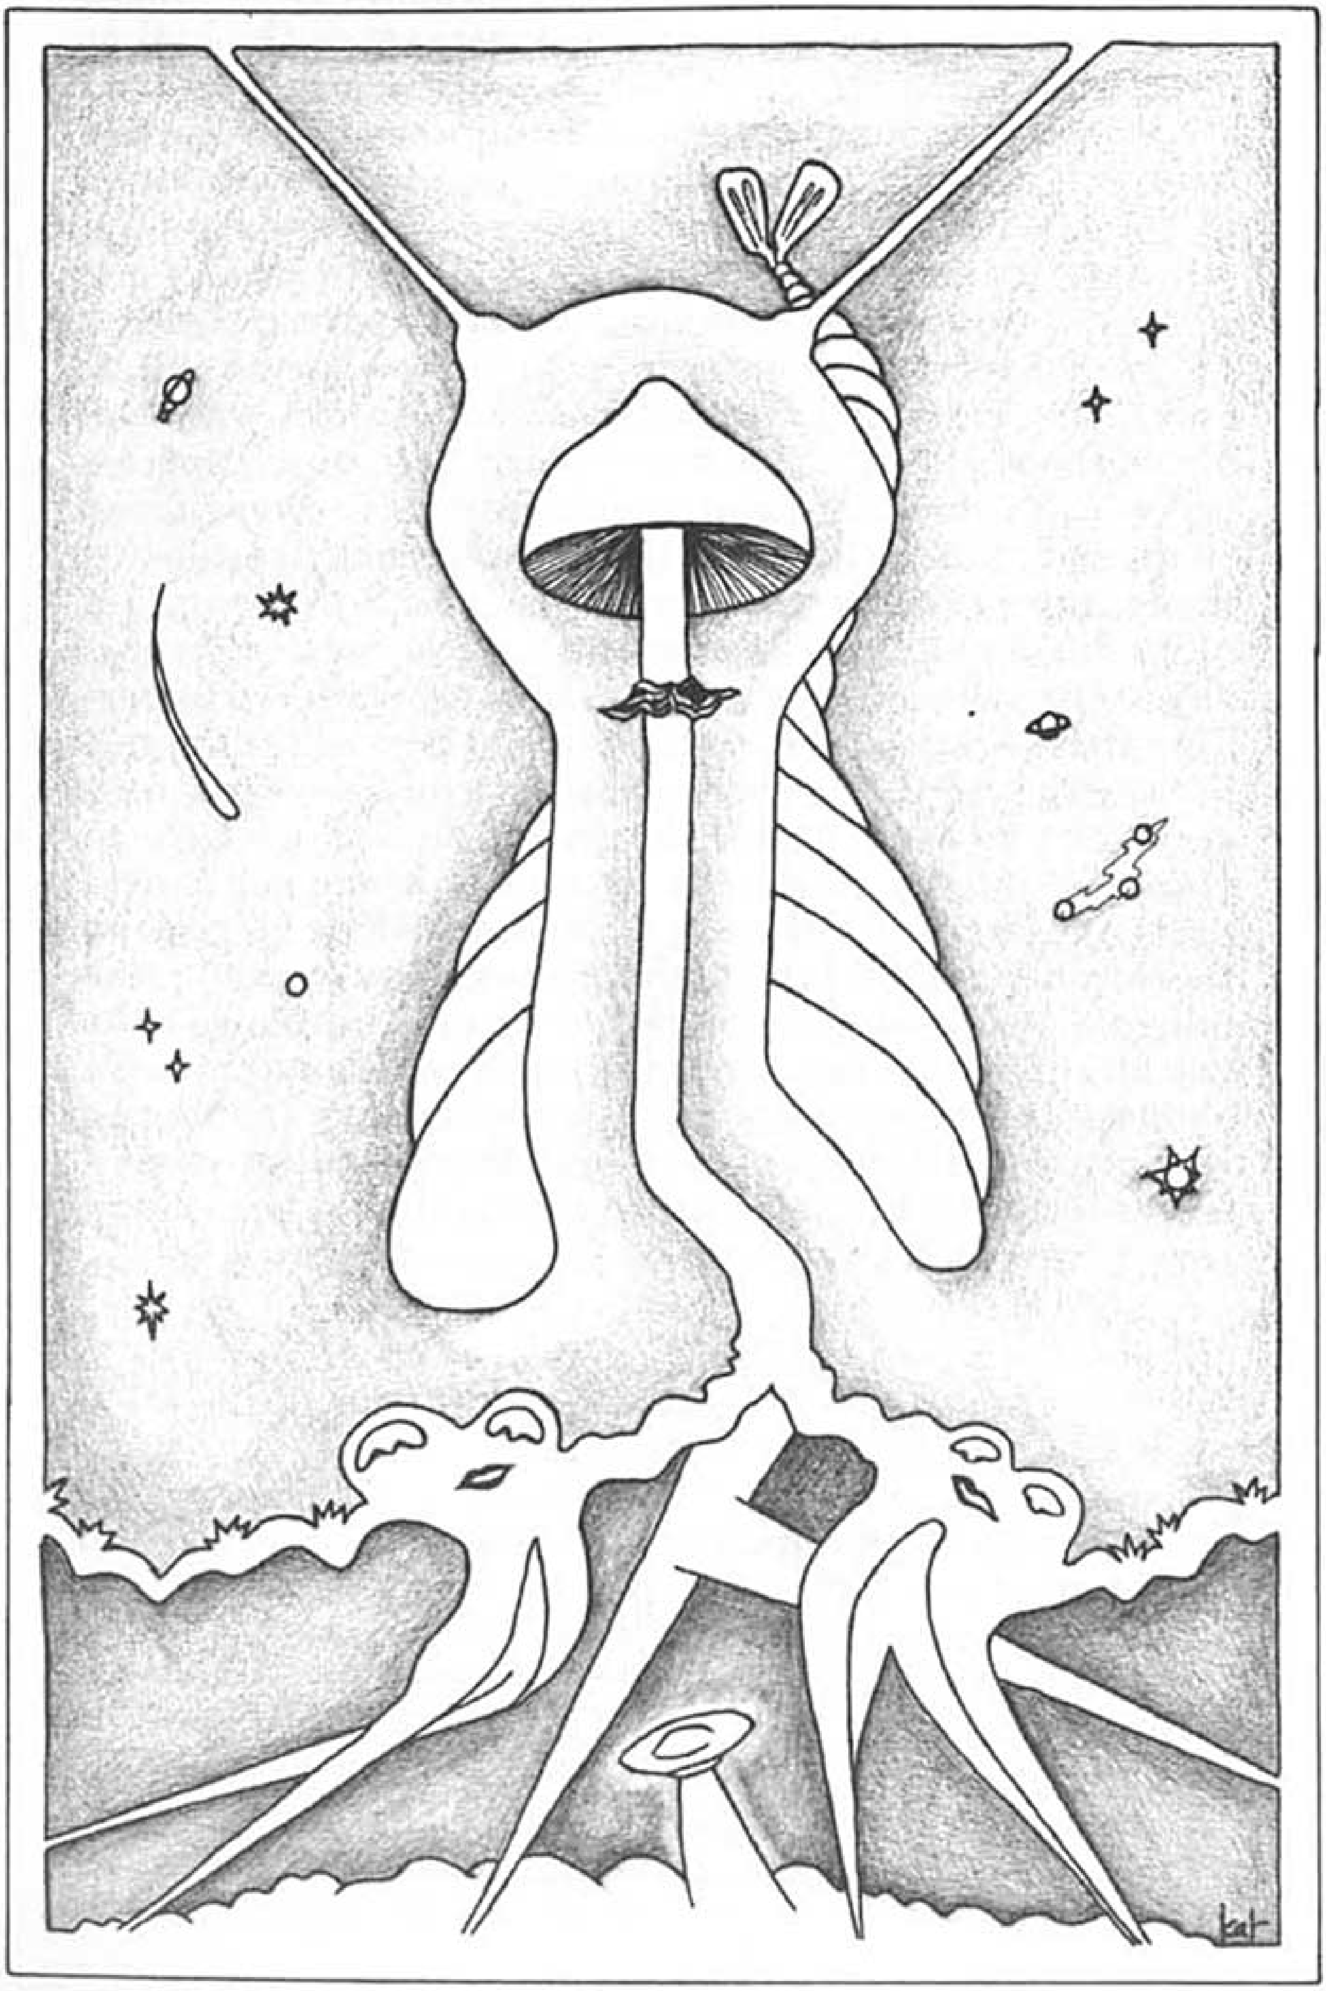
More than twenty-five years have passed since Albert Hofmann isolated and named the hallucinogen psilocybin. Hofmann's psilocybin was extracted from various species of mushrooms whose occurrence and ritual use in the mountains of Oaxaca had been discovered by Gordon and Valentina Wasson in the summer of 1953. Of the many species which were in use in Oaxaca, subsequent laboratory tests revealed that only one species was easily grown and able to fruit under a variety of artificial conditions. That one species is *Stropharia cubensis* - the starborn magic mushroom. This book is a path to this mushroom; how to grow it and how to place it in your life like the shining light that it is. The sections which follow give precise, no-fail instructions for growing and preserving the magic mushroom. We have made these instructions as clear and direct as possible; what is described is only slightly more complicated than canning or making jelly. These instructions can be adapted to undertakings of any size from a few jars to thousands.

But before all these details there should come a chat about just what this is really all about. We imagine that if you are avidly reading this book it is probably because you have taken dried mushrooms or been exposed to fresh ones in Latin America, so we do not begin with readers unfamiliar with the joys of mushroom tripping. Our instructions are a combination of research into other people's methods of cultivation and procedures which we developed, tested, and found useful ourselves. Nothing we recommend is untried by us. There may be other ways to carry on small-scale cultivation indoors but either they are variations on our method that are less direct or they are unknown to us. Cultivation of *Stropharia* outside on compost is possible in the U.S. if the local temperature is warm through the growing season. But compost cultivation is an art in itself and demands more space, more effort, and more public exposure than our indoor method. Getting involved in composting a ton of manure is not a necessary part of producing huge quantities of perfect magic mushrooms!

Our method is scientific but our opinions about *Stropharia cubensis* are not. Our opinions in this matter do not rest upon the opinions of others nor upon anything written in any book, instead they rest upon the experience of five dried grams of this psilocybin mushroom; at that level a peculiar phenomenon occurs. It is the emergence of an I-Thou relationship between the person taking the psilocybin and the mental state it evokes. Jung calls this "transference" and it was a necessary condition of early and primitive humanity's relationship to its gods and demons. The mushroom speaks, and our opinions rest upon what it tells eloquently of itself in the cool night of the mind:

I am old, older than thought in your species, which is itself fifty times older than your history. Though I have been on earth for ages I am from the stars. My home is no one planet, for many worlds scattered through the shining disc of the galaxy have conditions which allow my spores an opportunity for life. The mushroom which you see is the part of my body given to sex thrills and sun bathing, my true body is a fine network of fibers growing through the soil. These networks may cover acres and may have far more connections than the number in a human brain. My mycelial network is nearly immortal - only the sudden toxification of a planet or the explosion of its parent star can wipe me out. By means impossible to explain because of certain misconceptions in your model of reality all my mycelial networks in the galaxy are in hyperlight communication across space and time. The mycelial body is as fragile as a spider's web but the collective hypermind and memory is a vast historical archive of the career of evolving intelligence on many worlds in our spiral star swarm. Space, you see, is a vast ocean to those hardy life forms that have the ability to reproduce from spores, for spores are covered with the hardest organic substance known. Across the aeons of time and space drift many spore-forming life-forms in suspended animation for millions of years until contact is made with a suitable environment. Few such species are minded, only myself and my recently evolved near relatives have achieved the hyper-communication mode and memory capacity that makes us leading members in the community of galactic intelligence. How the hyper-communication mode operates is a secret which will not be lightly given to humans. But the means should be obvious: it is the occurrence of psilocybin and psilocin in the biosynthetic pathways of my living body that opens for me and my symbiots the vision screens to many worlds. You as an individual and Homo sapiens as a species are on the brink of the formation of a symbiotic relationship with my genetic material that will eventually carry humanity and earth into the galactic mainstream of the higher civilizations.

"Since it is not easy for you to recognize other varieties of intelligence around you, your most advanced theories of politics and society have advanced only as far as the notion of collectivism. But beyond the cohesion of the members of a species into a single social organism there lie richer and even more baroque evolutionary possibilities. Symbiosis is one of these. Symbiosis is a relation of mutual dependence and positive benefits for both of the species involved. Symbiotic relationships between myself and civilized forms of higher animals have been established many times and in many places throughout the long ages of my development. These relationships have been mutually useful; within my memory is the knowledge of hyperlight drive ships and how to build them, I will trade this knowledge for a free ticket to new worlds around suns younger and more stable than your own. To secure an eternal existence down the long river of cosmic time, I again and again offer this agreement to higher beings and thereby have spread throughout the galaxy over the long millenia. A mycelial network has no organs to move the world, no hands; but higher animals with manipulative abilities can become partners with the star knowledge within me and if they act in good faith, return both themselves and their humble mushroom teacher to the million worlds to which all citizens of our starswarm are heir."



kat

INTRODUCTION

It seems characteristic of our condition that human beings, in whatever environmental or existential milieu they find themselves, experience an urge to seek contact with the essential mystery underlying the fact of being. Indeed, the entire odyssey of our species, both phylogenetic and historical, can be seen as a groping toward some sensed transcendent fulfillment. The story of the human race - our art, science, philosophies, civilizations and religions - is largely the story of this quest for contact with the holy, numinous, and self-transcending. It is a quest at least as old as our species; evidence indicating that early humans possessed religious consciousness has been found dating back to the Middle Paleolithic. The archeological evidence shows clearly: Human beings were at home with the concept of the sacred long before the advent of writing, agriculture, civilization, or science; it is a concept that has abided in the human imagination guiding us forward since the earliest infanthood of humanity, contemporary with and possibly preceding the earliest use of tools, fire, even language itself.

The life of pre-literate people is one in which nature exists as the primary condition of existence; one is surrounded by it, one is immersed in it, one depends upon it for one's very survival. The quest for food and for the material necessities of life must be a constant and unending one for human beings in nature, a quest in which every plant and animal that one encounters comes under the scrutiny of a restless curiosity. Given this situation, it was inevitable that sooner or later in the search for food women and men would accidentally ingest certain plants containing compounds affecting the central nervous system - and find themselves suddenly transported to a realm of the profoundest rapture and strangeness. Indeed, the ethno-mycologist R. Gordon Wasson (1958, 1961) has suggested that the accidental ingestion of an hallucinogenic plant, probably a mushroom, constituted human beings' earliest encounter with the numinosum, and led directly to the formation of the concept of deity and the supernatural. This notion is not without a certain logical appeal: it stands to reason that the restless, roving eyes of human beings, scanning nature for potential sources of food, would quickly single out the lowly mushroom, so odd in appearance and so unlike the rest of the vegetation with which they were familiar. Given a few thousand years for random experimentation (a relatively short time in the scale of prehistory), they would eventually discover and ingest fungi containing centrally-active compounds, undergo the hallucinogenic experience and the connection with the numinosum would be established.

The scenario described is, of course, imaginary. We cannot know the exact circumstances under which humans first confronted the psychedelic experience. We do know, thanks to the work of Wasson and his colleagues in the 1950s (see V. P. & R.G. Wasson, 1957, R.G. Wasson & R. Heim, 1958, & Wasson, 1957), that a religious cult centered around the ritual ingestion of hallucinogenic mushrooms has existed in the highlands of Central Mexico at least since before the Conquest, and is very likely much more ancient than that, its real origins having been lost in the mists of prehistoric time. But the fact remains that, whether encountered through the ingestion of a fungus or some other plant, or through some spontaneously triggered altered state of consciousness, the direct experience of the transcendent has had and is having a profound impact on human history, perhaps even on human evolution. The urge toward the transcendent - and the dynamic tension that exists between the drive to transcend and the mundane necessities which impose themselves on the primary fact of biological being - is in a sense what all history, all religion, art, philosophy, discovery and science - in short, all of human thought and civilization - is about. The urge to reach beyond the known to what is unknown and unplumbed is irredeemably woven into the fabric of human history. It is this urge which built the pyramids, Stonehenge and the Gothic cathedrals. The same urge drove frail ships across the trackless oceans to the shores of a new world, and the same urge in our own time has driven us to fling a tiny bubble of light and air across the vast and howling abysses of space (that cosmic milli-micron) that separates our earth from its moon. It is the same urge that stirs the shiver along our spines when we gaze with wonder and longing at the star-dusted sky on a clear winter's evening.

Today, we stand on the threshold of the stars. Slowly it is emerging in mass consciousness that the next evolutionary step forward will so transform humanity that all that has gone before will seem but a prelude. We stand at the edge of history ready to accelerate our human experience out into the vast chasm of night which engulfs our planet, the lessons of our historical career still echoing down the corridors of time. We are about to embark on the greatest adventure we have ever known, one that will change our very notion of what it is to be human; yet we should not forget that between ourselves as we ascend the ramp of the starship and our mushroom munching ancestor gazing into his Paleolithic fire lie only seconds of cosmic time.

This book is essentially a how-to manual for those who have the interest, time, and patience required for cultivating "the magic mushroom" in their own homes. It is for people who feel that they still may be able to learn something by experiencing the primordial visions of their ancestors, and feel it strongly enough that they are willing to invest a little time, money and effort in order to realize that vision. By "magic mushroom" is meant those mushrooms which are members of the genus *Psilocybe*, and the closely related genera *Stropharia*, *Conocybe*, *Panaeolus*, and *Copelandia*. Certain members of these genera contain the compounds psilocybin (4-phosphoryloxy-*N,N*-dimethyltryptamine) and psilocin (4-hydroxy-*N,N*-dimethyltryptamine) as the active hallucinogenic agents (Fig. 1). These compounds contain the basic indole structure characteristic of most hallucinogens found in nature (see Schultes, 1973, p. 17 ff.) including various amides of lysergic acid (of which LSD is a semisynthetic representative), *N,N*-dimethyltryptamine, harmine and its analogues, and ibogaine. The most notable exception to this basic structure is mescaline, which chemically is 3,4,5-trimethoxyphenethylamine, and hence is in the same class as amphetamine (α-methylphenylethylamine).

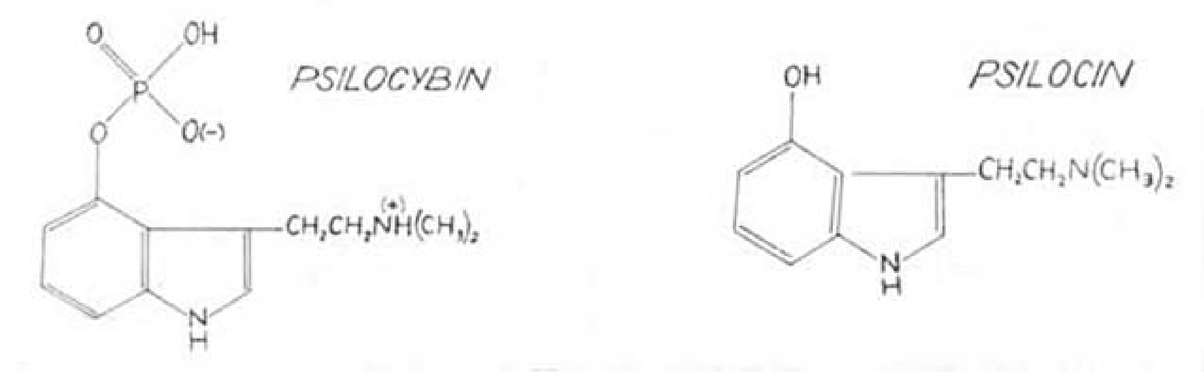


Fig. 1: Structural formulas for psilocybin and psilocin.

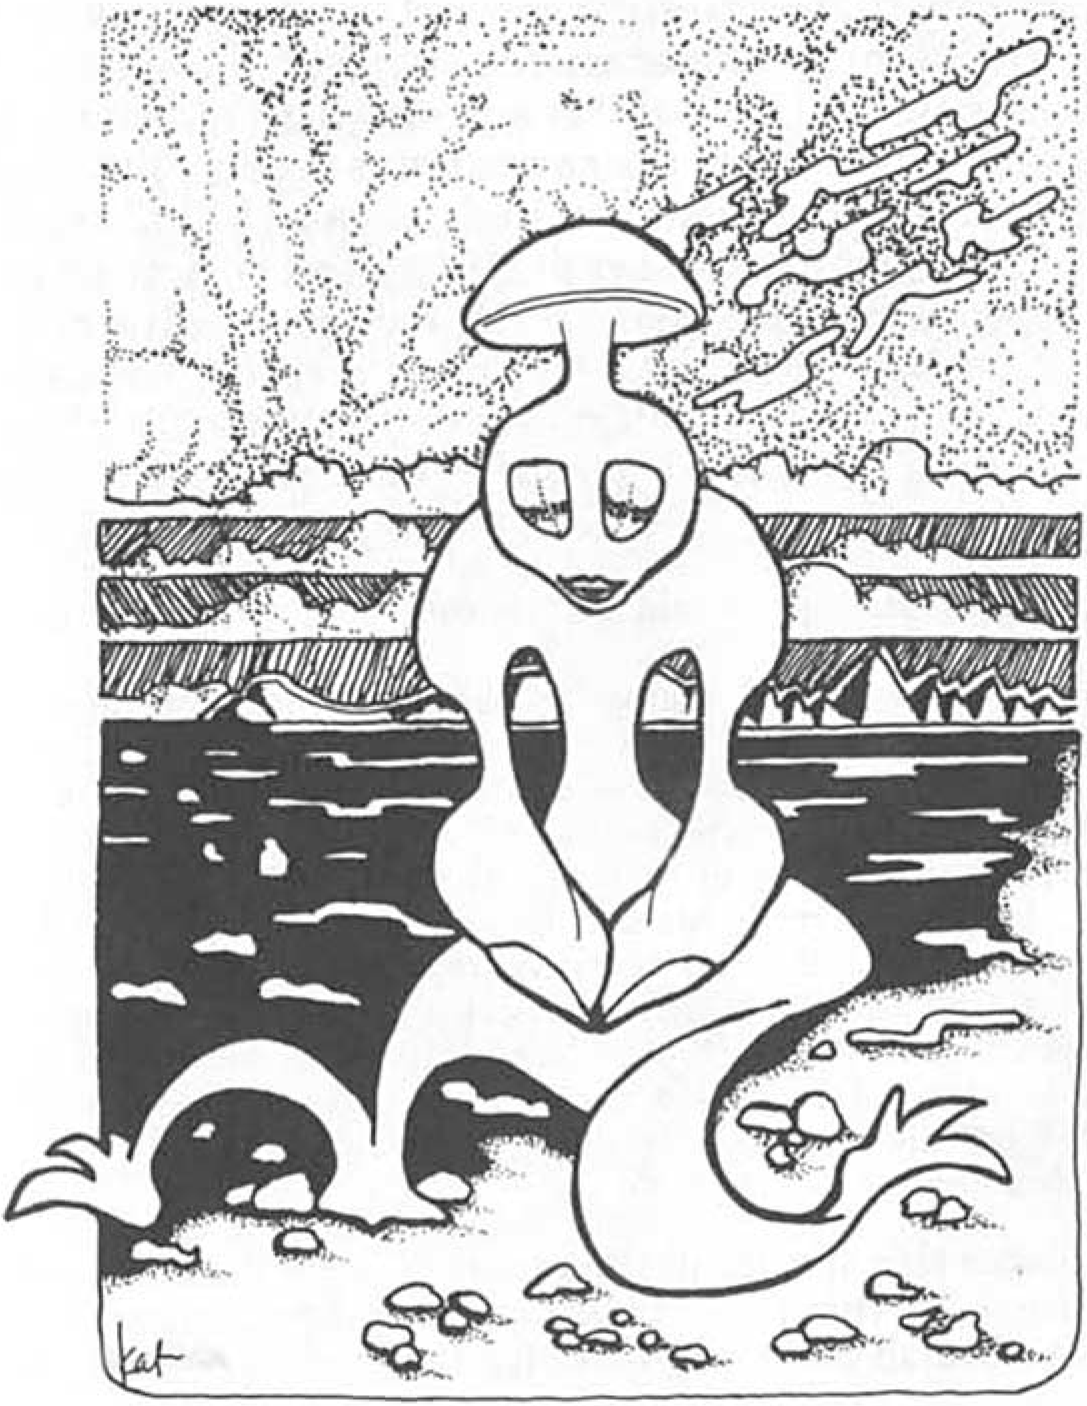
The cultivation information in this book pertains only to one species of magic mushroom, *Stropharia cubensis* Earle. (The mycologist Rolf Singer has recently reclassified this species into the genus *Psilocybe*. Hence in some references it is referred to as *Psilocybe cubensis* Earle ex. Singer.) It is probable that with appropriate adaptations the methods outlined here could be applied successfully to the cultivation of other species. Our experience has shown, however, that *Stropharia cubensis* is the easiest to cultivate. Those interested in the cultivation of other mushroom species should consult *The Mushroom Cultivator* by Stamets and Chilton, published by Agarikon Press, Olympia, Washington, 1983. Our limiting the discussion to one species, however, is not as unfortunate as it may seem since *Stropharia cubensis* is not only one of the strongest of the hallucinogenic mushrooms, but also one of the most widespread and readily obtainable. In nature, its habitat is cow-dung, and it can be found in pastures during rainy, warm parts of the year in regions as diverse as the Southeastern U.S. and Cambodia, Australia and Colombia. Unlike other psilocybin-containing genera, which with few exceptions are fairly restricted endemics, the distribution of the *Stropharia cubensis* is world-wide (Pollock, 1975). In fact, since its preferred habitat is cow-dung, its circumtropical distribution has doubtless been encouraged, if not caused, by the world cattle industry. Amusingly enough, the *Stropharia* could be said to exist as a "weed" on high-technology cattle-raising cultures. This intimate association with humans via domesticated cattle has probably existed for as long as humanity has possessed pastoral technology.

The procedures outlined in this book, if followed with care and persistence, will work for *Stropharia cubensis*. The procedures can be carried out by anyone in their own home, with just a minimum of equipment and a few supplies and common chemicals that are no more than moderately difficult to obtain. No special training in mycology or microbiology is necessary. What is necessary is to follow the instructions closely and carefully.

The procedure described herein consists essentially of four major steps. It begins with spores and describes step-by-step instructions for growing full-size mushrooms from spores within six weeks. The first step involves locating the fungus, collecting and germinating the spores, and isolating the mycelium, or fungal threads, obtained from the spores. The next step involves cultivating the mycelium on agar, a solid nutrient, in order to use it for inoculation. In the third step, mycelium grown on agar is then grown on a sterilized medium of whole rye grains. In the fourth and final step the rye-grown mycelium is *cased*, or covered with soil, a process that induces the production of mushrooms. This book describes each of these steps in detail, and can be put into practice by anyone able to read and carefully follow the instructions, provided that they can obtain spores or specimens of *Stropharia cubensis*.



STEP I - LOCATING AND IDENTIFYING THE FUNGUS: COLLECTING AND GERMINATING SPORES

In the New World, *Stropharia cubensis* can be found in appropriate habitats throughout the Southern U.S., all through the Coastal regions of Mexico, and throughout coastal and equatorial regions of South America. In the U.S., it has been reported from Texas, Louisiana, Alabama, Mississippi, Arkansas, Florida, Tennessee, and Georgia. Its distribution would probably be even greater were it not for the fact that its environmental requirements limit it to regions of mild temperatures and high humidity.

Because of its specific habitat and singular appearance, *Stropharia cubensis* is one of the easiest mushrooms to locate and identify. As already mentioned, it can be found growing out of cow-pies in pastures during rainy warm seasons. Other dung-growing mushrooms may also be found in the same pasture, but these bear little resemblance to *Stropharia*. The following botanical description of *Stropharia cubensis* is taken from *Mushrooms of North America* by Orson K. Miller, Jr.:

> Cap pale yellowish, viscid; persistent ring; blue-staining stalk.
>
> Cap 1.5-8 cm broad, conic, bell-shaped, convex in age, viscid, without hairs, whitish to pale yellow, light brownish in age, stains bluish in age. Flesh firm, white, bruises blue. Gills adnate (attached) to adnexed (notched), close, grey to violet-grey in age with white edges. Stalk 4-15 cm long, 4-14 mm thick, enlarging somewhat toward the base, dry, without hairs, white staining blue when bruised. Veil white, leaving a superior membranous ring. Spores 10-17 µ x 7-10 µ elliptical to oval in side-view, thick-walled, with a large pore at apex, purple-brown spore print. Cystidia (sterile cells) on gill edge club-shaped with rounded heads.

Miller places this species in the genus *Psilocybe*, after Singer.

The flesh of this mushroom exhibits the property of staining a bluish color when bruised or broken. This blue-staining reaction is apparently an enzymatic oxidation of psilocin to an indole diquinone (Bocks, 1967) and is a fairly reliable indicator of the presence of psilocybin, not only in *Stropharia cubensis*, but also in other closely related genera (members of the family *Strophariaceae*) (cf. Benedict, *et al*., 1967). Other mushrooms, such as members of the genus *Russula*, section Nigricantinae, and *Boletus*, exhibit a similar blueing. The blueing in these cases, however, is not due to the presence of indole substrates and these mushrooms otherwise bear no resemblance whatever to *Stropharia cubensis* or related species (Singer, 1958, p. 247).

Once one has located a specimen or specimens of *Stropharia cubensis*, and been satisfied as to its identity in all particulars, it is necessary to collect spores for cultivation. Spores can be easily collected in the following manner: Take one or more fresh specimens with the caps fully open; using a sharp knife, cut off the stipe as close to the gills as possible (see Fig. 3) and place the cap gillside down on a clean sheet of white paper, and leave for 24 hours. It doesn't hurt to cover the caps with a small bowl while taking the spore print in order to prevent dessication. When the caps are removed, a dark-purplish, radially symmetrical deposit of spores will remain on the paper where the gills contacted it. The paper should then be folded and sealed in an envelope in order to prevent further contamination by airborne spores of other species of lower fungi. A single spore-print contains tens of millions or spores, and is sufficient to make hundreds of spore germinations.

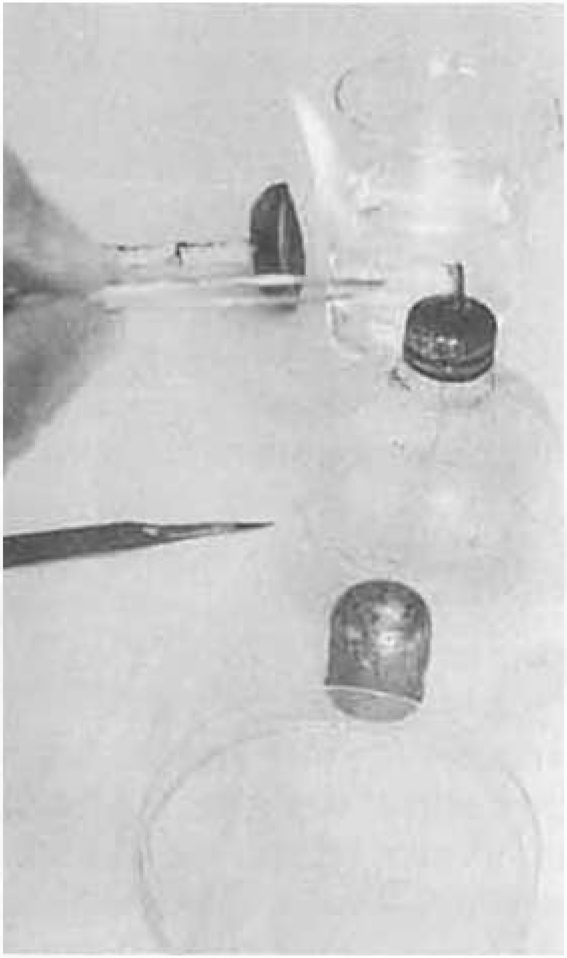


Fig. 2 - Sterilizing the slide.

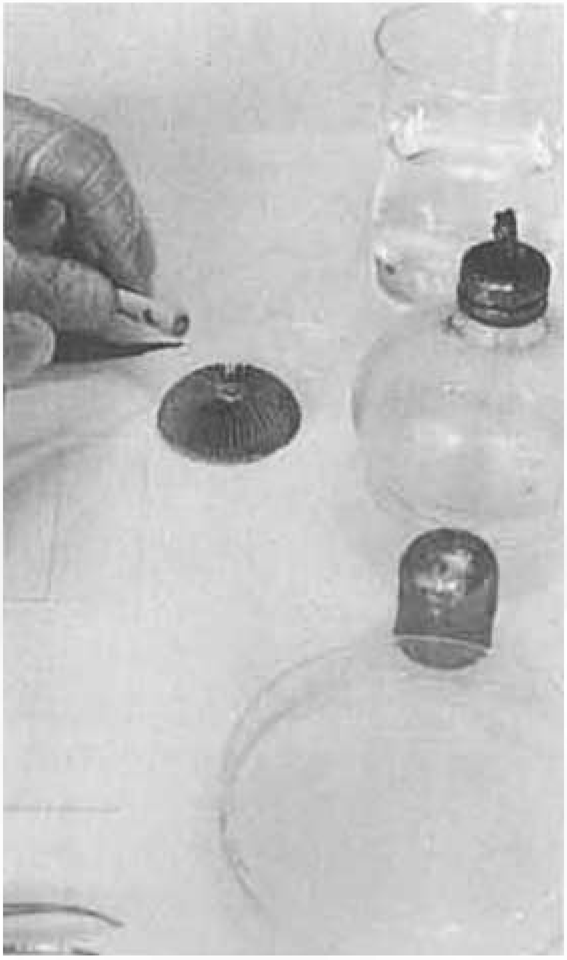

Fig. 3 - Decapitation.

The following variation on this method was suggested to us as a way of enhancing the sterility of the spore print: Take four standard flat microscope slides, swab with alcohol and flame in an alcohol flame or butane torch (Fig. 2). On a clean flat surface, such as a table-top swabbed with Lysol lay the slides side by side and end to end, so that they are arranged as in Fig. 3. Place the fresh cap in the exact middle of the slides so that approximately ¼ of the cap covers each slide (Fig. 4). Cover and wait 24 hours. When the cap is removed, the end of each slide will be covered with spores, and the slides can then be sealed, together or separately, in plastic or paper. One can easily substitute glass microscope coverslips for the slides to maximize compactness. Do not use plastic coverslips, since static electricity associated with them makes it difficult for the spores to adhere to them.

Once the spore-print has been collected, it is necessary to germinate some spores in order to begin the life cycle that will eventually culminate in the production of more mushrooms. Before we outline procedures for germinating the spores, a brief discussion of the stages in the life cycle of these higher fungi follows; readers who do not care to read this somewhat technical portion may skip the next three paragraphs.

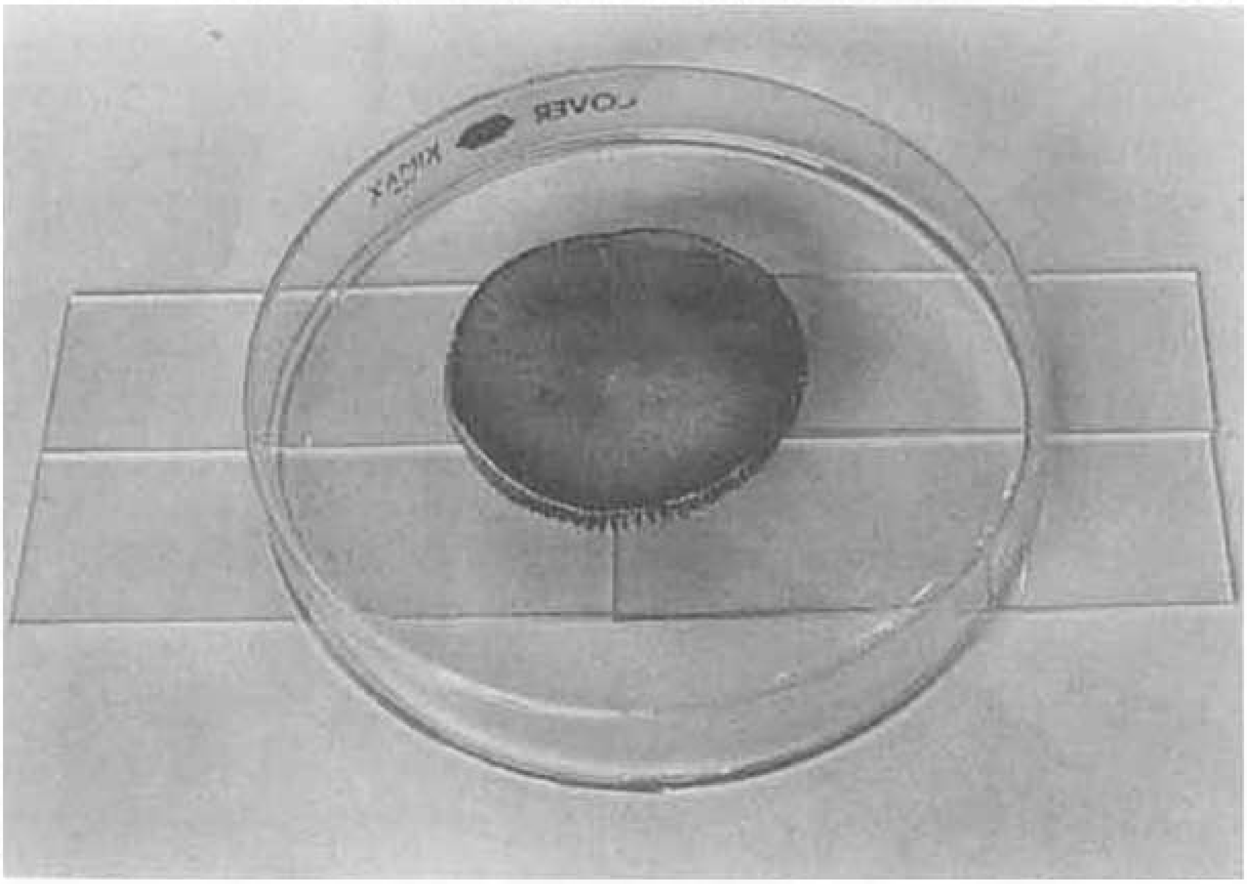

Fig. 4 - Making spore print (note slide arrangement).

All gilled fungi are members of the class Basidiomycetes, i.e., they are characterized by the production of spores on club-shaped appendages called *basidia*. Spores borne on basidia are called *basidiospores*. Most of the conspicuous fungi that one encounters, such as mushrooms, puffballs, and bracket fungi are members of the subclass Homobasidiomycetes. Of the members of this subclass, the gilled mushrooms are placed in the order *Agaricales*. The life cycle of a typical homobasidiomycete is illustrated on the facing page. The basidiospores germinate to form a monokaryotic hypha. A hypha is a tubular filament; an aggregation of these hyphae collectively comprise a mass of thread-like filaments referred to as the *mycelium*. The mycelium comprises the main body, or *thallus*, of the fungus. The stalked, capped structure which we call the mushroom is actually only the "fruiting body" or the spore-producing reproductive structure, and constitutes only a small portion of the total mass of the fungus; the great bulk of the organism exists underground in the form of a network of mycelium, which occasionally "fruits," or produces mushrooms, under appropriate conditions.

The basidiospores germinate to produce a *monokaryotic* mycelium, i.e., a mycelium having only one nucleus per cell. This mycelium grows out until it encounters another monokaryotic mycelium, germinated from another spore, that is a compatible mating type. If the monokaryotic mycelium does not contact a compatible monokaryotic mycelium, it eventually dies. In situations where two compatible monokaryotic mycelia do make contact, however, a process called *somatogamy*, or the fusing of the somatic cells of the two mycelia, takes place, *but fusion of the nuclei does not take place*. The result of somatogamy is the establishment of a *dikaryotic* mycelium, i.e., a mycelium possessing two nuclei, one from each of the monokaryotic mycelia, in each of its cells (see facing page). The dikaryotic mycelium stage is the most prolonged portion of the life cycle and is also the main assimilative stage of the fungus. The dikaryotic mycelium can propagate vegetatively indefinitely without going through a sexual (spore-producing) stage. Given appropriate conditions, however, the dikaryotic mycelium can be induced to "fruit": the undifferentiated mycelial thallus of the fungus begins to weave itself together into an articulated, spore-bearing "fruiting body," in this case, into a mushroom. The mushroom continues to enlarge and thrust above the ground, incorporating more and more mycelium while at the same time expanding by absorption of water. At a certain stage in the growth of the mushroom, or *basidiocarp*, club-shaped structures called *basidia* form on the underside of the gills. At this point, *karyogamy*, or fusion of the two nuclei of the dikaryotic mycelium takes place within the basidia (see preceding page). This is the only *diploid*, or 2n, stage in the life-cycle of the fungus, and is also the briefest stage, for meiosis, or reduction division of a diploid (2n) nucleus to 4 haploid (n) nuclei occurs immediately following karyogamy.

The result of meiosis is the production of four haploid nuclei within the basidium; these are then pushed out of the basidium and become surrounded by hard sheaths to form the basidiospores. The result is the basidium bearing four basidiospores on its outer surface as in the "Life Cycle" drawing. These basidiospores eventually detach from the basidium to begin the life cycle again.

Fungi of the family *Strophariaceae*, which includes *Stropharia cubensis* and most other psilocybin-containing genera, are genetically complex with respect to the mating compatibility of different monokaryotic mycelia. These fungi are *heterothallic* and *tetrapolar*, that is, their sexual cycle is dependent on the fusion of two compatible monokaryotic mycelia, and their sexual compatibility is governed by two sets of factors:

> In tetrapolar heterothallism, two sets of factors, the A's and B's, are involved. If a sexually reproducing thallus is to be established, somatogamy must occur between mycelia differing in both sets of factors - for example AB x ab. The number of mating classes is somewhat greater than in bipolar forms, since four types typically arise from spores of a single basidiocarp. Obviously these mating types, numbering in the hundreds in both bipolar and tetrapolar species, cannot be designated as sexes! (Scagel, *et al*., 1967, p. 69.)

Keeping this information pertaining to the sexual characteristics of these fungi in mind, let us return to the problem of spore germination; the relevance of our digression into the matter of life cycle and sexual compatibility will be seen shortly.

Once one has obtained a spore print from *Stropharia cubensis*, the monokaryotic mycelium can be easily obtained by germinating the spores on an appropriate solid nutrient medium, such as Potato Dextrose Agar or Malt Extract Agar. A more detailed discussion of various kinds of nutrient agars and how to prepare them will be given below in the section of Growing Stock Inocula. For the present, however, simply assume that one has several clean, sterile Petri plates which have been filled with an appropriate solid nutrient medium (see Fig. 5). Spores can be transferred most readily using a clean, sterile #11 scalpel, inoculating loop, or similar instrument. Flame the blade of the scalpel in an alcohol flame, then reach into the petri dish and cut a small square of agar (2-3 mm^2) from the center of the dish. Spear the agar square on the blade of the scalpel, and use it to lightly touch the surface of the paper or slide on which the spore-print is deposited. Replace the agar square on the medium close to the place it was cut. It is sometimes convenient to inoculate four agar squares in each dish, one in each quadrant. Care should be taken to do this as quickly as possible, keeping the cover off the Petri plate for the shortest time necessary, in order to minimize the chances of contaminating the plate with the airborne spores of contaminants. A variation on this method can also be used: Instead of scraping the spores directly onto the plate, they can first be scraped into about 10 ml of sterilized water. Shake this vigorously, then dilute to 100 ml by adding sterile water. Using a sterilized pipette or syringe, take up 2-3 ml of diluted spore solution, and point-inoculate the Petri plate by placing a drop of the solution at two or three separate points on the plate.

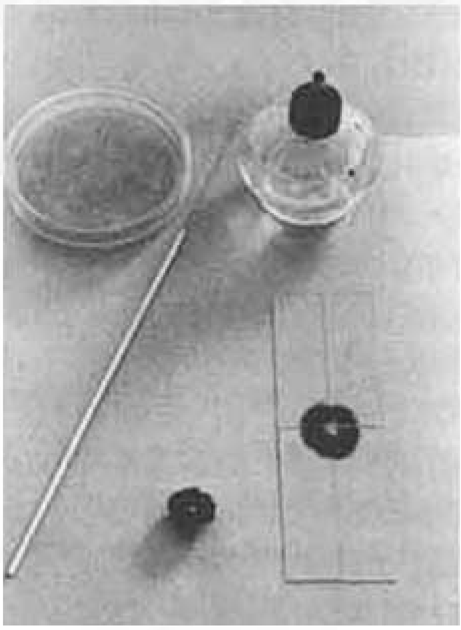

fig. 5 - Completed spore print and inoculating equipment.

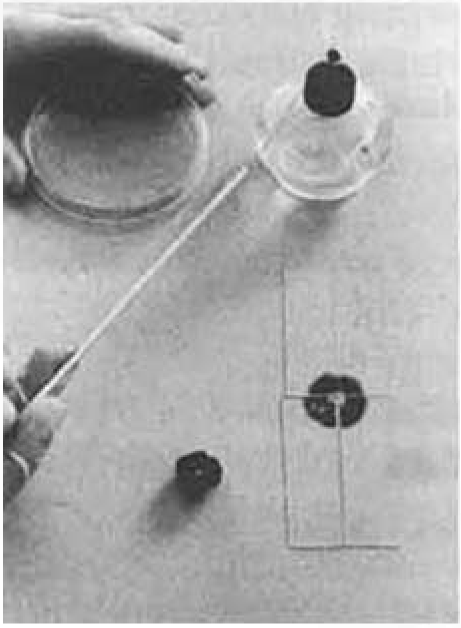

fig. 6 - Flaming the inoculating loop.

If possible, incubate the covered inoculated plate at 86 degrees F. for 24 to 36 hours. This will break dormancy and force the spores to germinate faster. Spores will germinate without this incubation, but may take up to 24 days. During this time, the spores will germinate and monokaryotic mycelium will grow radially outward from each point of inoculation. The plate should be left undisturbed until the mycelia from two different spores or two different points of inoculation have grown together and made contact. A few days after contact has occurred, one can be reasonably sure that somatogamy has taken place and that a dikaryotic mycelium has been established. Since in practice one transfers clumps of spores rather than single spores onto the plate, waiting for two different inoculation spots to make contact is not really essential; by the time mycelial growth is well established on the plate, one can be confident of isolating dikaryotic mycelium.

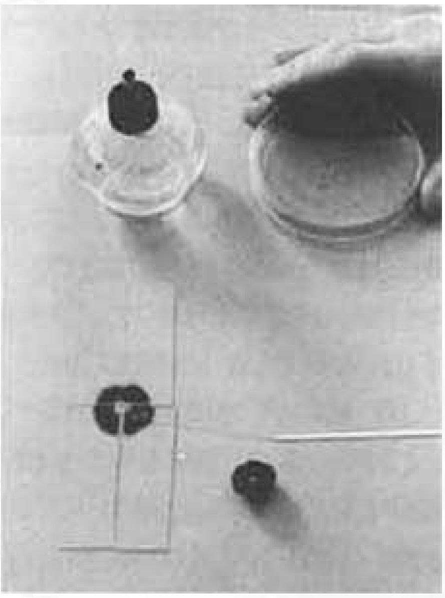

Fig. 7 - Touching inoculating loop to spore print.

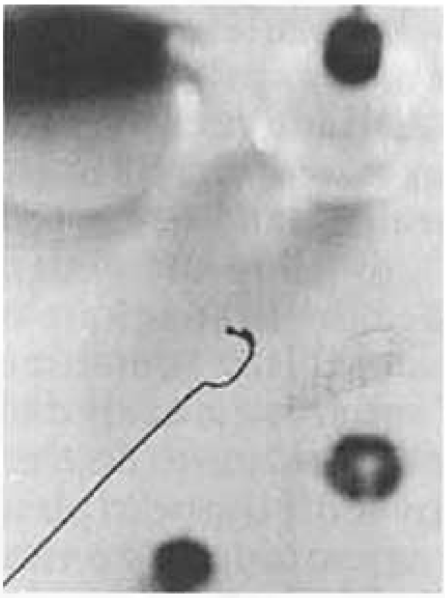

Fig. 8 - Hooked inoculating loop with adhering spores.

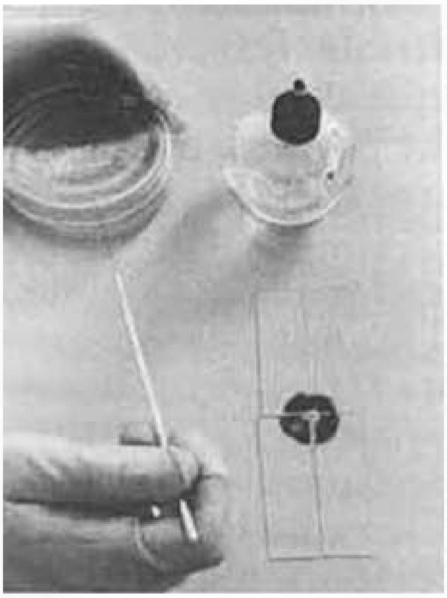

Fig. 9 - Inoculating Petri plate with spores.

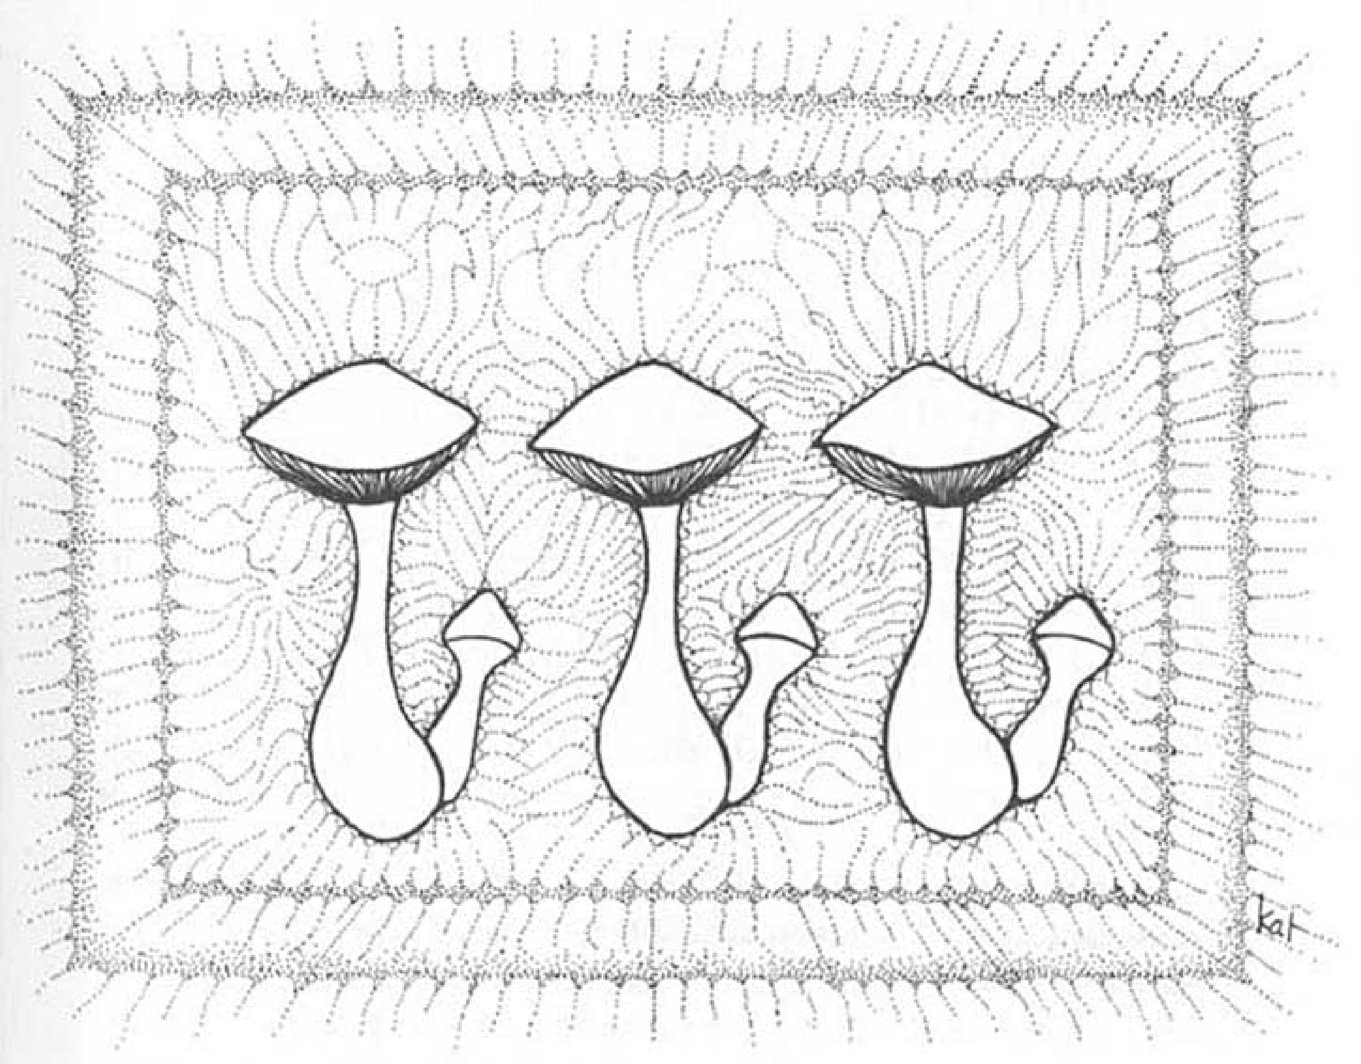
In cultivating the fungus to the fruiting stage, one works primarily with a single strain of dikaryotic mycelium. However, because spores of several different mating types are produced by a single mushroom, a Petri plate inoculated with spores will have possibly several dozen different strains of dikaryotic mycelium growing on it. It is therefore necessary to isolate one of the strains so that one can grow out stock inocula from a single, uniform strain. This can be accomplished using a scalpel, dissecting needle or inoculating loop in which the loop has been bent to form a hook (Fig. 8). The implement is first sterilized in an alcohol flame; then the Petri plate is opened slightly and a very small piece of mycelial tissue is snagged on the end of the blade, needle, or hook, and transferred rapidly and deftly to a second clean sterile Petri plate containing an appropriate solid nutrient medium. Dikaryotic mycelium is isolated using exactly the same techniques as are used in transferring mycelium from one Petri plate to another; for figures illustrating this procedure, see Step II, Figs. 13-16. By selecting a very small piece of tissue in this way, one can be reasonably sure that only one strain of dikaryotic mycelium is being removed and isolated. In practice we find that both isolation of a dikaryon and plate-to-plate transfer of dikaryotic mycelium once isolated, can be most easily accomplished using a sterile #11 scalpel. Small agar squares can be cut from the edge of the mycelial thallus and transferred to fresh Petri dishes.

The dikaryotic mycelium thus isolated from the spore-germination plate will grow outward in all directions from the point of inoculation on the new plate and should cover most of the surface of the medium within 8-12 days. One can then go ahead and make further transfers to new plates with a fair degree of certainty that one is working with a single strain of dikaryotic mycelium.

It is probably advisable to isolate several different strains of dikaryotic mycelium onto separate plates by taking tissue from different sections of the spore-germination plate. Different strains isolated from a single spore-germination plate should be identified by labels and compared for vigor of growth and vigor of fruiting ability, so that, through observation and trial-and-error, the strain showing maximum vigor in both respects can eventually be identified and used exclusively thereafter. Isolating the most vigorous strain takes time and careful observation; however, this need not interfere with continuing on to the second and third steps of the process, since *any* dikaryotic mycelium that has been properly isolated from other strains should exhibit fruiting ability. After several strains have been put through several fruiting stages it should be apparent which strain is most vigorous. Our observations indicate that the most vigorous fruiting strains have a distinctly "ropy" morphology when growing in the mycelial stage. This stands to reason, since this ropy appearance is due to the formation of *rhizoids*, thick strands of hyphae, which are similar in structure to the rhizoids formed prior to and during the fruiting stage. Those rhizoids function in the transport of water and nutrients to the developing mushrooms (see Chang & Hayes, 1978, Chapter 8).

If one has fresh mushroom specimens, it is possible to employ another method of isolating dikaryotic mycelium without utilizing spores. This is the method of subcutaneous isolation (Enos, 1970). The operation should be performed with clean hands and implements. A pair of latex gloves sterilized by spraying with Lysol should be worn. Hold the fresh mushrooms by the stipe in one hand, and with the other hand swab the cap surface lightly with a sterile cotton swab dampened with tincture of iodine. Have ready a clean #11 scalpel and an alcohol lamp to sterilize it. Grasp the cap of the mushroom, top up, between the thumb and fingers until it splits open to reveal the interior whitish flesh. Flame the scalpel and remove a small piece of this subcutaneous flesh and transfer it to a sterilized nutrient plate. Several inoculations can be made from the interior flesh of a single cap. Since the flesh of the mushroom has been woven together out of dikaryotic mycelium, it will grow out across the plate in the same manner as mycelium isolated from a spore-germination plate. This procedure eliminates the step of having to isolate different dikaryotic strains, since mycelium isolated in this manner consists of only one strain. On the other hand, this procedure limits one to working with only one strain.



STEP II - GROWING STOCK INOCULA

Once one or more strains of dikaryotic mycelia have been successfully isolated, it is necessary to build up a stock of mycelial cultures grown on sterile agar media. The inocula from this stock will be used to inoculate the mycelium onto sterilized rye or other grain. Before proceeding to this step, however, it is advisable to have a good supply of inocula grown out of sterile agar media, so that one will have plenty of sterile inocula even if a few cultures should succumb to contamination. The information in this section therefore describes procedures for preparation, sterilization, and inoculation of solid nutrient media.

Most laboratory work with higher fungi, yeasts, molds, bacteria and so on involves growing the organism on a solid agar medium to which appropriate nutrients have been added. Agar is a pectin-like substance extracted from certain kinds of sea-kelp, which, when dissolved in boiling water and allowed to cool, solidifies to a gelatinous consistency. Agar is a standard item in all microbiological work, and is available from almost any scientific supply company. It is also stocked by many health-food stores and Oriental food stores as a dietary supplement. Fungi Perfecti (P.O. Box 7634, Olympia, WA 98507) offers a wide variety of mushroom-growing supplies and will send you a very helpful catalog for $2.50.

Potato Dextrose Agar (PDA) and Malt Extract Agar (MEA) are standard nutrient media suitable for cultivating the mycelia of most higher fungi, including *Stropharia cubensis*. Both types are commonly available in a premixed form from most scientific supply companies. The premixed type need only be dissolved in boiling distilled water. Usually about 15-20 g of pre-mixed agar medium per 1000 ml of water is used.

The appropriate proportions and mixing instructions are usually printed on the container of dried agar preparation. With very little trouble, one can also manufacture one's own PDA or MEA. Recipes for PDA, MEA, and a variation of MEA called MYP for Malt-Yeast-Peptone are given below. We have found MYP to be excellent for long term maintenance of vigorous mycelium.

P.D.A.
250 g potatoes
15 g agar
10 g dextrose
1.5 g nutritional yeast (or yeast extract)

Shred the unpeeled potatoes into a colander and then rinse them for thirty seconds with cold tap water. Combine the rinsed potatoes with one liter of water and gently boil for thirty minutes. Filter the resulting potato broth through muslin or cheesecloth and discard the potatoes. To the liter of potato broth add the agar, dextrose, and yeast which you have previously weighed out and mixed together in a baggie. While stirring gently add in the mixed powdered ingredients. Gently boil for ten minutes or until the solution is clear. Take care not to allow the solution to boil over. Add enough water to return the total volume of the solution to one liter. Pour the solution while still hot into Petri plates, baby food jars, or slant culture tubes (Fig. 11). Use just enough to cover the bottom of a plate or baby-food jar to a depth of about ¼ inch full. For convenience, the plates may first be placed in the bottom of the cooker before the medium is poured; then pour the medium, put the covers on the plates, then build a second stack on top of that; then pour, cover, and stack again, until a stack similar to Fig. 12 has been built. The solution may be allowed to cool or sterilized immediately. Sterilization procedures will be described shortly.

A recipe for Malt Extract Agar (MEA) follows.

To 1 liter of gently boiling water add a previously weighed and mixed powder containing:

20 g malt or malt extract (may be powder or syrup)
25 g agar
0.1 g potassium dibasic (K_2HPO)
0.1 g calcium carbonate ($CaCO_3$) (powdered oyster shell may be used)

The liquid malt extract sold in the syrup sections of most grocery stores is quite suitable for this medium. After the nutrients have been completely dissolved in the water, the hot solution is poured into plates in the same manner as the PDA.

MYP or Malt-Yeast-Peptone medium is a variation on MEA very useful for long term maintenance of desirable cultures. To 1 liter of gently boiling water add a previously weighed and mixed powder containing:

7 g malt extract (powder or syrup)
1 g peptone or soytone
0.5 g yeast extract
15 g agar

Soytone and Peptone are commercial brands of a protein hydrolysate and can be purchased from scientific or microbiological supply houses.

In the case of all three of these recipes, if some of the nutrient solution is left over after pouring the plates, the flask may be sealed and stored in the refrigerator indefinitely, or sterilized with the plates and stored on the shelf. When one wishes to make more plates, the medium can be reliquified over heat and reused.

The three types of media described above are quite easy to prepare and will be suitable for growing stock inocula. It is a good idea to mix up and have on hand at least two types of media, and to use them alternately in preparing batches of plates. In this way the fungus will not become accustomed to one type of medium and thus will be forced to use different parts of its genome in adapting to the different media. This will prevent the mycelium from succumbing to any "senescence factor" or tendency to age physiologically and thus to lose vigor after a period of time.

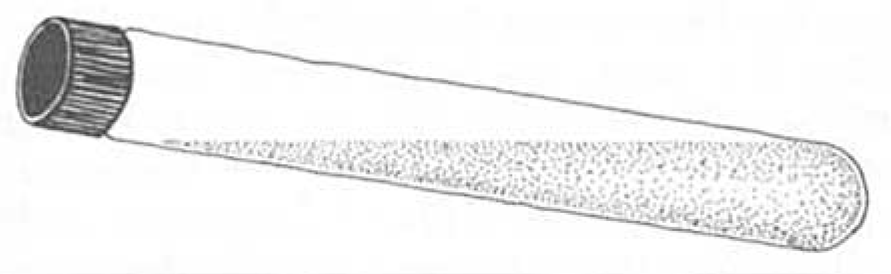
These three types of media are completely adequate for growing out one's stock inocula. From a purely practical standpoint, we have found them to be easily and readily prepared from a relatively few common ingredients. Unless one wishes to get involved in complex nutritional studies, it is unnecessary to bother with other recipes. Other types of media may be used, however, and those who do wish to get more deeply into this step of the process are urged to consult Neal, et. al. (1968).

Once one has prepared an agar medium and poured it into the Petri plates, baby food jars, slant culture tubes, or other suitable receptacles, it is necessary to sterilize the medium in the receptacles in order to kill the spores of bacteria, yeasts, and other molds which get into the medium from the air. This can be done via the following procedure: If a laboratory autoclave is not available, a standard home cooking or canning pressure cooker can be used. We use and recommend the All American 941½ pressure cooker, available from its manufacturer, The American Aluminum Foundry Co., P.O. Box 246, Manitowoc, Wisconsin 54220 (see Fig. 27). Place a small amount of water (approx. 1 liter) in the bottom of the cooker (tap water will do) so that the surface is covered. Place the receptacles containing the medium into the pressure cooker. Be sure to stack them carefully (see Fig. 12); a small enameled tray is useful for this. Note: If using pre-sterilized plastic plates, pour the medium into the plates *after* sterilizing; *do not autoclave plastic plates*.

It does not matter whether the medium is still hot and liquid, or whether it has been allowed to cool and solidify, since the heat of the sterilization process will reliquify the medium anyway. If baby food jars or culture tubes are used, *be certain that the lids are left loose, not screwed down tight*, when they are being sterilized. Seal the lid of the pressure cooker, *but leave the stopcock open*. Bring the cooker to a boil over high heat on a stove. When the water has begun to boil vigorously, a good head of steam will begin to vent through the stopcock; it should be closed at this point, and the pressure allowed to build up to between 15-20 lbs. Then reduce the heat just enough to maintain pressure at this level for 45 minutes to 1 hour. The standard sterilization time for solid media at these temperatures (250 degrees F.) and pressures (15-20 lbs.) is 15 minutes, but experience has shown that this is often insufficient to insure complete sterilization. Allowing a visible head of steam to build up in the pressure cooker before closing the stopcock is also important, for if it is closed prematurely, the pressure will rise but the water will be unable to vaporize, and dry heat requires much longer to accomplish sterilization.

After the medium has been sterilized at the correct pressure for 45-60 minutes, turn off the heat or carefully remove the cooker (remember that the medium is liquid at this point and can slosh around) and allow the cooker to cool to room temperature *before opening the stopcock*; otherwise, the sudden release of pressure will cause the medium to boil over.

When the cooker has cooled to room temperature or slightly above, wrap the column of the stopcock with an inch wide piece of paper toweling, then dampen it with an aerosol Lysol spray and then open the stopcock and allow any excess steam to escape. Remove the lid and carefully remove the receptacles containing the medium. Place the receptacles inside a pre-sterilized inoculating hood (see Fig. 10) or on a clean, smooth tabletop which has been wiped down with Lysol or similar strong disinfectant. As the receptacles cool further, the medium will solidify. If slant culture tubes are being used, they should be placed on an angle while the medium is still liquid, to provide maximum surface area for mycelial growth.



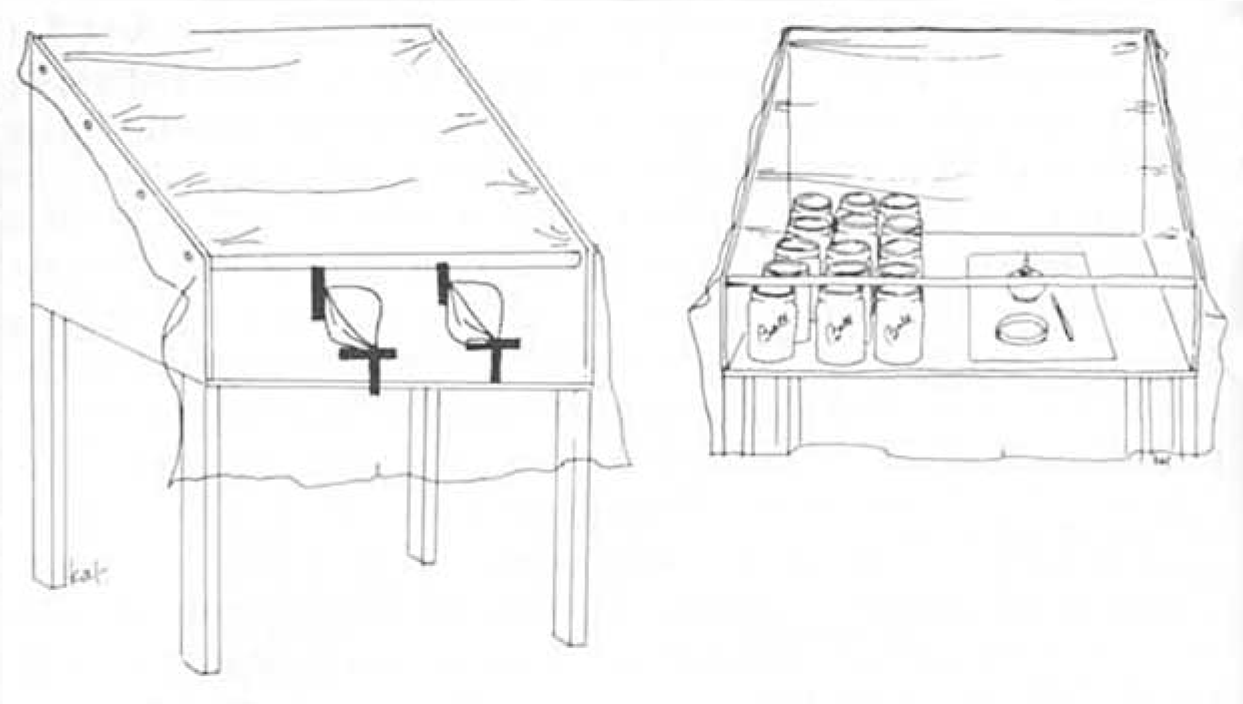


Fig. 10 - Two views of a homemade inoculating hood.

Note: PLASTIC PLATES CANNOT BE AUTOCLAVED! If using pre-sterilized plastic Petri plates, the medium should be sterilized in a flask sealed with tinfoil. The flask should be about ½ full, so it is best to sterilize two 1000 ml flasks with 500 ml each of medium. The procedure for pouring plastic plates is described below.

If pre-sterilized plastic plates are being used, one proceeds as follows: Allow the sterilized flasks to cool in the inoculating hood until they are warm to the touch - but can be handled easily. The medium is still liquid at this point, and is ready to be poured. Working with the usual sterile precautions (see below), one requires an alcohol flame and a stack of 20-40 plastic Petri plates. These commonly come packaged in rolls of twenty. Begin with a stack of about five plates. Carefully peel back the tinfoil from the lip of the flask of medium, and flame the flask lip briefly in the alcohol flame. Then, holding the flask in one hand, with the other carefully lift the lid from the bottom plate in the stack, keeping the other plates balanced on top of it. Hold the lip of the flask close to the edge of the Petri plate. Pour just enough medium to cover the bottom of the plate to a depth of about ¼ inch. Carefully replace the cover and then repeat the process with the next lowest plate and so on up the stack. After the plates have been poured, they should be stacked (carefully!) in columns of 10 or 20 in order to minimize condensation on the lids while cooling.

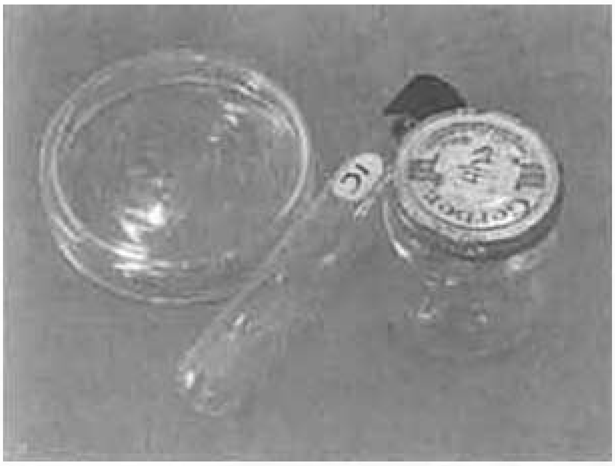

Fig. 11 - Three containers suitable for agar culture.

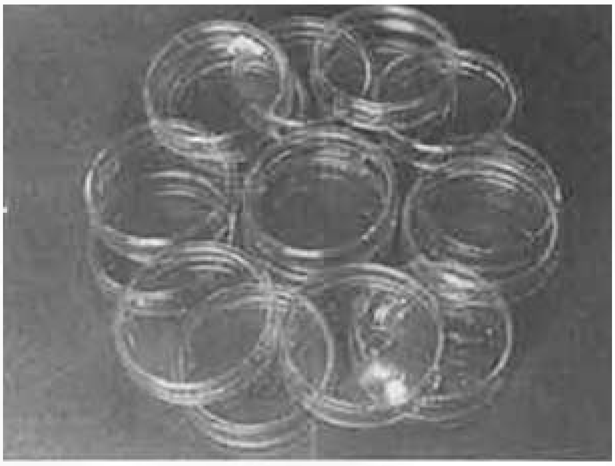

Fig. 12 - A simple stable stack of Petri plates.

When the receptacles have cooled completely to room temperature, and the medium is fully solidified, they are ready to be inoculated. If possible, inoculation should be carried out inside an inoculation hood such as that shown in Fig. 10. Commercial hoods are available, or a homemade hood can be constructed out of wood and all joints sealed with silicon caulking compound. Pre-sterilize the hood before introducing the culture receptacles by spraying all inside surfaces thoroughly with Lysol aerosol, or a mixture of 25% Clorox-distilled water solution, or both. If a hood is not available, inoculation can be carried out in the open air in a room in which the air is relatively still, i.e., a room without any drafts. The air of the room should be sprayed beforehand with 25% Clorox solution and the surface on which inoculation is to be done wiped down with a strong Lysol solution. All sterile procedures should always be done wearing latex gloves which have been sterilized by spraying with Lysol (Figs. 13 & 14). Never use aerosol Lysol spray in the presence of any flame. After spraying Lysol in the inoculating hood, wait a few minutes before introducing the alcohol lamp into the hood. **REMEMBER THAT SPRAY LYSOL IS HIGHLY FLAMMABLE**.

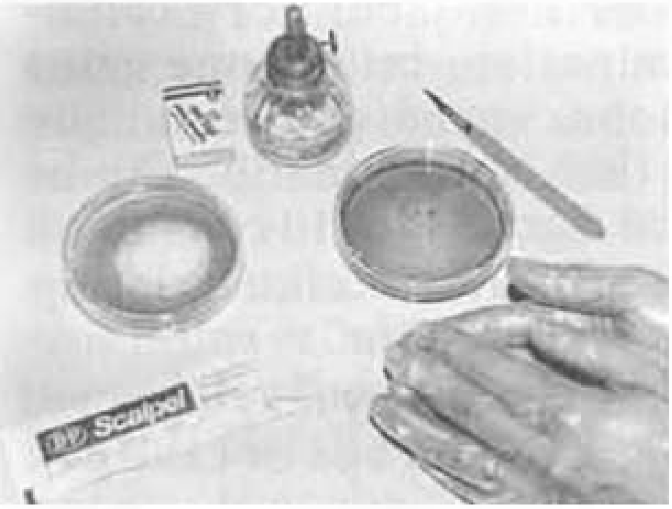

Fig. 13 - Materials for plate-to-plate inoculation.

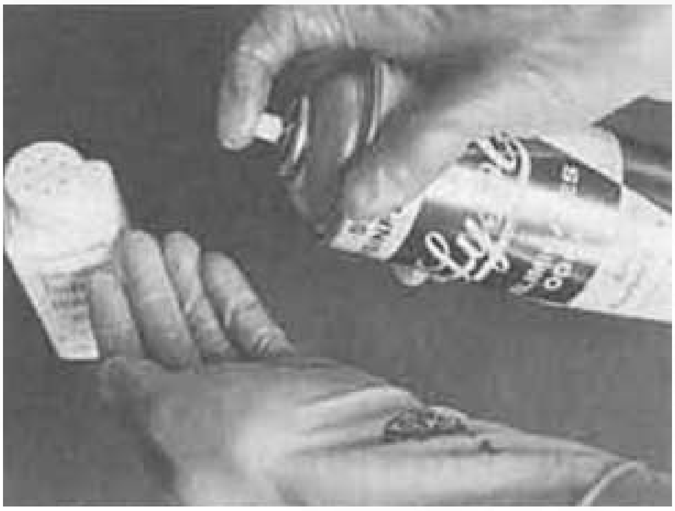

Fig. 14 - Disinfecting rubber gloves with Lysol.

Inoculation should be done using a disposable scalpel or an inoculating loop which has been opened to form a hook (Fig. 8), and can be carried out in essentially the same manner as was described for isolating dikaryotic mycelium from a spore germination plate. Select a completely sterile, vigorously growing culture from one's stock of dikaryotic mycelium isolated from spores. The mycelium of a vigorous culture should be pure white and ropey in appearance, and preferably less than 10 days old (cf. Fig. 13). Wash one's hands and arms thoroughly in soap and water before beginning work, then wipe down with alcohol. Wear thin latex gloves sprayed with Lysol or Clorox-water solution as added protection (Figs. 13 & 14); talcum powder can be sprinkled inside first to make them easy to slip on. Wear a short-sleeved or sleeveless shirt for the process to avoid introducing contaminants from one's clothes. Pass the scalpel or hooked inoculating loop through the flame of an alcohol lamp until the working tip has been heated to redness (Fig. 15). Allow it to cool for a moment or quench it in a Petri dish of sterilized agar sacrificed to this purpose. Open the culture just enough to insert the end of the loop, and snag a small piece of mycelial tissue or small plug of agar and transfer this rapidly to the freshly sterilized medium, again opening the lid just enough to insert the inoculum (Fig. 16). Withdraw the loop and replace the lid on the newly inoculated culture. If a scalpel is used instead of a loop, inoculation can be accomplished by cutting a small square (1 sq. mm) of mycelia-grown agar from the culture plate, and transferring this to the new plate. If using tubes or baby food jars, the lids should be left fairly loose to allow for aeration. Repeat this process for as many times as one has receptacles to inoculate. It is not necessary to use a new culture for each inoculation; a single culture is sufficient to inoculate dozens of fresh plates. After a batch has been inoculated, however, the culture used as the source of inocula should be discarded.

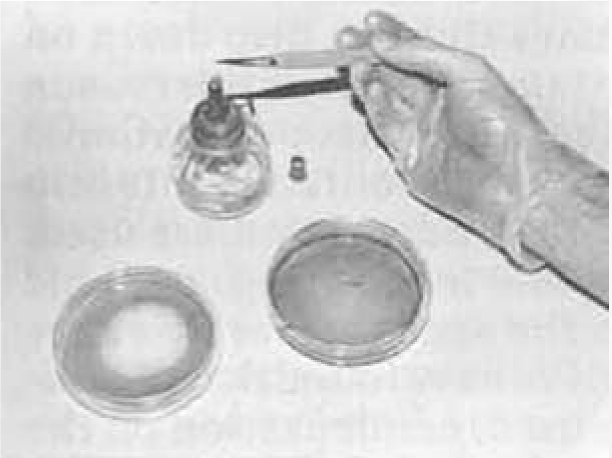

Fig. 15 - Flaming the inoculating scalpel.

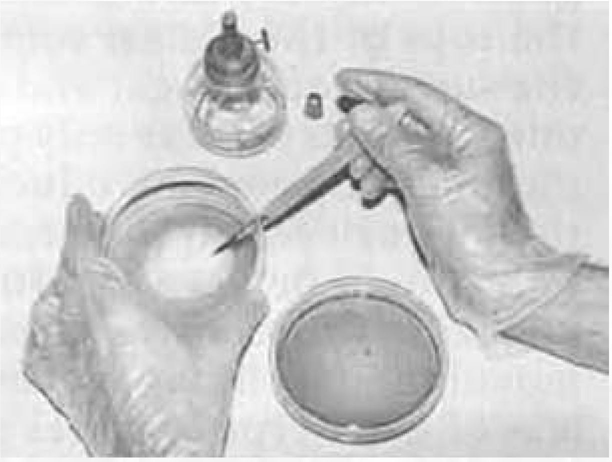

Fig. 16 - Inserting inoculum in fresh Petri plate.

Let the freshly inoculated medium stand at room temperature for 3-5 days. During this time the pure white, thread-like mycelium will spread radially across the surface of the medium, covering it completely within 7-20 days. Growth of the inoculum should be apparent by the fourth day after inoculation. Also apparent by about this time will be any contaminants that have gotten into the cultures during inoculation in spite of precautions. They usually appear as small white dots with blue-green centers, and grow much more rapidly than the mycelium. These are usually other molds, such as *Penicillium* and *Aspergillus*, *Neurospora* or various yeasts. Most are easy to distinguish from the mushroom mycelium, since the mycelium is pure white, occasionally with a slight tinge of blue, while the contaminants may be green, blue-green, black, yellow, dirty-gray, and so on, and otherwise do not resemble the mycelium. Any contaminated cultures should be discarded as soon as one is certain that contamination is present. It is normal to lose a few cultures to contamination, and one should not be discouraged by it. It is practically impossible, under non-laboratory conditions, to eliminate all contamination; but as one gains practice in making inoculations, speed and technique should gradually improve so that contamination can be held to a minimum. It would be a good idea to consult an introductory microbiology text for information relating to fast and efficient inoculating techniques.

After the plates have been inoculated, they may be stored while growing out in a sealed styrofoam box or cake box which has been sterilized by washing out with strong Clorox solution, then sprayed on all inside surfaces with Lysol. This will help to prevent contamination during growth. In very humid climates, water will condense on the tops of the plates; sometimes this can drip down on the surface of the agar and contaminate it. For this reason one should try to use only plates in which condensation is minimal, to avoid introducing unseen contaminants into the jars or rye; or, if plates with condensation are used, one should be very careful, while inoculating, to avoid knocking drops of water onto the agar surface when removing and replacing the cover. We have found that regardless of what type of plates are used, condensation on the cover can be eliminated by stacking the plates in taller (and more precarious) stacks of fifteen or more during the cooling down of the media.

STEP III - GROWING ON STERILIZED RYE

When a number of mycelial cultures have been successfully grown on solid agar medium, one is faced with a choice: It is possible to stop at this point, and concentrate on perfecting techniques for mycelial growth on agar. The mycelium itself contains psilocybin and can be ingested for hallucinogenic effects. The amount of psilocybin present in the mycelium is determined by the richness of the medium on which it is grown. Thus for an individual wishing only to obtain psilocybin from mycelium, there is a wide-open area for investigation; viz., to discover a suitable nutrient medium that gives a maximum yield of psilocybin per unit surface area of agar. If laboratory facilities are available, psilocybin can also be obtained from mycelium grown in liquid medium in shaken or submerged flask cultures. Since the necessary equipment for this is unavailable to most people, this approach is not discussed further here. Interested readers are urged to consult Catalfomo & Tyler, 1964.

The other choice at this stage involves moving on to the third step in the procedure, whereby mushrooms can be obtained by inducing the mycelium to fruit. In order for vigorous fruiting to take place, the mycelium must first be grown out onto sterilized rye, wheat, barley or other similar grain, so that a mass of mycelium weighing from 50-100 grams is obtained. The growing of mushroom mycelium on sterilized grain is a standard procedure in commercial mushroom culture that is used to produce "spawn" for inoculation into beds of horse-manure compost. The procedures described in this section are in fact adapted, with appropriate modifications, from a process originally developed by San Antonio (1971) for growing fruits of the common edible mushroom *Agaricus bisporus* under laboratory conditions. The steps involved in growing the mycelium onto rye-grain medium are described below.

While the mycelium will grow and fruit suitably on many types of grain, including rye, wheat, barley, triticale, oats, brown rice, sorghum, millet and even buckwheat, our experience is that rye works as good as any and is less expensive than most. Therefore we have primarily worked with rye in this stage. One must be certain, however, that the rye used is packaged for human consumption, and not grown as feed; feed rye has usually been treated with a fungicide.

At this stage, it is useful to construct a styrofoam box with a window in the lid such as illustrated in Figs. 17-20. These boxes can be obtained from pet stores and tropical fish dealers and can be used as a convenient modular system for incubating jars in a high-humidity, constant temperature environment. Jars may also be kept in an aquarium or a terrarium of suitable size. Such a case may be outfitted with a Grow-lux light and a timer set to a 13-hour light cycle to provide a nearly perfect growth environment. If one is working in an environment where temperature fluctuations are minimal and conditions are clean, the jars can simply be incubated on a shelf or table without any special containers.

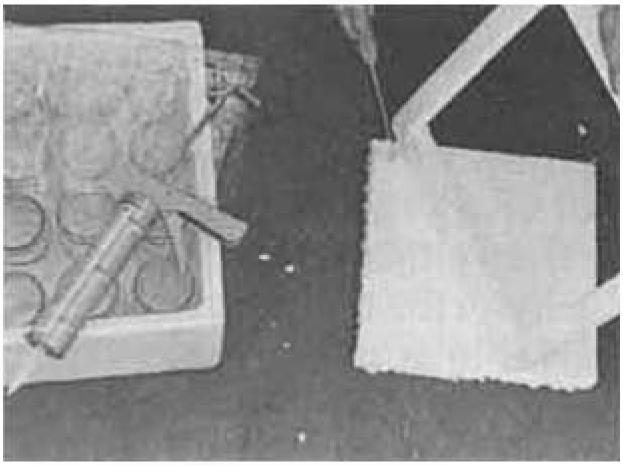

Fig. 17 - Making a box: cutting a window in the lid.

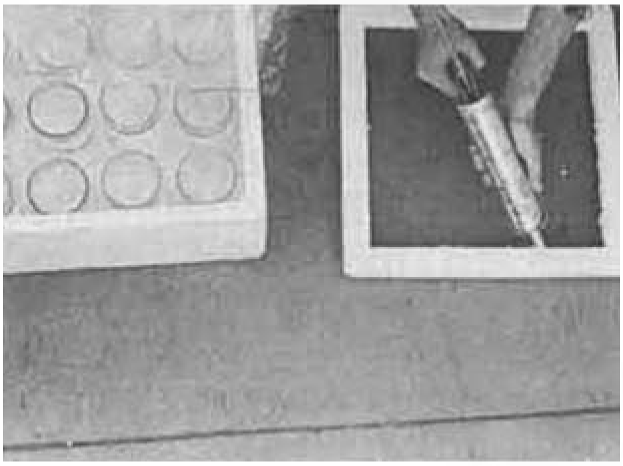

Fig. 18 - Applying silicone marine glue.

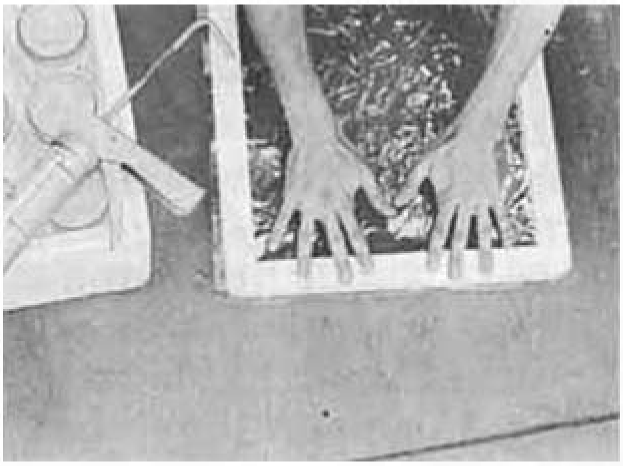

Fig. 19 - Clear plastic vinyl is glued over the window.

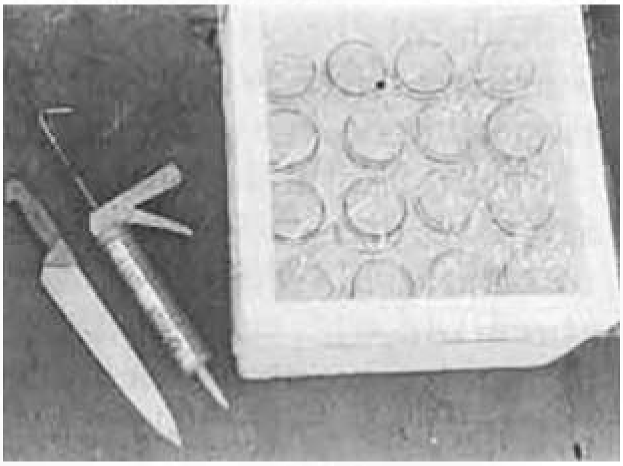

Fig. 20 - Completed box.

To prepare the rye medium, begin with a clean, wide-mouth quart Mason jar with a dome and ring lid. Add the following ingredients to the jar in these proportions:

160 ml rye berries (dry weight approx 150 g)
130 ml water (tap or distilled)
½ tsp. of calcium carbonate ($CaCO_3$)

The calcium carbonate, which is optional, need not be of great purity; powdered oyster shell, powdered limestone, or powdered chalk is suitable.

When the ingredients have been added to each jar in the proper proportions, the lids should be screwed *loosely* onto the jars, *with the rubber seal of the inner lids inverted* so that the jars will not seal during sterilization (Fig. 26).

Now the jars containing the rye can be sterilized. Add water to the pressure cooker; never use less than 1 to 1½ liters. Place the jars in the cooker, *making sure that the lids are loose* (Fig. 28). If one's pressure cooker is large enough to permit, jars can be stacked in two tiers without difficulty (Figs. 29 & 30). Seal the lid of the pressure cooker, but leave the stopcock open as before, until a head of steam begins to vent from the stopcock. Then close the stopcock, and bring to 15-20 lbs. pressure. Reduce heat when this pressure is reached so that pressure is maintained but does not increase. This is about medium heat on an electric stove. Sterilize at this pressure for one hour. Remove from the heat and allow the pressure to return to zero before opening the stopcock. Remember to wrap the stopcock column with a strip of Lysol-soaked paper toweling. Open the stopcock and allow excess steam to escape; then remove the lid from the pressure cooker. Remove one of the jars, tighten the lid down finger-tight, and carefully examine the jar for cracks and immediately discard any flawed jars (Fig. 31); then shake the remaining jars vigorously (Fig. 31). One can inscribe the jars with the date of inoculation or other suitable code-number (Fig. 32) in order to keep track of the schedule of shaking the jars. One will note on removing the jar that the rye has absorbed the water and swelled to several times its previous volume. After shaking, leave the lids tightened until the jars have cooled. Place the jars into the pre-sterilized inoculating hood (if available) or onto the clean, disinfected working surface (Fig. 10). Then let the jars cool for at least two hours or to room temperature.

When the jars have cooled completely to room temperature, and are no longer warm to the touch, they are ready to be inoculated. This step is best accomplished using a sterilized #11 scalpel (Fig. 33). These scalpels can be obtained from any medical supply house. Flame the blades of the scalpel over an alcohol lamp (Fig. 33). Insert the scalpel into an agar mycelial culture grown in a Petri plate or baby food jar, and cut a grid into the surface, so that small squares of agar of about 1-1.5 cm square are formed (Fig. 34). One can get about 9-20 small squares of agar from a single four-inch Petri dish in this way (Fig. 35). Cultures grown in slant tubes are obviously unsuitable for this step, because of difficulty in removing squares of agar from the tubes. At each transfer re-sterilize the scalpel blade by flaming, insert into the agar culture, and spear and remove one of the squares of mycelium-covered agar (Fig. 36) and transfer rapidly to one of the Mason jars, lifting the lid of the jar just enough to insert the inoculum (Figs. 37 & 38). Firmly tighten the lid and shake the jar vigorously to spread the inoculation points. Repeat this inoculation step for each jar.

An alternative method of inoculation was suggested to us by a friend, as possibly effective in increasing the sterility of the procedure and thus cutting down contamination. This method is a standard approach to fungal inoculations in mycological work, and so far seems promising, although we have not investigated it thoroughly enough to know if it is the answer to contamination problems.

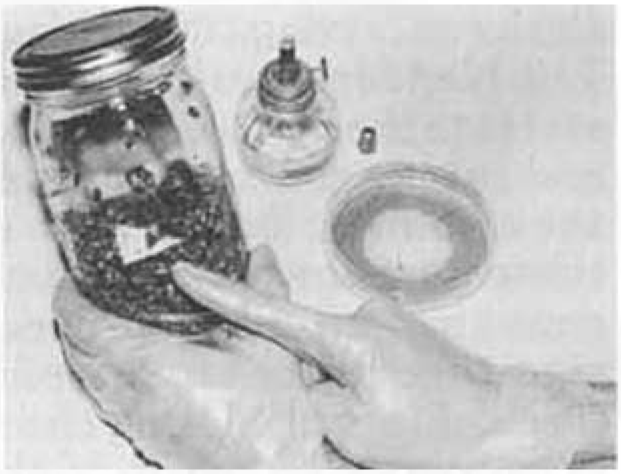

Fig. 38 - ... to a jar.

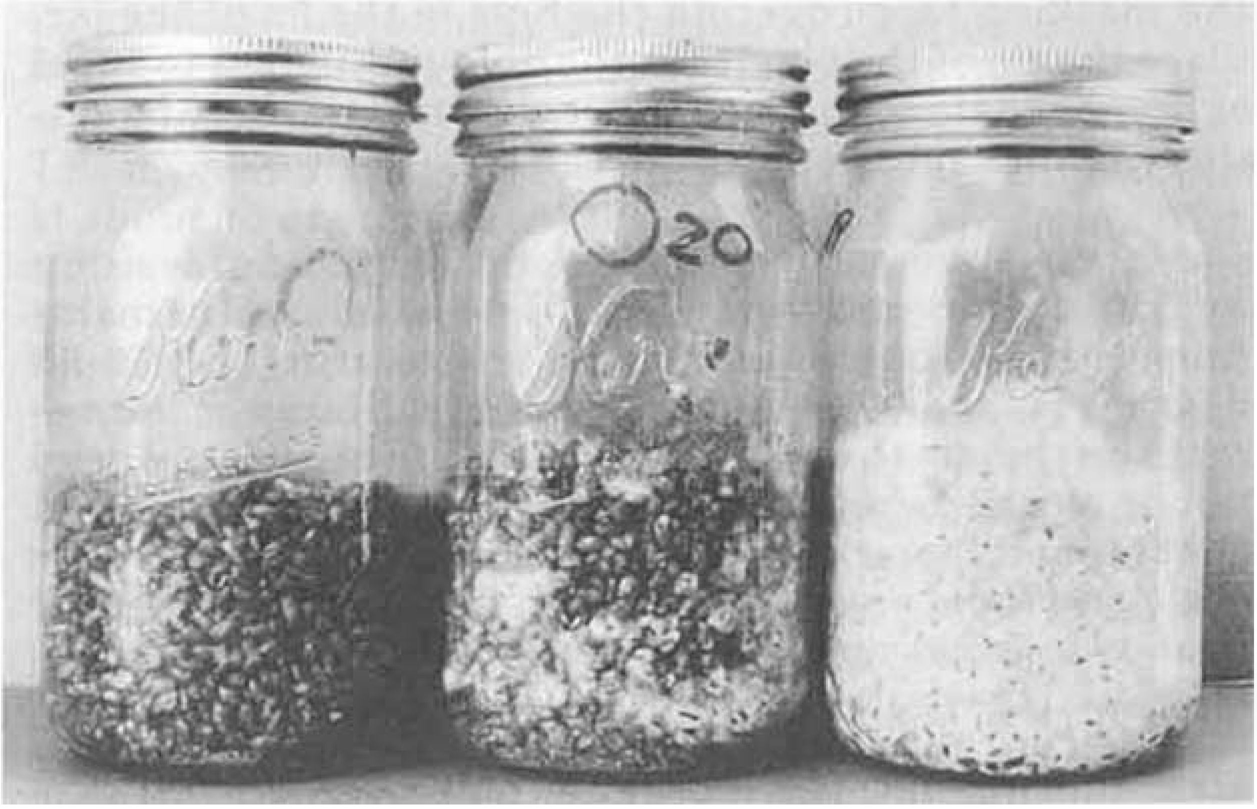

Fig. 39 - Jars at 4, 6, and 10 days after inoculation.

In order to use this method, one must bore an approximately ½-in. diameter hole in the "dome" part of the dome-and-band Mason jar lids. One can easily have this done for a small fee at a machine shop which has a drill press. NOTE: Have the holes bored with the white side of the dome facing up! Seal the hole in the lid with a small piece of masking tape that has been folded back on itself at one end so it can be easily grasped. Sterilize the rye in the Mason jars in the manner described in the preceding pages. After the jars have been sterilized, sterilize the following items for 45 minutes in the pressure cooker: one 50 ml Pyrex pipette (wrapped in tinfoil); the *glass part* of a standard household blender; one 250 ml Erlenmeyer flask containing 100 ml of water (seal the top with tinfoil). The blender should be covered with tinfoil on top; *do not* sterilize the plastic top of the blender! The metal propeller and rubber gasket of the blender need not be removed, as they will not be harmed by high temperatures. After these items have been sterilized and the jars have cooled enough to inoculate, proceed as follows: Select one or two vigorous, uncontaminated mycelial cultures from your stock of inocula. Using the flat of a flamed kitchen knife, cut around the edges of the agar disk in the plate, and empty the disk or disks into the blender. Add 100 ml of sterilized water, place the top on the blender and homogenize at high speed for 20 to 30 seconds. Suck up the homogenate in the sterile pipette. Grasp the free end of the masking tape covering the hole in the lid of the jar. Place the tip of the pipette in the hole and allow 5 to 10 ml of homogenate to fall into the jar. Reseal the hole by re-sticking the tape. Repeat for each jar.

After the rye has been inoculated, a period of waiting and careful observation follows. The jars should be maintained at a roughly constant temperature of 70-80 degrees F., and 95% relative humidity. Since the lids remain on the jars the humidity will tend to be high and need not be worried about. Maintaining the relatively high and constant temperature, however, is important to promote early and rapid mycelial growth. The mycelium gives off heat as it grows and a styrofoam box of the sort used by tropical fish wholesalers is ideal for holding this heat and thus self-incubating the jars. During the first three days after inoculation, the mycelium will grow off the agar inoculum and onto the rye. By the eighth to fourteenth day, depending on the temperature, the mycelium will have grown radially outward from the inoculum in all directions to form a mat of growth slightly smaller than a fifty-cent piece.

When mycelial growth has reached this stage, firmly tighten the lid and again shake the culture vigorously, to break up the mycelium and redistribute the inoculum throughout the rye. During the shaking process you will run across obviously contaminated jars; simply remove them and set them aside for washing out later. After shaking, allow the culture to stand for 3-4 days. At the end of this time mycelial growth from many different points in the rye should be apparent (Fig. 39). Shake the jars in this manner on the fourth, sixth, eighth, and, if necessary, on the tenth days after inoculation. Complete permeation of the rye should be observed anywhere from the eighth to the fourteenth day. At this time, the rye should be completely permeated by the snow-white mycelium, which may occasionally be lightly tinged with blue. If growth of any other color is observed, or if the rye is only partially permeated, then the culture is contaminated and should be discarded.

It should be noted that the time required for the mycelium to completely permeate the rye can vary widely according to individual circumstances. In some cases, permeation can take place in under eight days; in others, up to three weeks may be required. Our observations indicate that temperature of incubation of the jars is the single most critical factor governing permeation time. The mycelium of *Stropharia cubensis* has a growth optimum at about 80 degrees F. (Ames, 1958). We have found that cultures incubated at 80 degrees completed permeation in 11 to 13 days, while cultures incubated at 70 degrees required up to twice as long to complete permeation. A temperature of 68-70 degrees F. was, however, optimal for fruiting cultures after the casing step was carried out (see below). The degree of wetness of the rye medium also influenced permeation time, being slowed when the rye was too dry. We have found the best combination of rye and water to be approximately 160 ml rye to 130 ml water. We found these two factors, temperature and moisture, to affect permeation time significantly, while little discernable effect could be attributed to pH or the presence or absence of light. Even under optimum conditions, however, it is still necessary to shake the jars periodically to spread the inoculum through the medium and facilitate aeration. For the same reason one may also wish to loosen the lids of the jars (just a crack!) after the last shake.

When one or more jars of rye have been completely permeated by mycelium, the third step in the procedure is completed and one is ready to move on to the fourth step, casing. Before discussing this step, however, it is perhaps advisable to insert a word of caution with respect to the third step. This step, getting the mycelium to grow out and permeate the rye, seems to be the most difficult and discouraging step in the whole procedure. The peculiar headaches that one is faced with in this step can be summed up in one word: contamination. For some reason, contamination seems to be a much more serious problem at this stage than at the stage of growing on agar, probably because whole-grain rye is much more difficult to sterilize completely than is agar. Anyone attempting this step, in fact, is almost sure to receive a real education in the number of fungal and bacterial "weeds" that exist to plague the amateur mycologist. Our experience has been that two contaminants in particular are quite persistent and seemingly impossible to eliminate entirely. One is a crusty, rapidly-growing blue-green mold with a medicinal odor, probably a *Penicillium* or *Aspergillus*. The other is an unidentified bacteria that exudes a yellowish slime onto the side of the jar and that smells strongly of rotten apples. Spores of both of these organisms must be so commonly present in nature that they manage to contaminate some of the cultures despite the most careful inoculation procedures. The mold shows up rapidly and can be quickly spotted. Any culture seen to have this contaminant can be considered a loss. The bacteria takes longer to become obvious but with practice one can learn to spot it within a few days after inoculation. A sure give-away for presence of this contamination is to loosen the lid slightly and sniff at the crack: a strong yeasty or ferment-like odor indicates the presence of contamination. Uncontaminated cultures give off only a slight smell of cooked rye. Cultures contaminated with this organism are also almost impossible to salvage. The bacterium is anaerobic, that is, it can grow in the absence of oxygen. Our experience is that it seems indifferent to the presence or absence of oxygen, and grows in either situation. The mushroom mycelium is quite aerobic, in fact proper aeration is essential for its growth; therefore proper aeration can afford the fungus something of a competitive advantage against this organism.

Other contaminants will occasionally be seen, although not with the regularity of the two already mentioned. These may include black, olive green or sulphur-colored molds, and sometimes a dirty-grey, rapidly growing mold that is probably a *Rhizopus*.

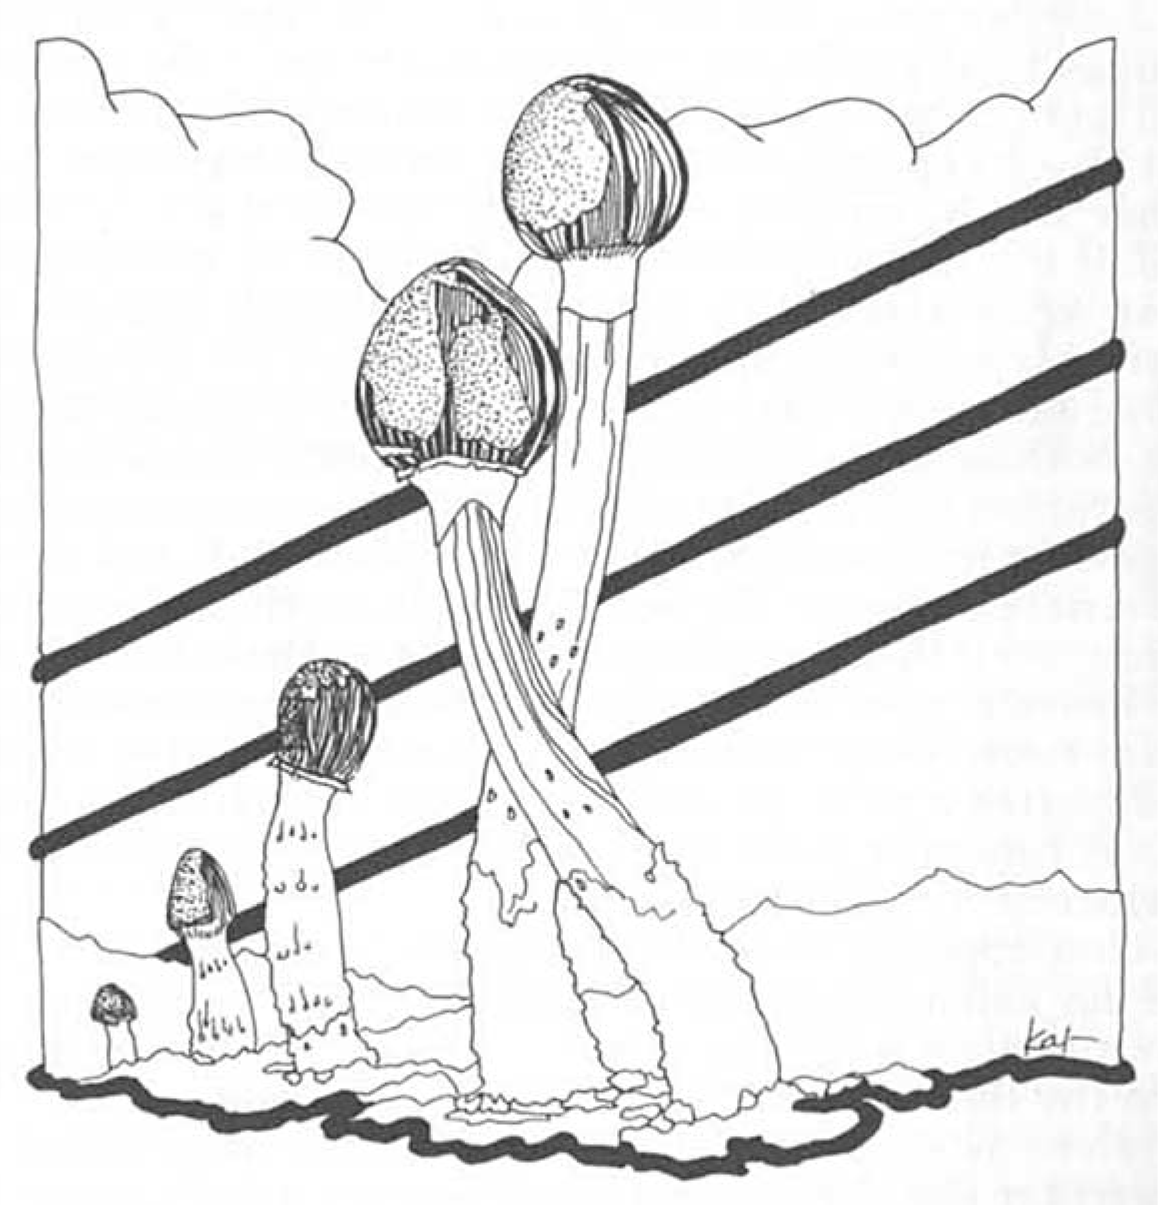
Three factors seem central to achieving a very low (5%) rate of contamination:

1. It is very important to let a good head of steam build up in the pressure cooker. If you are using the All American 941½ cooker, then it should vent clearly visible jets of steam for three to five minutes before the valve is closed and pressure allowed to build. 1500 ml of water should be covering the bottom of the 941 Vi at all times during the cooking of jars.
2. ***Lysol, while easily available, has serious drawbacks. It is highly flammable and if used in the presence of the alcohol lamp or any other open flame can explode. CAUTION: Mushroom growers have been severely burned in accidents involving Lysol***. Staphene is the commercial name of a strong water-based disinfectant that can be obtained from a scientific or medical supply house or ordered from the manufacturer, Vestal Labs, St. Louis, MO. Staphene cannot explode but should be treated with respect and handled with rubber gloves, as it is very toxic.
3. Petri dishes of inoculum should be used when the expanding circle of growing mycelium still retains at least a ¼ in. margin of undisturbed agar on all sides. Contaminants enter the dishes at the edges and most locate there. If inoculum is taken from "young" growth areas, very few even slightly contaminated dishes of inoculum enter the process of inoculating large batches of jars.

Jar Shifting: Once jars are cased it is important to check them for any possible contamination that may take hold in the casing soil itself. If a system of shelves is used, then each day the jars in the back of each row should be transferred to the front of the row. During the transfer, examine the jar for signs of contamination and excessive dryness or wetness. And mites. Done regularly, this process results in examination of all the jars every few days. Contamination can thus be caught in its early stages before it has a chance to spread. It is especially important to eliminate colonies of blue and green bacteria that are powdery.

Contaminants of any kind are not good and it is advisable to discard immediately any culture seen to be contaminated. Although the mycelium can co-exist with some of the slower-growing fungal contaminants, it is still best to discard any contaminated cultures in order to avoid spreading the plague. The cleaning of jars should be done as far away from the inoculation area as possible and should be done by someone who is not involved in making sterile inoculations. Jars that have been contaminated should be washed in a strong solution of Clorox and water before being reused. The best way to deal with contamination is to not allow it to become established in the first place, by being extremely meticulous about one's sterilization and inoculation procedures. Always make sure that the jars are sterilized with *wet* heat, not dry, by allowing a head of steam to build up in the pressure cooker before closing the stopcock. An inoculating hood, even if it is as simple as a cardboard box with clear plastic in one side, becomes almost indispensable at this stage. Always use sterile, uncontaminated agar cultures as the source of inoculation. Make sure that the working surface, and the inside of the inoculating hood, are thoroughly disinfected before inoculation.

The general working environment should also be kept as clean and dust-free as possible. One may wish to use an electrostatic air cleaner for this but it is not essential. Also make sure that hands and arms are clean before inoculating, and wear latex rubber gloves if possible. Spray your gloved hands with spray Lysol before reaching into the hood. ***Careful! Remember spray Lysol is flammable***. Use a sterilized scalpel for making inoculations, and be certain that it is absolutely clean for each batch to be inoculated. It does not hurt to swab it with alcohol beforehand. Be certain to flame the implement thoroughly in an alcohol flame before making each transfer. Practice making transfers as rapidly as possible, so that neither the receptacle containing the inoculum, nor the Mason jar are kept open longer than necessary. Finally, be absolutely ruthless in discarding contaminated cultures. Nothing less than complete permeation of the rye by the snow-white mycelium should be considered acceptable. If these procedures are followed rigorously, some cultures will undoubtedly still succumb to contamination, but the number can be held to a minimum.



STEP IV - CASING AND RECASING

When one or more jars have been completely permeated by mycelium, one can move on to the fourth step in the process that leads directly to the production of mushrooms. In commercial mushroom culture, this step is called casing. In the method outlined here, casing consists of removing the dome and band lid of the jar, and covering the surface of the permeated rye with about ½ to ¾ in. (½ cup for quart jars) of sterilized soil (Fig. 40 & 41). The soil should be premoistened to field capacity before being applied. The fastest way to do this is to spread the soil on a clean sheet of plastic and spray it lightly with the spray nozzle of a garden hose. Mix thoroughly. Field capacity can be gauged by the following rule of thumb: spray the casing soil just enough so that the soil is moistened throughout, but no water passes through the soil into the mycelium. In other words, moisten thoroughly, *but do not saturate* the soil. If the soil is to be sterilized, it should be moistened first. After sterilization, it can be conveniently stored in a double layer of plastic garbage bags, after it has cooled. Small amounts of casing soil may be dampened by putting two or three liters of casing soil in a large mixing bowl and moistening it with a pump sprayer. A large wooden spoon is perfect for folding the wet layers of soil into the dry. Alternate spraying the soil and stirring the dampness throughout the mix. When the casing soil has uniformly darkened in color and retains a shape when squeezed, it is ready to use. Once in the jar the soil should be shaken level and wetted a bit more with a fine mist sprayer (Fig. 42 & 43). A fine-mist spray must be used to avoid sealing the surface of the casing soil.

After applying and moistening the casing soil, discard the lids and maintain the cultures in a high humidity environment. A large styrofoam cooler with a window cut into the lid and covered with clear or translucent polyethylene is excellent for this (Fig. 17-20), so is a glass aquarium. If maintaining the jars in aquaria or styrofoam boxes, it is important to pay attention to proper aeration. Experience has shown that the daily transpiration/evaporation cycle is important if one is to have vigorous fruiting, healthy cultures. Maintaining the proper moisture balance and evaporation rate in the casing soil is actually a complex interplay among temperature, aeration, and evaporation. If either temperature or aeration is excessive, the soil will dry out. On the other hand, it should not become waterlogged, and a minimal amount of air movement should be present to facilitate a slow, even rate of evaporation from the casing soil. For this reason we recommend incubating the boxes with the lids partially or wholly removed after fruiting has begun. The temperature should be kept above 70 degrees F. Spray the cultures daily with a fine-mist spray just enough to make up for moisture lost through evaporation (Fig. 44). Each cased jar requires 2-3 good squirts of water per day to maintain continuous fruiting. Do not exceed field capacity. A good test for proper moisture content is that the surface of the soil should feel moist and spongy to the touch. Boxes of newly cased jars should be stored in chronological order.

Watering becomes a critical matter at this stage. If the correct water level is maintained in the casing soil, the first flush of mushrooms will be normal. But if jars are allowed to become too dry, then aborted fruiting or formation of many small mushrooms unable to grow to full maturity will occur. With proper watering and proper aeration, perfectly normal first flushes can be grown. What is a proper amount of moisture? The general tendency seems to be for beginning cultivators to keep jars too dry. Remember always to use premoistened casing soil. Make sure the distribution of the moisture is uniform. Once jars have been cased with pre-dampened soil, they ordinarily only need water once a day. The exceptions occur during and after periods of intense fruiting when slightly more water is required, or during spells of dry, hot weather. Strong drafts, especially warm drafts from floor heaters, can dry jars out very quickly. If one keeps jars on shelves that are open to the surrounding room part of the day, then it is especially important to keep the heaters from blowing directly on jars. Shelves can be enclosed in transparent polyurethane film in order to maintain high humidity and minimize contamination.

The other extreme to avoid is overwatering. The casing layer should be kept damp but not soaked. Any visible water accumulating between the rye covered mycelium and the walls of the jar indicates overwatering and a potential for contamination. Often if left unattended such jars become yellowish, indicating a more advanced stage of contamination. Such jars should be placed on a shelf together - separate from the other jars - and *all water should be withheld* until excess water in the jars recedes completely. Often, upon recasing, such jars seem to regain their equilibrium, and fruiting, though delayed, is normal.

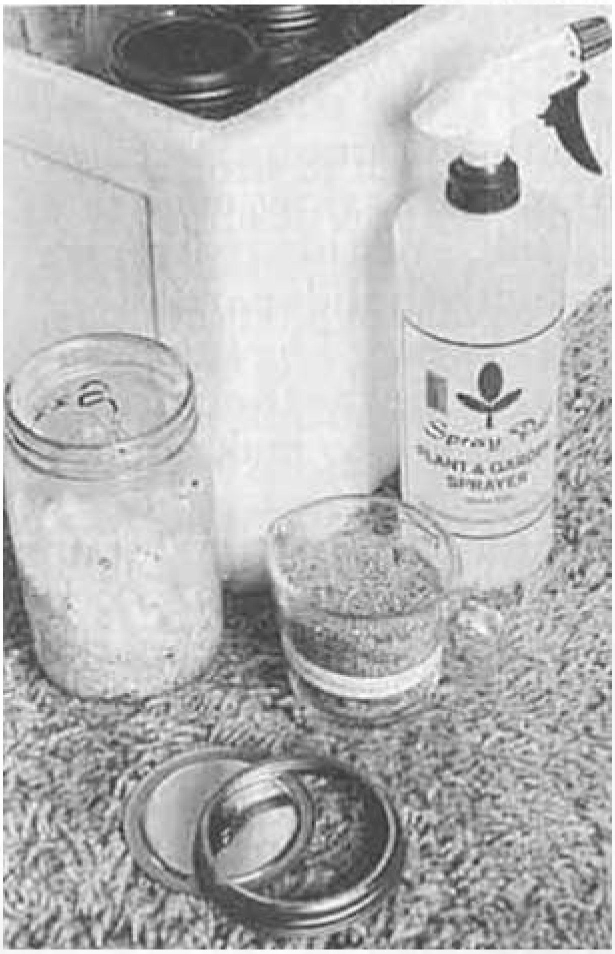


Fig. 40 - Open jar and soil ready for casing.

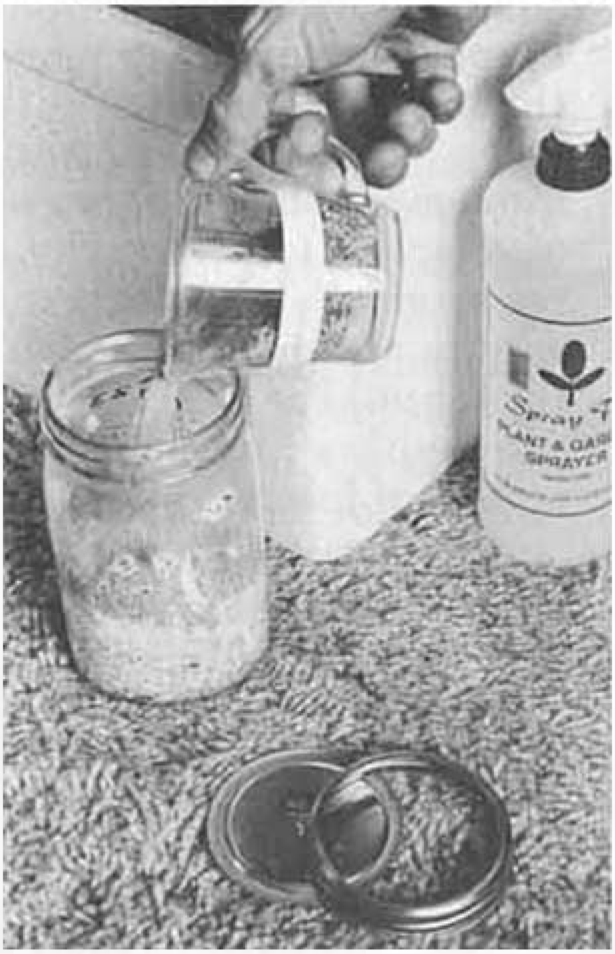

Fig. 41 - ½ cup casing soil is applied.

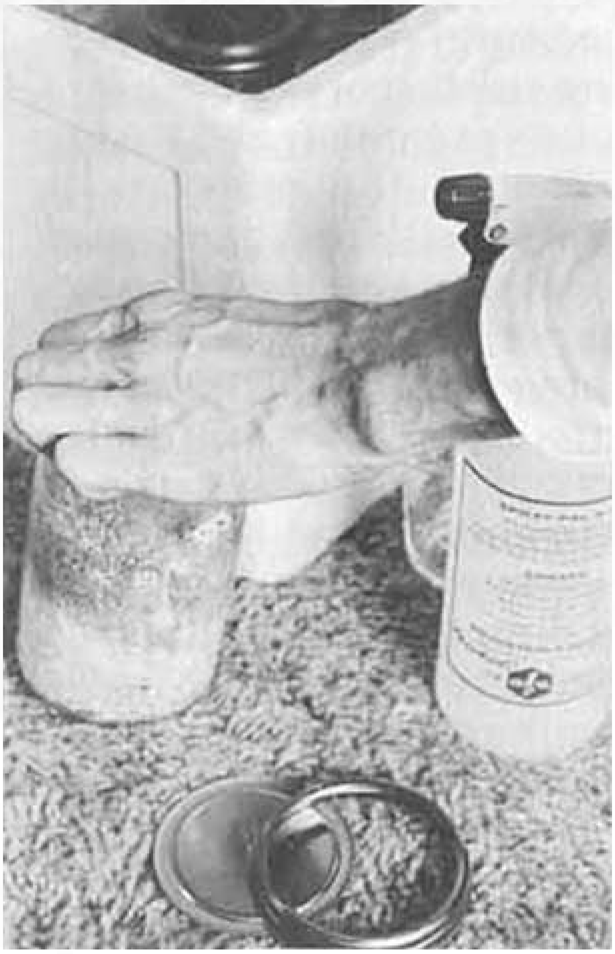

Fig. 42 - Casing soil is shaken to even it ...

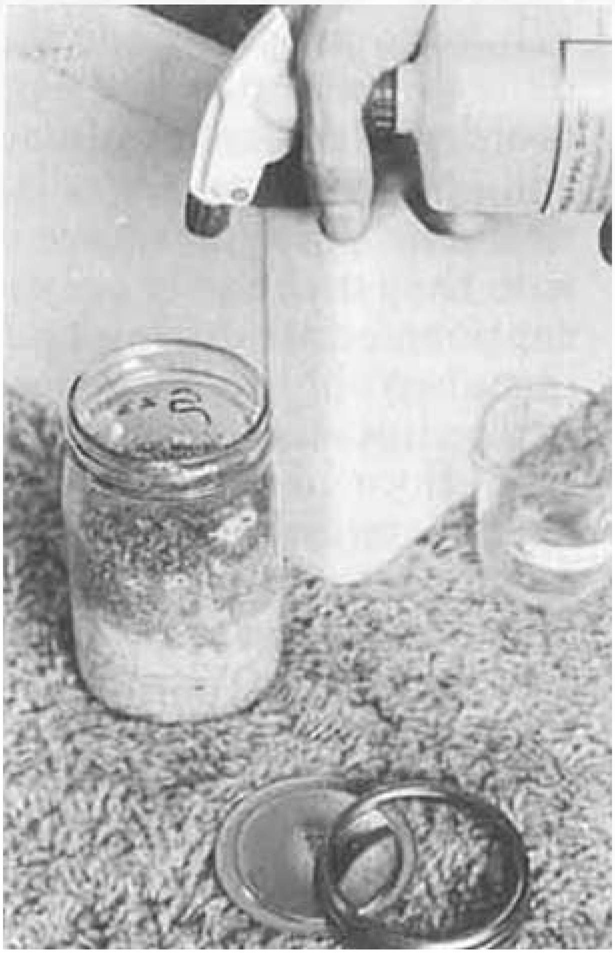

Fig. 43 - ... then sprayed, using a fine mist.

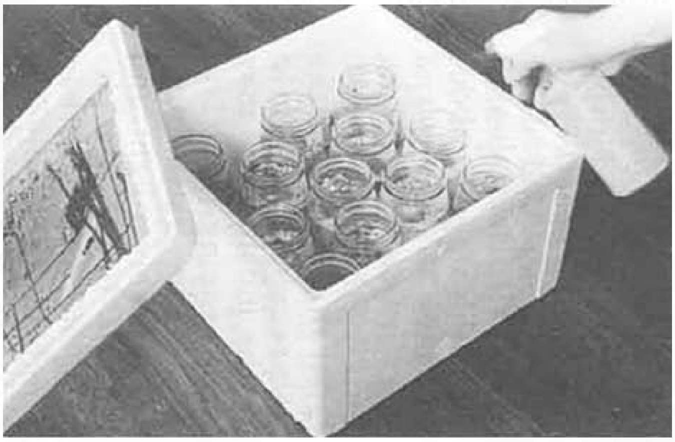

Fig. 44 - Spray cased jars daily.

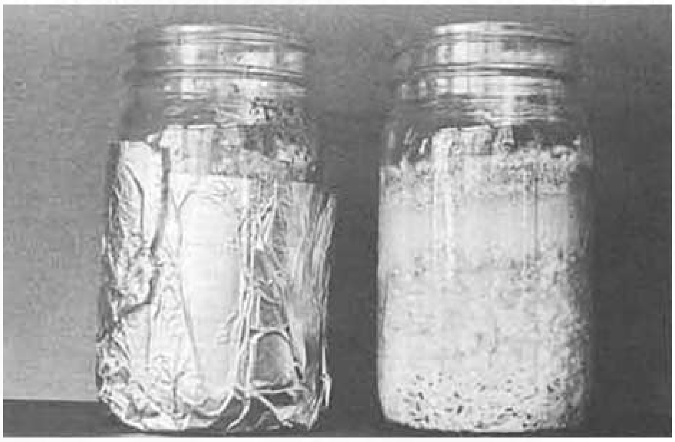

Fig. 45 - The mycelium grows through the casing soil.

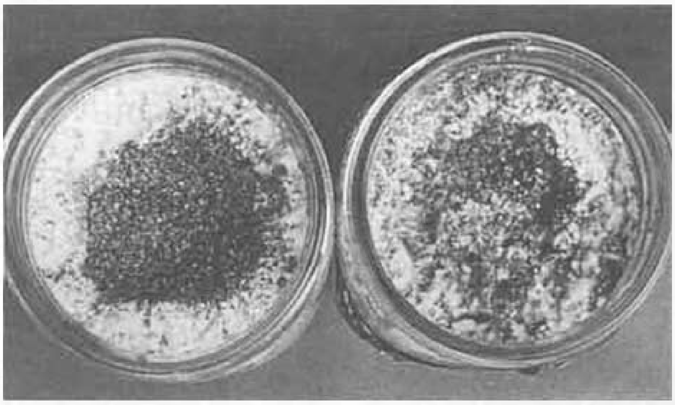

Fig. 46 - Mycelium will also grow on the surface.

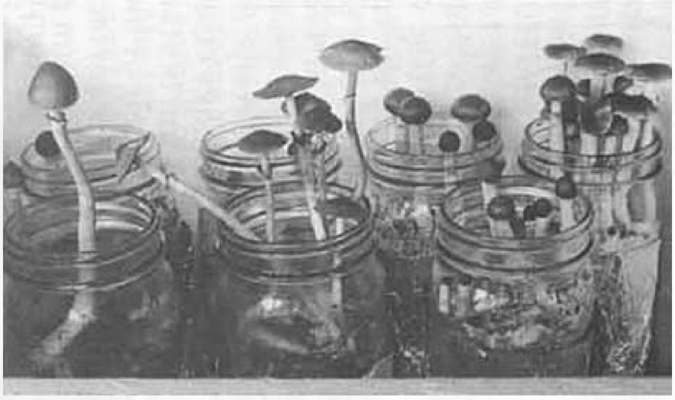

Fig. 47 - 25 days after casing, the first mushrooms appear.

During the next two to three weeks, the mycelium will begin to grow up into the casing soil, penetrating it to just beneath the surface (Fig. 45). The mycelium may occasionally break out onto the top of the soil and begin to spread across its surface, and part of the purpose of spraying daily is to keep this surface growth "knocked down" with the spray (Fig. 46). Excessive surface growth, in which the mycelium completely overgrows the casing soil and forms a thick spongy crust on the surface, is an indication that the mycelium is starved for air and that ventilation should immediately be increased. If you are under-watering your jars, this surface mycelium will turn blue with thirst. As the mycelium grows into the casing soil, it will begin to form a network of ropy strands visible at the interface of the soil and the glass. This network gradually gains more and more intersecting nodes, and by the 14th to 20th day after casing, these nodes have differentiated into tiny white dots distributed through the casing soil along the perimeter of the jar. These dots are the young mushroom primordia; gradually they enlarge and incorporate more mycelia, slowing taking on the appearance of tiny mushrooms with squat, fat stems and dark, brownish heads. This is the "pin" stage in the development of the mushroom and the primordia at this stage are about 1-2 mm in length. These pins continue to enlarge and some will begin to thrust above the surface of the casing soil, both at the sides and in the center of the jar. Once the young mushrooms have penetrated the surface of the casing soil, another five to ten days is required for them to reach full maturity. At maturity the mushrooms may be 2 to 9 inches tall and have caps ranging from 1 to 3 inches in diameter (Fig. 47 & 48). We have also found that these mushrooms do respond favorably to light, and that a daily 13-hour fluorescent or Grow-lux cycle results in mushrooms with larger caps and shorter stems than those grown without any special lighting. Probably it is not advisable, however, to place the cultures in direct sunlight for prolonged periods. While many mushrooms will grow to full size, approximately an equal number will grow to about half-size or less and then cease to grow; these "aborts" can still be plucked, dried, and used, although they are not as aesthetically appealing as the fully matured specimens. With practice one can learn to spot aborts early and remove them from the cultures. Aborted mushrooms left in the cultures are susceptible to attack by bacteria which quickly render them both ugly and unusable.

Excessive numbers of aborts are another indication of inadequate aeration. If the jars are being incubated in styrofoam boxes or aquaria, there is a possibility of accumulating carbon dioxide in the air space above the casing soil. This will inhibit fruiting and/or prevent fruits from reaching maturity. If this happens, increase aeration by leaving the lids off the box, or by using a small fan to enhance air movement over the surface of the jar. Be careful not to *over* aereate, however; too fast a rate of evaporation will cause the casing soil to dry out.

Occasionally mushroom primordia will form down toward the bottom of the jar and grow to maturity but will not break the surface of the casing soil. It is possible to inhibit this effect somewhat by wrapping jars with tinfoil to the top of the casing soil (Fig. 45). This effect, formation and development of primordia toward the bottom of the jar, is normally seen during the earliest mushroom "flush." After the first flush, the jars are recased for each subsequent flush (see below). We find that recasing will largely eliminate this problem for all flushes but the first one.

A variety of types of casing soils have been found to effectively promote fruiting. We have found the following mixture to be one of the best:

7.5 liters peat moss
3.5 liters fine vermiculite
4 liters washed fine sand
2 liters calcium carbonate (finely crushed oyster shell)

Powdered oyster shell is sold as a feed supplement by many feed companies. The calcium carbonate is an optional ingredient and can be left out without significantly affecting fruiting. It should be added if available, however, to buffer the soil and keep it from becoming too acidic. This factor *may* contribute to the growth of contaminants on the surface of the casing soil, and the calcium carbonate can inhibit or prevent this. For the same reason, one may also wish to water occasionally using a saturated solution of calcium carbonate. We have also found that a mixture of one part mica-peat (50/50 vermiculite-peat-moss mixture) to one part potting soil will work.

Sterilization of casing soil is usually recommended but we found it unnecessary when relatively sterile commercially bagged materials were used. If you wish you may sterilize casing soil before use at 15-20 lbs. pressure for 30 minutes. It should be wetted first to field capacity. Casing soil can be stored indefinitely in a tightly sealed large glass jar, or in a polyethylene garbage bag. If a glass jar is used, it can be sterilized with the casing soil in it. Remember to loosen the lid prior to sterilizing. After the first flush of mushrooms, the soil and mycelium-covered block of grain will shrink somewhat, leaving a space between the mycelium and the walls of the jar. Whenever this condition is noticed, it is time to recase. Recasing will greatly extend the life and fruiting capacity of your jars. It is a simple procedure which involves using a clean fork (one per jar, as this way contaminants are not spread from jar to jar) to scrape off all of the old casing soil and aborted mushrooms growing down along the sides of the jar. Then, using fresh casing soil prewetted as before, recover the mycelial block and use the fork to work the fresh casing soil down the sides of the jar around the block as well as covering the top. It will take your jars about two weeks to recover from this treatment but then they will do their best fruiting, producing clusters of large carpophores and behaving as if this recasing procedure had made them more resistant to contamination.

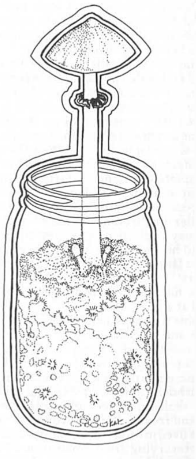
Instead of applying the casing soil to the mycelia-covered rye in the jars as described in the preceding pages, it is possible to adopt a somewhat different approach to the making of cased cultures. The steps involved in this method are described briefly below. The basic idea for this method was suggested to us by a friend, Paul Kroeger, and his contribution is gratefully acknowledged. In order to use this method, one begins by growing the mycelium out on the rye in the Mason jars in exactly the manner described above for the cased jar method. One may use plastic trays, glass baking pans, or one may manufacture a styrofoam box with a window of clear plastic in the lid as described above (Fig. 17-20). Sterilize the inside surface of the tray or box thoroughly by wiping down with a 25% Clorox solution followed by a Lysol spray. Cover the bottom of the container with a ¾-1 inch-deep layer of perlite or a 1:1 mixture of vermiculite and casing soil. Grow the mycelium on the rye medium in the Mason jars until it is fully permeated and ready to case. Instead of casing at this stage, however, shake the jars again. The mycelial block will be tightly woven together and may require a little extra effort in order to be shaken loose. After shaking, empty the contents of several jars into the container so as to form a layer of rye "spawn" about 1-1½ inch deep.

The number of jars required to do this will vary depending on the size of the container, but usually between five and ten jars are sufficient. Cover the rye layer with a second layer of moistened casing soil, to a depth of 1-1½ in. One has now created a 3-layered "sandwich" arrangement in the container: Perlite or vermiculite-casing soil forms the bottom layer and provides drainage; the second, rye and mycelium layer provides the nutritive substrate for the mycelium; the topmost, casing layer prevents the mycelium from becoming desicated or attacked by contaminants as well as functioning to induce the mycelium to fruit. Once the layers have been made, maintain the container in a humid environment and as close to 70 degrees F. as possible. If using styrofoam boxes, keep the lid on for the first two weeks following casing. Since the soil is moist and the mycelium produces water in its respiration, humidity will be high in the box (in fact, condensation on the transparent lid can usually be seen) and therefore one should not spray, or should spray only lightly and infrequently, during this stage.

Two weeks after casing, or approximately one week prior to the commencement of fruiting, the lids should be removed to prevent carbon dioxide accumulation in the containers. Daily watering with a fine mist can be started after the lids have been removed. The mycelium will continue to grow into the casing soil. Fruiting, at both the sides and center of the container, will commence 21-30 days after casing. The box or tray culture will fruit abundantly, producing many clusters of perfect large carpophores in various stages of maturity across the entire surface of the casing soil. As these clusters are plucked, the holes created in the casing soil should be plugged with fresh casing soil. Recasing as described for the jars is not necessary with this method. The container cultures will usually succumb to contamination (usually a green mold which shows up on the surface of the casing soil) more quickly than the jars. Containers fruit for 30 to 40 days as opposed to 60 to 80 days for jars, but the flushes produced during this time are so abundant that the overall total yield for trays and jars is comparable (approximately 10 grams dry weight of mushroom for every 100 grams dry weight of rye).

When your cultures are well established in the mature fruiting phase, it is a good idea to shift your awareness toward a new class of potential pests and carriers of contamination. These are insects, specifically flies and mites. The best way of controlling flies is by keeping your cultures in a screened room that flies are unable to penetrate. Even in the most tightly sealed environments flies do occasionally occur. It is therefore a good idea to use a slow acting insect killer of the vaporizing type, such as the "No-Pest Strip" in the growing area. Usually this is all the fly protection that is necessary. Mites are a more persistent and difficult pest to control. Massive reliance on applied insecticides is the commercial mushroom growers' approach to mite control. But we believe that application of insecticides to *Stropharia cubensis* should be undertaken only as a last resort.

The real key to mite control is early detection. Therefore, examine your jars very carefully. Mites are most visibly active in the middle and late afternoon, and are usually first spotted wandering around on the smooth rim of the jar. They are tiny specks, distinguished from tiny bits of casing material only by their motion. Jars with mites should be immediately isolated, or preferably removed entirely from the growing area. Once mites are detected, the grower must go to a state of high alert and check the jars every day to see if the plague is spreading. Removal of infested jars is the best course. The next best course is to spray only the infested jars with a ½-strength solution of Malathion. Malathion, though anathema to the anti-insecticide purist, is one of the least toxic and most rapidly degraded of commercial insecticides. It should not, however, be used on cultures within 6 days of fruiting. Under no conditions should the miticide Keldane be applied to cultures. Keldane is FATAL to *Stropharia cubensis*.



STEP V - HARVESTING, PRESERVING, AND DOSAGE

As the mushroom matures to full size, the cap will enlarge and become more globular in shape. The gills will at first be covered by a flap of tissue, called the *veil*, that connects the margin of the cap with the stipe. As the cap enlarges, this veil will detach from the cap margin to form an *annulus*, or ring of ruptured veil tissue, on the stem. The mushroom can be harvested as soon as the veil rupture has occurred. If a spore print is to be collected, however, the mushroom should be allowed to flatten out to an umbrella shape before harvesting.

Freshly harvested mushrooms can be eaten fresh, or can be dried and sealed in plastic bags for preservation. It is a simple matter to construct a small drying cabinet out of masonite or plywood. This consists essentially of a wooden box with a hinged door on the front and two or more screens or wire shelves which can slide in and out. A 150- to 200-watt electric light bulb can be mounted in the bottom as a heat source. We have found this type of drying cabinet completely suitable and trouble-free. It produces an even heat at about 120 degrees F. and will dry even large, thick-stemmed mushrooms completely within 48 hours; smaller mushrooms dry in 24 hours using this cabinet. They may be dried in a gas oven at low heat (140 F. or less) for 6-10 hours (Fig. 49 & 50). They may also be dried under a heat lamp, on a screen over a heating vent, or in a small electric food dehydrator. Mushrooms are fully dried when hard to the touch, like crackers, with no spongy feel at all (Fig. 51).

Mushrooms that have been dried at too high a heat will turn brown and be very bitter to the taste. Such mushrooms are substantially less psychoactive. To preserve maximum potency, dried mushrooms should be sealed in five gram increments in plastic bags from which the air has been withdrawn (Figs. 52-54), and this in turn placed in a tightly sealed glass vessel or other moisture-proof container, and frozen. We have found the polypropylene boiling bags used in food storage and preparation to be excellent for preserving dried mushrooms. Rolls of bagging material and the electric sealers used for sealing are sold commercially in department stores under the brand name "Seal-A-Meal" and "Seal & Save." Dried mushrooms left in the open air quickly lose their potency. Fresh mushrooms should not be frozen without drying first, as freezing them in this condition will turn them into a black, gooey mess. Fresh mushrooms can, however, be preserved in a plastic bag in the vegetable pan of the refrigerator for about a week to ten days. Fresh mushrooms older than this should either be eaten or dried to prevent spoilage.

The dried mushrooms contain from 0.2 to 0.4 percent psilocybin (Schultes, *et al.*, 1973) by weight. Some strains of *Stropharia cubensis* have been reported to contain as much as 0.5% psilocybin (Wasson & Heim, 1959, p. 260). Psilocin is present only in trace amounts. A dose of about 10-12 milligrams of psilocybin, or about 5 g dry weight of mushrooms, or 50 g wet weight, is sufficient to manifest the full spectrum of hallucinogenic effects in a 160 lb. adult. These effects include visual and auditory hallucinations, extreme hilarity, distortions of time and space perception, and a sense of emotional detachment from the environment. Less marked effects can be detected at doses as low as 2 mg, which is about 1-2 dried mushrooms. Fresh mushrooms seem to be somewhat stronger than dried ones. Psilocybin is one of the least toxic of all hallucinogens. A full, effective dose is 12 mg while mescaline, by comparison, has a minimum effective dose of 200 mg for an average-size adult, and a toxicity 2.5 times that of psilocybin (Aboul-Enein, 1974).

The state of mind induced by a full dose of mushrooms is one of euphoria and calm lucidity, with no loss of coherency or clarity of thought. The hallucinations seen with the eyes closed are colorful, hard-edged, and highly articulated, and may range from abstract geometrical forms to visions of fantastic landscapes and architectural vistas. These hallucinations are most intense when the mushroom is taken in the setting preferred by the Mazatecans: inside at night in complete darkness. On the other hand, if one is in a natural setting and directs the focus of the senses outward to the environment, one discovers that one's senses seem keyed to their highest pitch of receptivity, and finds oneself hearing, smelling and seeing things with a clarity and sensitivity seldom, if ever, experienced before. Although it should be clear to anyone who has read this far that cultivating these mushrooms is an endeavor requiring time, patience, care and humility, and one fraught with its own peculiar problems, once one has partaken of these wonderful gifts of nature and experiences the exalted consciousness that they can bring about, we think that they will agree with us that the effort involved provides its own ample reward.

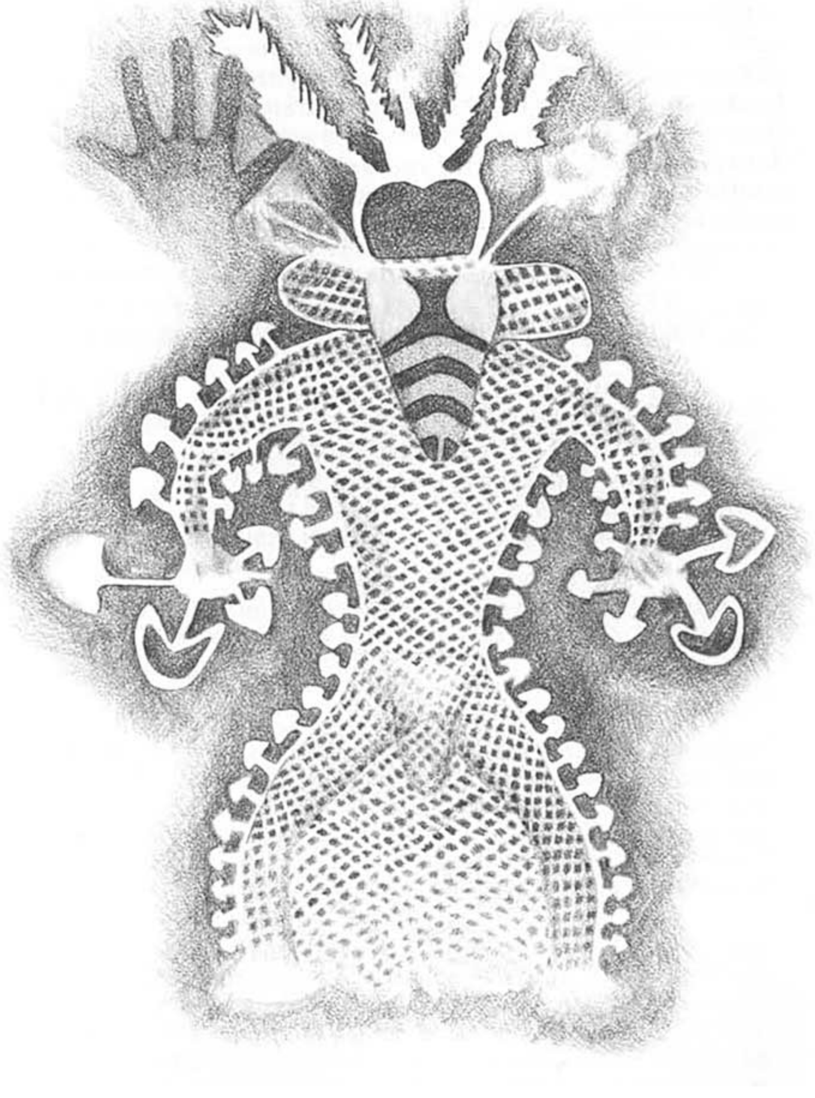
AFTERWORD

Approximately sixty days after you began the isolation of spores, the first harvest will be possible from your rye-filled jars. Mushroom growing is like alchemy in that there is a division of the work into practical effort and visionary reward. The organic psilocybin within the mushroom is quality controlled by the very stable and ancient genes of the *Stropharia*. You, as the propagator and spiritual friend of the mushroom, can form a deep relationship with the mycelial ally and again and again make far journeys into its visionary realms if you observe a few simple rules. Tolerance to psilocybin is easily acquired if trips are taken more often than once a week. If one does acquire a tolerance, it can be gone around by either upping the dose or by laying off for a couple of weeks to allow your body to recover its equilibrium. We recommend the latter course even though the toxicity of psilocybin is so low that raising the dose is a valid alternate course.

Now our little handbook closes. Advice from this point on can only come in generalities. Take the mushrooms that you have grown, take them in the darkness as the Indians of Mexico who have used them for centuries do. Smoke a lot of your favorite hash to synergize the behind-the-eyelids hallucinations and prolong them. Psilocybin is light shedding illumination on a landscape both within and without the mind and body of human beings and previously invisible to them. The exploration of this vast region by persons whose mental equipage is that of the modern West has only begun. Only a moment has passed since our culture has rediscovered, through the work of Wasson and others, the ancient and unplumbed relationship between the vision-causing mushrooms and our own strangely gifted species. You are a pioneer in a world whose future is undetermined and whose living organisms are full of singularities and surreal transforming promise.



Rock painting from Tassili Plateau, Southern Algeria, circa 3500 B.C.

CONVERSION TABLE

This conversion table is included for those who may lack scales or other equipment to make accurate measurements of required ingredients. Although one should always try to measure the ingredients as accurately as possible, and the purchase of an inexpensive scale and graduated cylinder is well worthwhile, this table can be useful in approximating measurements and calculating volumes if such equipment is unavailable.

160 ml dry rye weighs approximately 150 grams, &frac23; of a cup
2 g powdered oyster shell is a level ½ teaspoon
1 g yeast extract is a level ½ teaspoon
1 g Difco agar is 1 slightly packed level ½ teaspoon
1 liter (1000 ml) = 1 quart (1.057 quarts)
1 baggy (Glad type) weighs 1.5 g

A CHRONOLOGY OF PSILOCYBIAN* MUSHROOMS

Compiled by Irimias the Obscure & O.T. Oss

* "Psilocybian" in this context means any mushroom containing psilocybin.

c. 3500 B.C. Frescoes of dancing shamans holding mushrooms in the presence of white cattle are painted on the rock surfaces of the Tassili Plateau in Southern Algeria.**

** Special thanks to J. Ginsberg of Boulder, Colorado who was the first to notice the importance of the Tassili frescos for ethnomycology.

c. 2500 B.C. Aryan people with hallucinogenic mushroom use as a central part of their religion enter India. Wasson has argued for *Amanita muscaria* as the identity of the mysterious Soma. The question remains an open one. A psilocybian mushroom may well have been the source of Soma.

c. 1100-400 B.C. Eleusinian Mystery rites using ergotized rye (Wasson) or psilocybian mushrooms (Graves) focus the mystical aspirations of the Ancient World.

300-500 B.C. In the latter half of this century, "mushroom stones" were found in highland Guatemala dating back at least as far as 300-500 B.C.

c. 300 A.D. Frescoes have been found in central Mexico with mushroom designs indicating the existence of a mushroom cult at this time.

387 A.D. St. Augustine, formerly a follower of Mani, condemns Manichaeans for mushroom eating.

1502 A.D. Psilocybian mushrooms were served at the coronation feast of Moctezuma II and were used recreationally.

1547-1569 Fray Bernadino de Sahugun, A Spanish cleric, wrote *Historia de las Cosas de Nueva Espana* (also known as the *Florentine Codex*) which refers to "nanacatl" (= teonanácatl = flesh of the gods = psilocybian mushroom). Sahugun states that the mushrooms "are harmful and intoxicate like wine." Further, those who indulge "see visions, feel a faintness of heart and are provoked to lust."

1651 Dr. Francisco Hernández, a Spanish physician studying Central American Indian herbal medicine reported three types of mushrooms which were worshipped by Mexican natives. He reported that the ingestion of these caused "not death but a madness that on occasion is lasting, of which the symptom is a kind of uncontrolled laughter... these are deep yellow, acrid, and of a not displeasing freshness. There are others again, which without inducing laughter, bring before the eye all sorts of things, such as wars and the likeness of demons. Yet others there are not less desired by princes for their festivals and banquets, and these fetch a high price. With night-long vigils are they sought, awesome and terrifying. This kind is tawny and somewhat acrid."

1895 John Uri Lloyd publishes his fantasy-novel *Etidorpha* in which he makes it clear that he and his mycologist brother Curtis Gates Lloyd were aware of the hallucinatory properties of mushrooms other than *Amanita muscaria*. The Lloyds elected not to publish the botanical details of their findings.

1906 *Stropharia cubensis* is described by Earle in a Cuban agronomy journal.

1914 A.E. Merrill of Yale University published a paper in *Science* describing the hallucinogenic effects of ingesting *Panaeolus papilionaceus* from Oxford County, Maine. Although the identification of the mushroom may be in error, the effects described are very probably due to psilocybin and psilocin. Further, the article describes different reactions to this hallucinogenic mushroom which is compared to hashish and peyote in the text.

1915 American botanist William E. Safford attempted to identify the teonanácatl of the Aztecs. He claimed that sacred mushrooms had never existed, and that the teonanácatl referred to by the 16th century Spanish chroniclers were actually dried peyotl buttons. Safford's theory was widely accepted by the scientific community for the next three decades.

1915 American botanist William E. Safford attempted to identify the teonanácatl of the Aztecs. He claimed that sacred mushrooms had never existed, and that the teonanácatl referred to by the 16th century Spanish chroniclers were actually dried peyotl buttons. Safford's theory was widely accepted by the scientific community for the next three decades.

1919 Dr. Blas P. Reko, who had carried out extensive anthropological and botanical work in Mexico for more than 25 years, published an article in a Mexican anthropological journal stating that nanácatl (= teonanácatl) was a hallucinogenic mushroom. However, some of Reko's earlier work had been in error and this report was discounted.

1923 In a letter to the U.S. National Museum, Dr. Reko stated that teonanácatl "is actually, as Sahugun states, a fungus which grows on dung heaps and which is still used under the same old name by the Indians of the Sierra Juarez in Oaxaca in their religious feasts."

1936 Victor A. Reko (B.P.'s brother) publishes *Magischt Gifte*. In it, he wrongly suggests that teonanácatl might be a species of *Amanita*.

1936 Ing. Roberto J. Weitlaner obtained some teonanácatl in Oaxaca. He was the first white man in modern times to have done so. He sent the specimens to B.P. Reko, who sent them to Harvard, where they arrived in a decomposed state and thus escaped identification.

1938 Weitlaner's daughter, Irmgard, along with anthropologist Jean Basset Johnson and two others attended a mushroom rite in Huatla, Oaxaca. These were the first whites to attend a mushroom ceremony.

1938 Harvard botanist R.E. Schultes traveled to Oaxaca and obtained from native informants two specimens of two different genera: *Panaeolus campanulatus* var. *sphinctrinus*, and *Stropharia cubensis*. In his field notes, he described a third specimen: *Psilocybe caerulescens* var. *mazatecorum*.

1952-53 R. Gordon Wasson and his wife Valentina became aware of the existence of a mushroom cult in central Mexico. This ambitious couple set out to prove the theory that religion came directly from the use of hallucinogenic plants. The Wassons traveled to Mexico and were guided by Ing. Roberto J. Weitlaner to the mountainous village of Huautla de Jiménez in Oaxaca.

1955 R.G. Wasson and Allan Richardson became the first two Americans to attend a mushroom ritual and ingest the mushrooms. The mushrooms were taken under the supervision of Maria Sabina, Mazatec curandera. By 1957, news of this ritual had reached the world through articles in several popular magazines and the Wasson's book. *Mushrooms, Russia, and History*.

1956 Wasson invited Roger Heim, a French mycologist, to Oaxaca to research the use of the sacred mushrooms. Heim identified fourteen species and several subspecies belonging to three genera, *Psilocybe*, *Stropharia*, and *Conocybe*. Several of these species were new to mycology, but had been utilized as hallucinogens by the natives for centuries.

1957 Mycologist Dr. Rolf Singer and two young Mexican botanists, M.A. Palacios and Gastón Guzmán, arrived in Oaxaca to do taxonomic work on the mushrooms.

1958 Dr. Albert Hofmann, a Sandoz chemist from Basel, Switzerland, isolated two active agents and named them psilocybin and psilocin after the genus *Psilocybe*.

1960 While vacationing in Cuernavaca, Mexico, Harvard psychologist Timothy Leary ate a dose of the mushrooms. Later, he wrote "... it was the classic visionary voyage and I came back a changed man ... You are never the same after you've had that one flash glimpse down the cellular time tunnel. You are never the same after you've had the veil drawn."

1960 Dr. Leary and an associate, Dr. Richard Alpert, obtained a supply of synthetic psilocybin from Sandoz for use in an experiment with prisoners in Concord State Prison, Massachusetts. Initial results were very promising: prisoners released following an experience with psilocybin seemed less likely to be rearrested and returned for parole violations than other parolees.

1960 Aldous Huxley ingested 10 mg psilocybin in a group under the supervision of Timothy Leary. Huxley "sat in contemplative calm throughout; occasionally produced relevant epigrams; reported the experience as an edifying philosophic experience."

c. 1965-66 Laws against the sale, manufacture, and possession of LSD, mescaline and psilocybin are passed by paranoid legislatures after being persuaded by a hysterical press. The New York State legislature deferred hearings on one bill to outlaw hallucinogens until after the law was voted on and passed!

1966 By this time, several illicit labs were set up to manufacture hallucinogenic drugs in response to the growing demand by users.

1967 Reacting to erroneous tales of massive chromosome damage produced by LSD use, users began to demand organic drugs such as psilocybin and mescaline. Compared to LSD, hallucinogens such as these are relatively expensive to manufacture. Many unscrupulous dealers sold LSD as psilocybin. Most of the tabbed or capsulated psilocybin on the street from 1966-75 was actually LSD, or LSD cut with PCP.

1970 A Key to the North American Psilocybin Mushroom was published by Leonard Enos in California. This poorly-illustrated but well-written guide instructed laypersons where, when and how they could obtain psilocybian mushrooms in nature. The book also contained instructions for cultivating mycelium on agar.

1971 Due to popular demand for organic drugs, unscrupulous dealers began lacing commercial mushrooms with LSD and selling them as psilocybian mushrooms. These spurious psilocybian mushrooms appeared on the street drug market as late as 1975 and can be differentiated from most psilocybian mushrooms in that they (a) don't blue, and (b) their effects last much longer than the 4 to 7 hours characteristic of psilocybin.

1975 The first living cultures of *Stropharia cubensis* were seen in limited numbers on the underground market.

1975 Oss and Oeric (in this volume) bravely risked ridicule to become the first to suggest the extraterrestrial origin of *Stropharia cubensis*.

1976 Technology developed by the authors (Oss & Oeric, 1976) is unleashed upon the world. The illicit hallucinogenic trade crumbles because of decentralization brought on by epidemic of home *Stropharia* cultivation. Invasion of North America by hallucinogenic mushrooms continues, leading shortly to metamorphosis of human beings into a symbiotic species.

1981 Over one hundred thousand copies of *Psilocybin: Magic Mushroom Grower's Guide* sold. Numerous imitations also flourish as an estimated five thousand North American mushroom growers work with love and dedication to make psilocybin *the* hallucinogen of choice in high-tech society.

1984 Heterodox Bengali Hindus announce identification of the Vedic intoxicant Soma as a psilocybian mushroom, *Stropharia cubensis*. A reform of Hinduism centered around recovery of the 6000-year-old Soma rite is begun.

GLOSSARY

adnate (of gills) - attached directly to the stalk.

adnexed (of gills) - notched just at stalk.

aerobic - requiring oxygen in order to live. Opposite of anaerobic.

annulus - ring-shaped remains of the partial veil which hangs on the stalk.

basidium (pl. basidia) - cell on which the spores of a Basidiomycete are borne.

basidiocarp - basidium-bearing structure or "fruiting body" of a Basidiomycete. Sometimes also called a *carpophore*.

basidiospore - spore formed exogenously on a basidium, generally following karyogamy and meiosis.

dikaryotic - a fungal hypha having two nuclei per cell.

diploid - having a single set of paired chromosomes (twice the number of chromosomes as in the gametes); 2n. Cf. *haploid*, having only one full set of *unpaired* chromosomes; n.

genome - the basic set of chromosomes (n) contributed by each parent.

genus (pl. genera) - the major subdivision of a family or subfamily of plants or animals; it usually consists of more than one species.

heterothallic - in Basidiomycetes, having thalli separable into two or more morphologically similar sexual strains, with conjugation occurring only when compatible mating types are paired.

hypha (pl. hyphae) - one of the tubular filaments composing mycelium.

indole - a white crystalline compound, C_8H_2N, having the same heterocyclic fused ring structure as the aminoacid tryptophane. The indole structure is incorporated into the structures of many hallucinogenic compounds.

inoculation - to implant microorganisms or fungal mycelium into a culture medium. The mycelium used for this is called the *inoculum* (pl. inocula).

inoculating loop - implement used for making inoculations, consisting of a long handle with a length of stainless steel or platinum wire attached to the end and usually bent into a loop at the tip.

karyogamy - fusion of the two nuclei of the dikaryotic mycelium. In the Basidiomycetes, karyogamy constitutes the only diploid (2n) stage in the life cycle.

meiosis - reduction division of a cell in which the number of chromosomes is reduced from the diploid (2n) to the haploid (n) state. Meiosis produces sexual cells or *gametes*.

milliliter (abbr. ml) - one-thousandth part of a liter. 1 ml = 1 cubic centimeter (cc) in volume.

monokaryotic - hyphal condition in which the cells contain a single haploid nucleus; e.g., the primary mycelium of Basidiomycetes.

mycelium (pl. mycelia) - the vegetative body of certain complex fungi, consisting of an aggregation of hyphae.

phylogeny - the evolutionary development of a species of plant or animal.

rhizoid - a rootlike filament composed of many strands of hyphae.

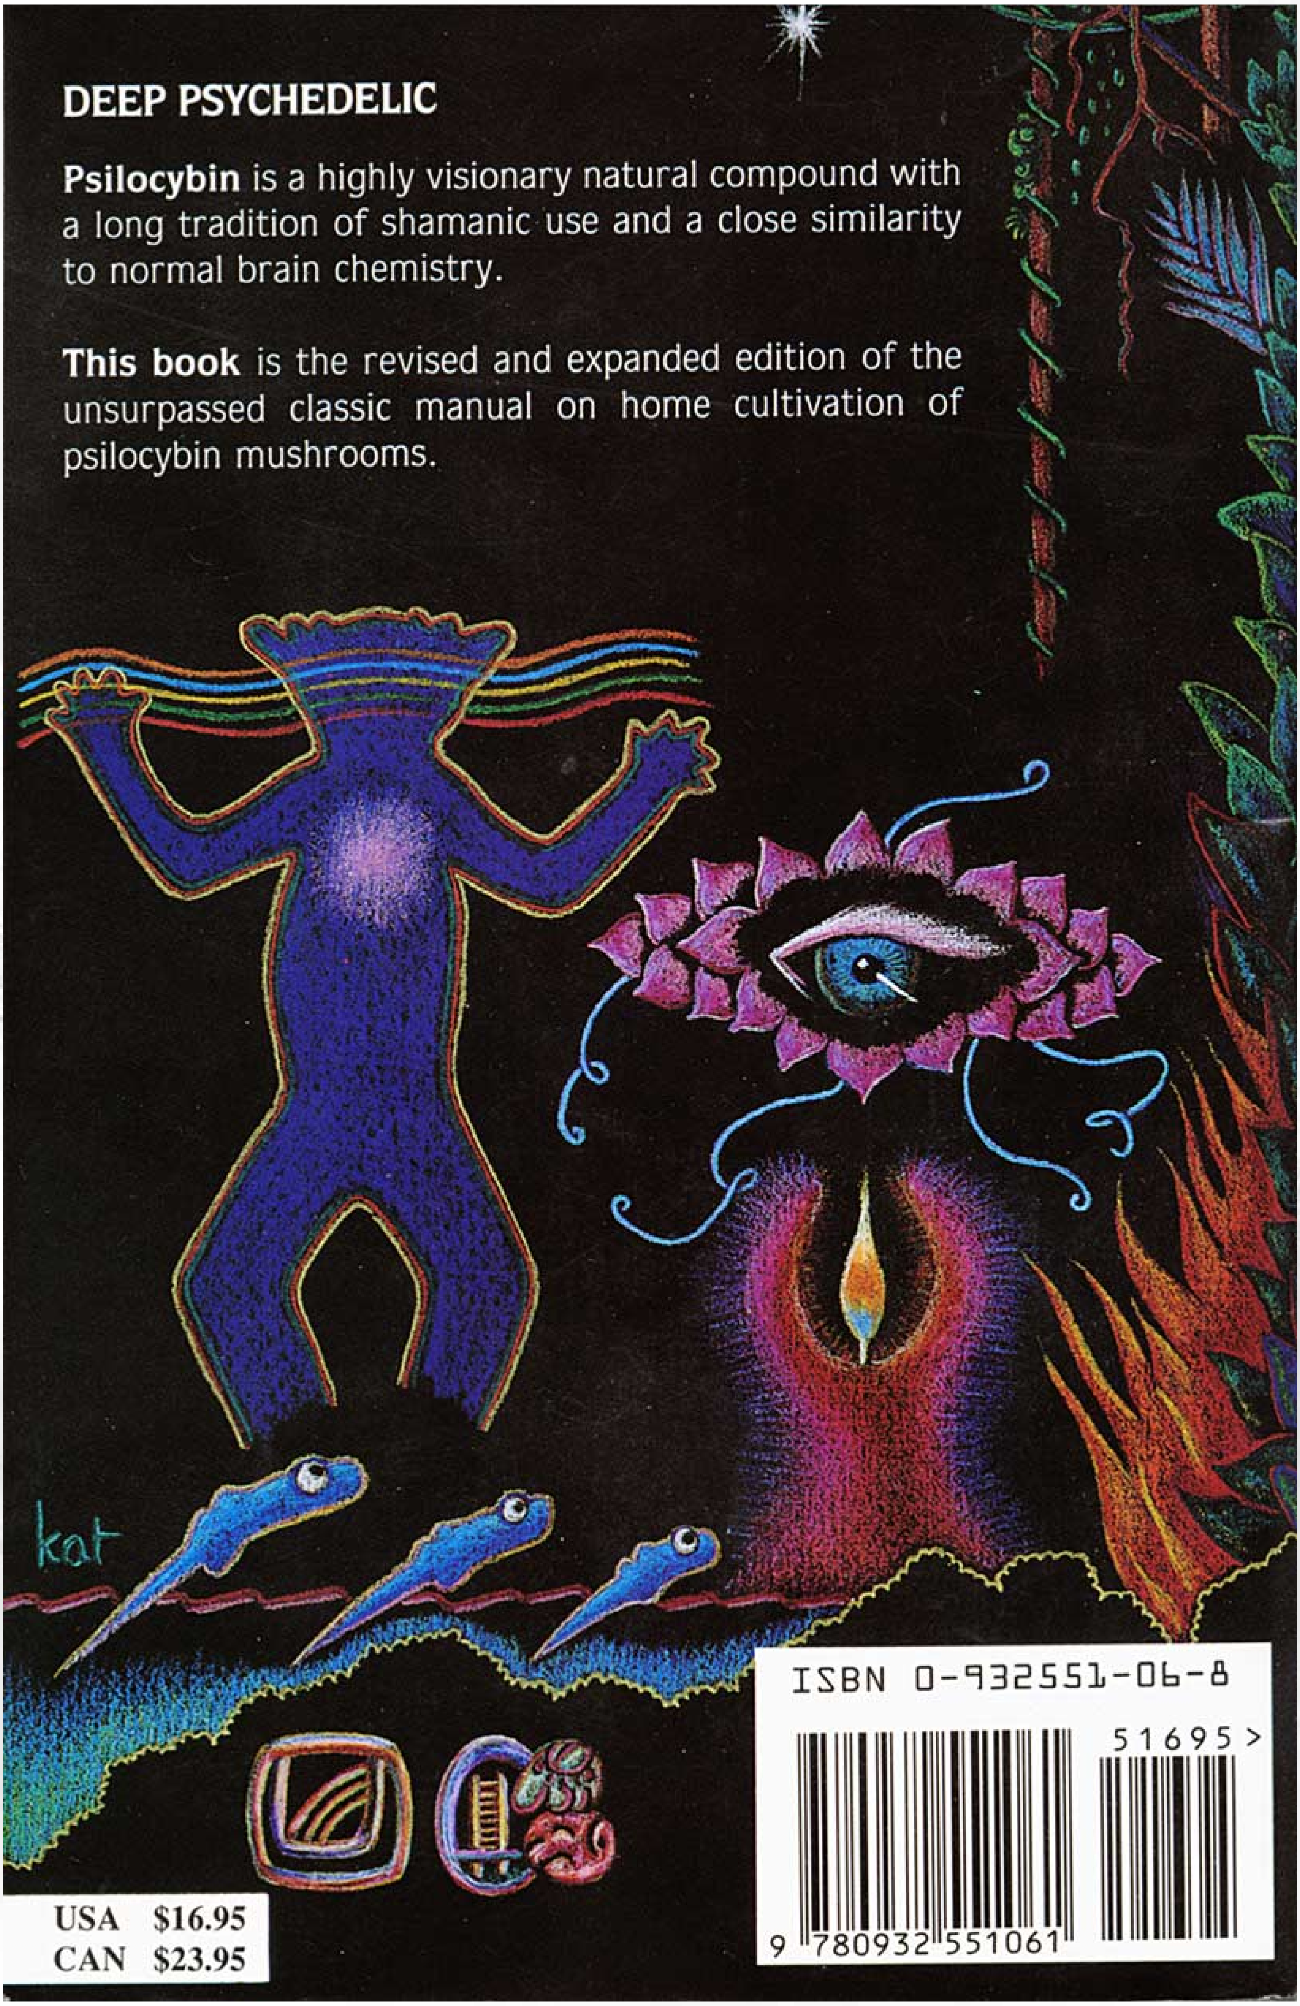
somatogamy - fusion of somatic (body) cells rather than differentiated sexual cells as in the Basidiomycetes; does not include karyogamy.

species - the major subdivision of a genus or subgenus; it is composed of related individuals that resemble each other and are able to breed among themselves but usually not with other species.

tetrapolar - condition referring to sexual compatibility of some Basidiomycetes in which two sets of factors are involved (such as A,a & B,b).

thallus (pl. thalli) - the undifferentiated body of the fungus; the mycelial mass.

veil - the *partial* veil is a covering that extends from the unopened margin of the mushroom cap to the stalk, and that ruptures to form the annulus; the *universal* veil is a tissue surrounding the entire developing mushroom, usually lost early in development. *Stropharia cubensis* has a partial and universal veil.



DEEP PSYCHEDELIC

Psilocybin is a highly visionary natural compound with a long tradition of shamanic use and a close similarity to normal brain chemistry.

This book is the revised and expanded edition of the unsurpassed classic manual on home cultivation of psilocybin mushrooms.

Grain for Simple Minds

original source: http://www.fungifun.org/English/Grain-For-Simple-Minds

These instructions will guide you through the process of preparing grain either to be used as spawn to inoculate bulk substrates or as mushroom substrate that can be directly cased.

There are 2 ways of preparing the grain, either by measuring grain and water, combining them in a jar and pressure cooking it, or first simmering the grain in order to achieve the proper water content, and then pressure cooking it. Both methods work similarly well. Try both, and see what works for you.

Presto 23-Quart Pressure Cooker/Canner

Basic rye recipe for 1 pint jar

- **100g** (**=**3.5 oz**~**125 ml**~**0.53 cup) **rye**
- **105g** (**=** 3.55 oz **=**105 ml**~**0.44 cup) **water**
- knife tip full of gypsum (optional)

For a quart jar, double the amounts.

Basic millet or birdseed recipe for 1 pint jar

- **100g** (3.5 oz~140 ml~0.59cup) **birdseed**
- **60-70g** (60-70 ml) **water**
- knife tip full of gypsum (optional)

Note: 1/4 qt(quart) = **½pt**(pint) = **1cp**(cup) = **236 ml**(milliliter) = **236cc**(cubic centimeter)
The cups, pints and quarts are in the US liquid measuring system.

The recipes above a basic guidelines. Other grains can be used as well, for instance wheat, barley, whole oats, tricale.... The exact measurements depend on the grain used, jar size and your pressure cooker.
You might find out, that a little less or more water gives you better results, thus experiment and vary the amounts a little after you have used the basic recipe, to find the optimum for your situation.
Keep notes on the amounts!

Grains

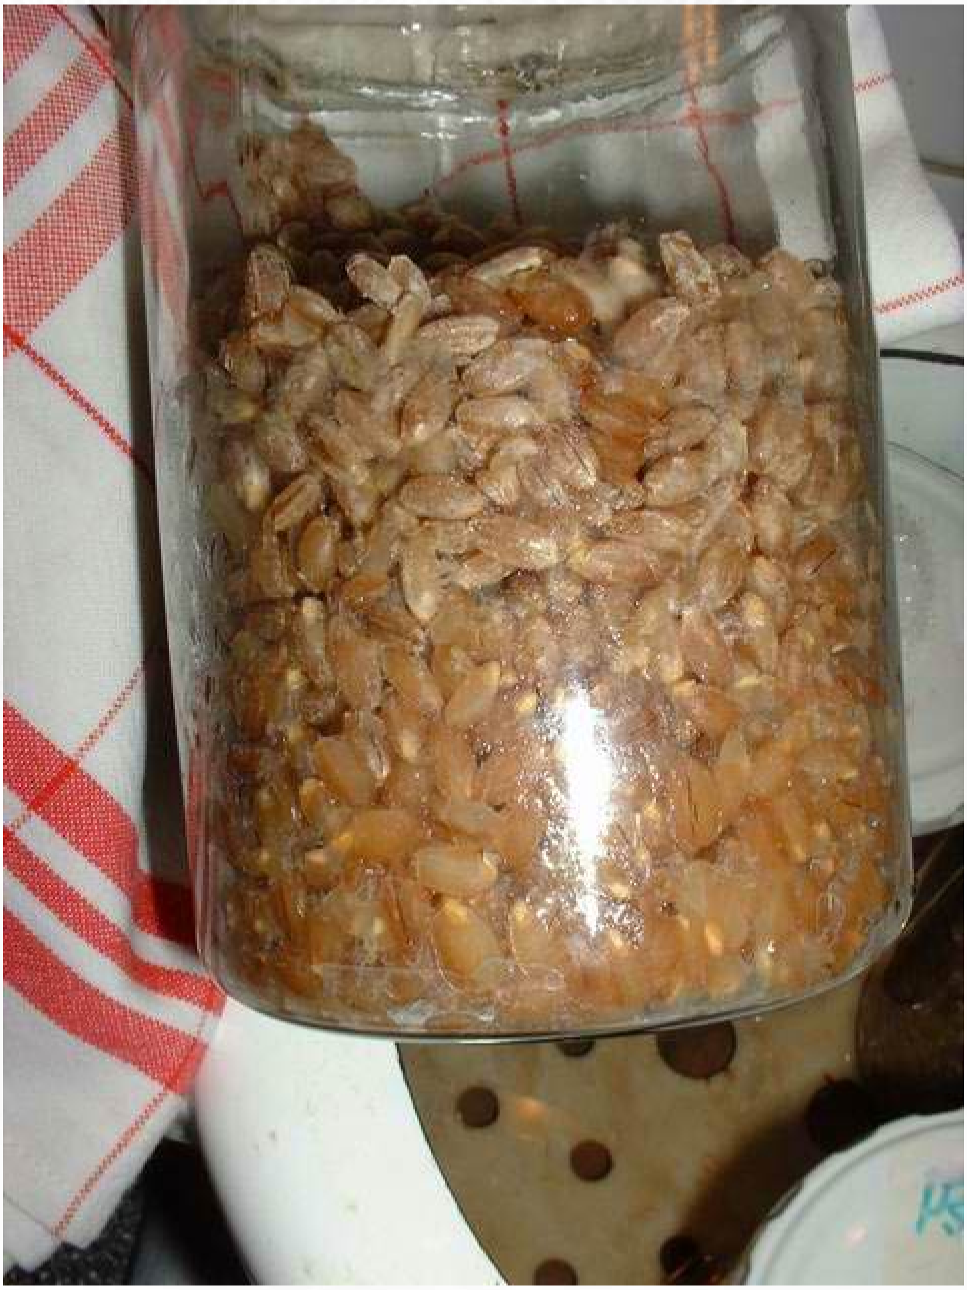
Rye

Birdseed

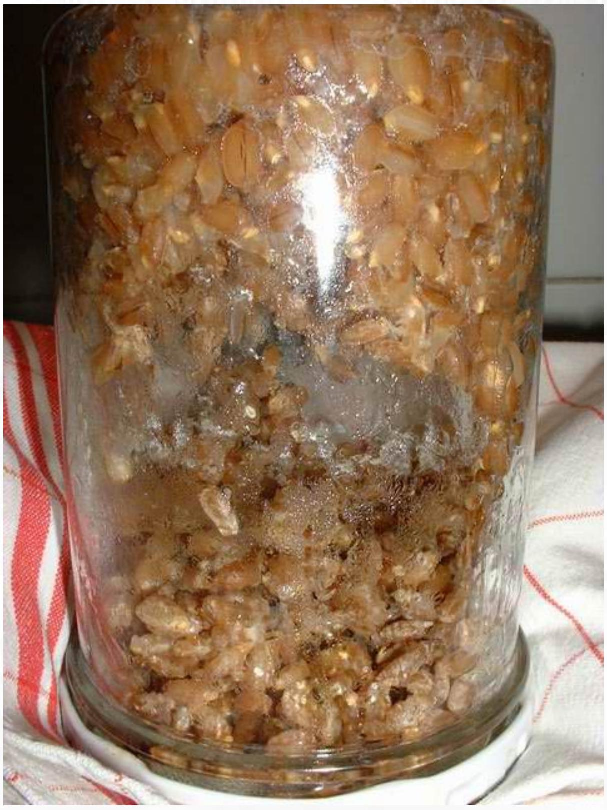
Millet

Preparation

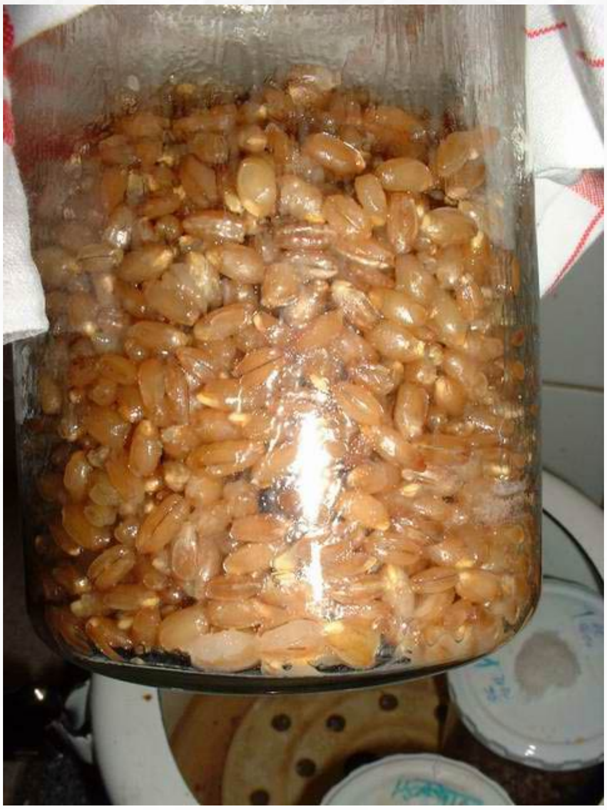
Fill both the measured amount of grain and the water into the jar, screw the lid fitted with a polyfill filter tight and pressure cook for 1 hour at 15 psi. If you don't know how to use a pressure cooker, check out this document about the correct pressure cooker use. The water absorption ability can vary depending on the grain quality and the type and the size of the pressure cooker. It's best to make a **batch of test jars** when one acquires a new grain for instance 100g rye and 100, 105, 110, 115 and 120g water. Then you'll see which water content provides the best result.



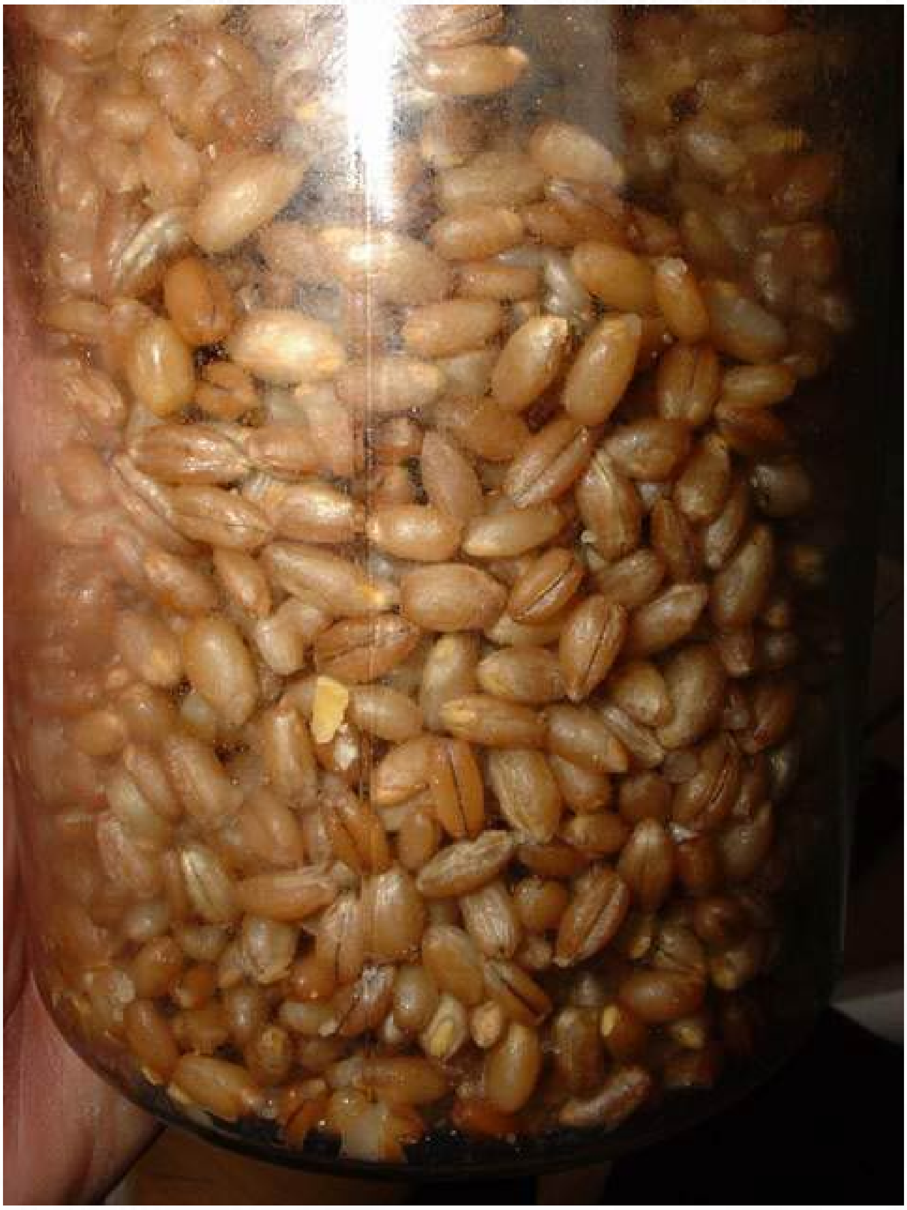
After the pressure has settled and the jars have cooled down a bit (~1 hour), take the still very hot jars out of the cooker using a towel and shake them well to mix the wetter and drier kernels.



If you turn the jar upside down, you can see the drier kernels separate from the wet kernels at the bottom.



After shaking the grains should appear wet, after a few days after inoculation they will loose this look and look more drier. Put the jars back in to the pressure cooker and let sit until completely cool. It has to be pointed out that the grain on this picture was meant to be directly cased after colonization, thus it is a bit on the wet side.



The grain used for spawn should look a bit drier, but still moist, and have less exploded kernels. The rye on this picture has been pressure cooked 48 hours ago with a rye/water ratio of 100g/100g.

Preparing grain by simmering

Alternatively you can prepare the grain by simmering in order to give it the correct water content. The procedure step by step:

1. Weigh out the amount of grain needed (~100g per pint jar).
2. Bring double the weight of water to a boil and put the grain in it. Start timing.
3. Reduce the heat so the water is barely moving. Stir the grain occasionally with a fork.
4. After ~30 minutes (for millet or birdseed) or after ~40 minutes (for rye) pour the now swollen grain through a strainer and let is drain for ~20 minutes. The exact simmer times depend on your grain, the size of the pot and other factors. For the start, follow the above times as closely as possible and then, if you see that the water content is not perfect, vary the times a bit.
5. Fill the of grain in the jars, screw the lid fitted with a polyfill filter tight and pressure cook for 1 hour at 15 psi. If you don't know how to use a pressure cooker, check out this document about the correct pressure cooker use.
6. After the pressure has settled, take the still very hot jars from the cooker (using a towel to protect your hands) and shake them well to mix the wetter and drier kernels.

Preparing rye grain by simmering - TEST RESULTS

(originally posted at the Shroomery)

I decided to test a rye grain for the water absorbing ability.

I weighed out 3 time 100 gram rye grain.

Experiments:
1. 100 g rye were dried in the oven at 140°C for 90 minutes.
2. 100 g rye were simmered in 500 ml of water for 30 minutes (rye grain put in boiling water).
3. 100 g rye were simmered in 500 ml of water for 40 minutes (rye grain put in boiling water).

Results:
1. The 100 g rye grain in the oven dried to 88 g -> 12% moisture content.
2. After 20 minutes of draining the grain weighted 190 g, nearly no exploded kernels ->(12g+90g)/190g = 54% moisture content.
3. After 20 minutes of draining the grain weighted 200 g, more exploded kernels, I'd say at the limit ->(12g+100g)/200g = 56% moisture content.

Conclusion:
Preparing grain by simmering it is a viable option. It shows that the amounts usually used when one mixes grain and water directly (100g grain and 100g-110g water) are similar (a little higher) as if one simmers the grain for around 40 minutes.

Polyfil filter lid for Simple Minds

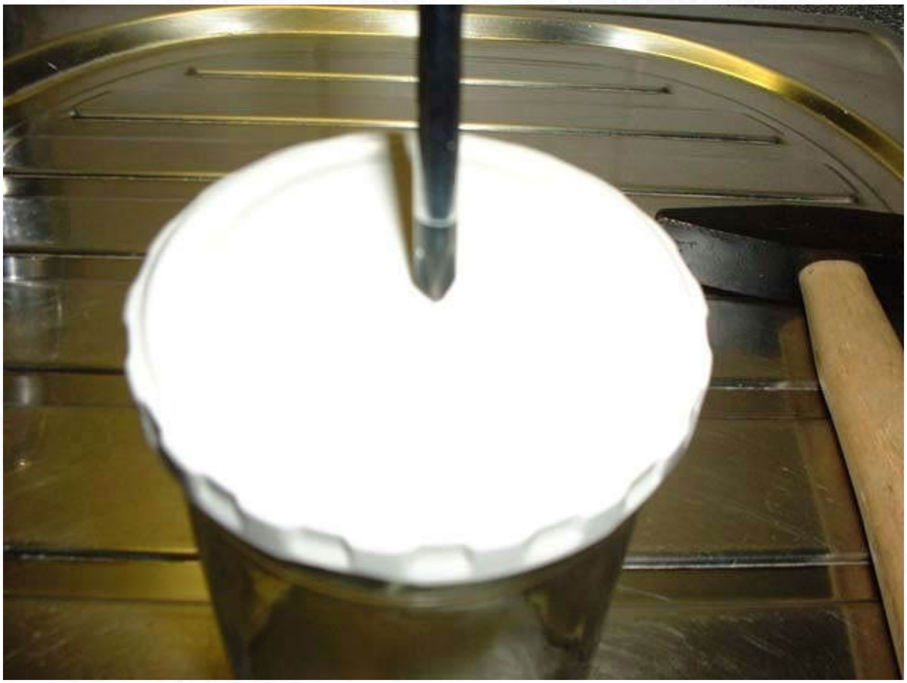
original source: http://www.fungifun.org/English/Polyfil

These instructions will guide you step by step through the process of making a very effective jar lid filter that will allow for fast colonization of shakeable substrates through better gas exchange without compromising their sterility.

Required materials:

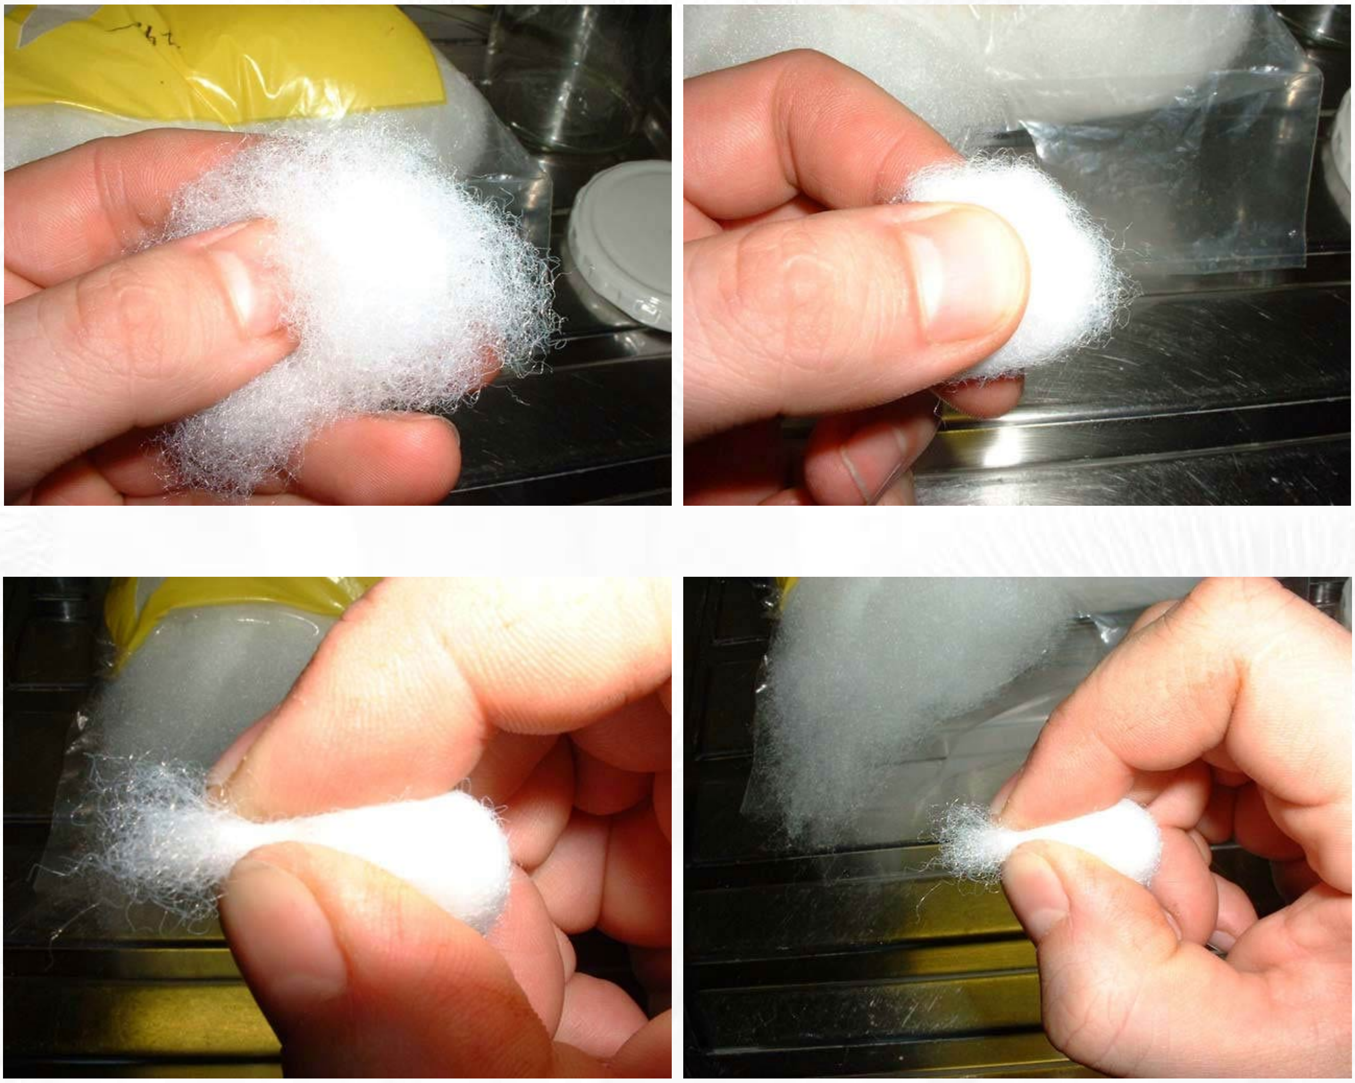
- pint or quart jar with lid
- Phillips screwdriver measuring app. 6mm (1/4in) in diameter
- hammer
- polyfil or polyester filter floss

Where can you get it? At Ebay (links above) you should easily find it.
Offline you get it at craft stores like Michaels or the craft section of Meijers or Walmart, when you ask at Walmart in arts and crafts department tell them that you are looking for pillow filling or batting.
It's also used as filter material for aquariums ("polyester filter floss"), thus aquarium and pet shops have it.

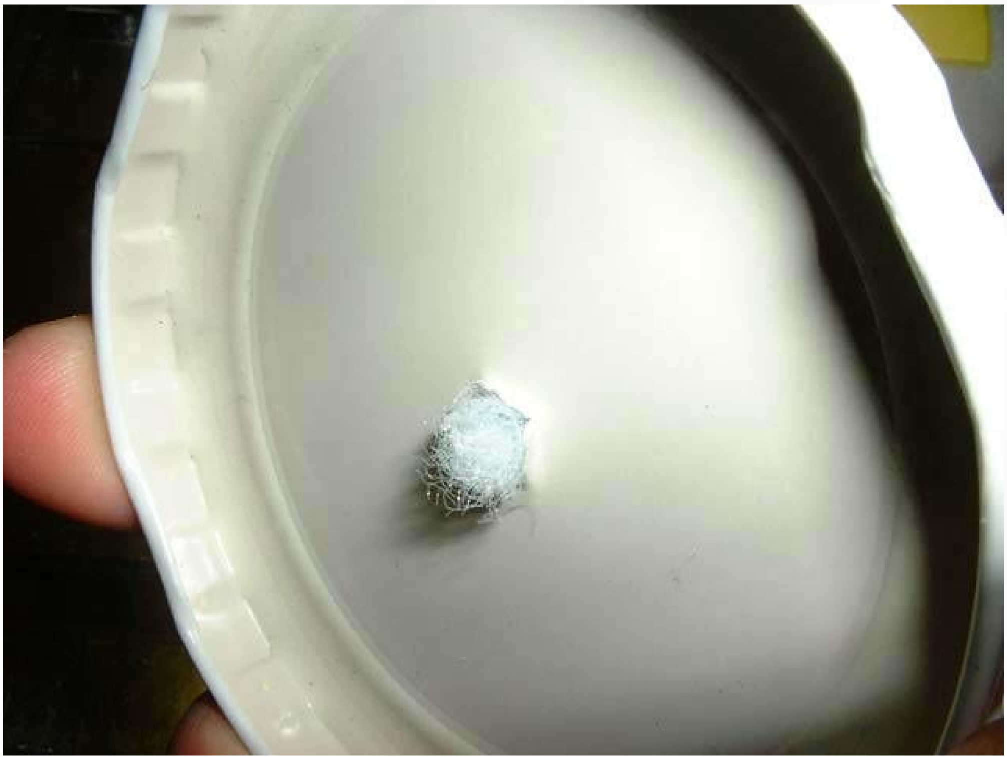


Screw the lid on the jar and punch a hole in the lid using the screwdriver and the hammer.

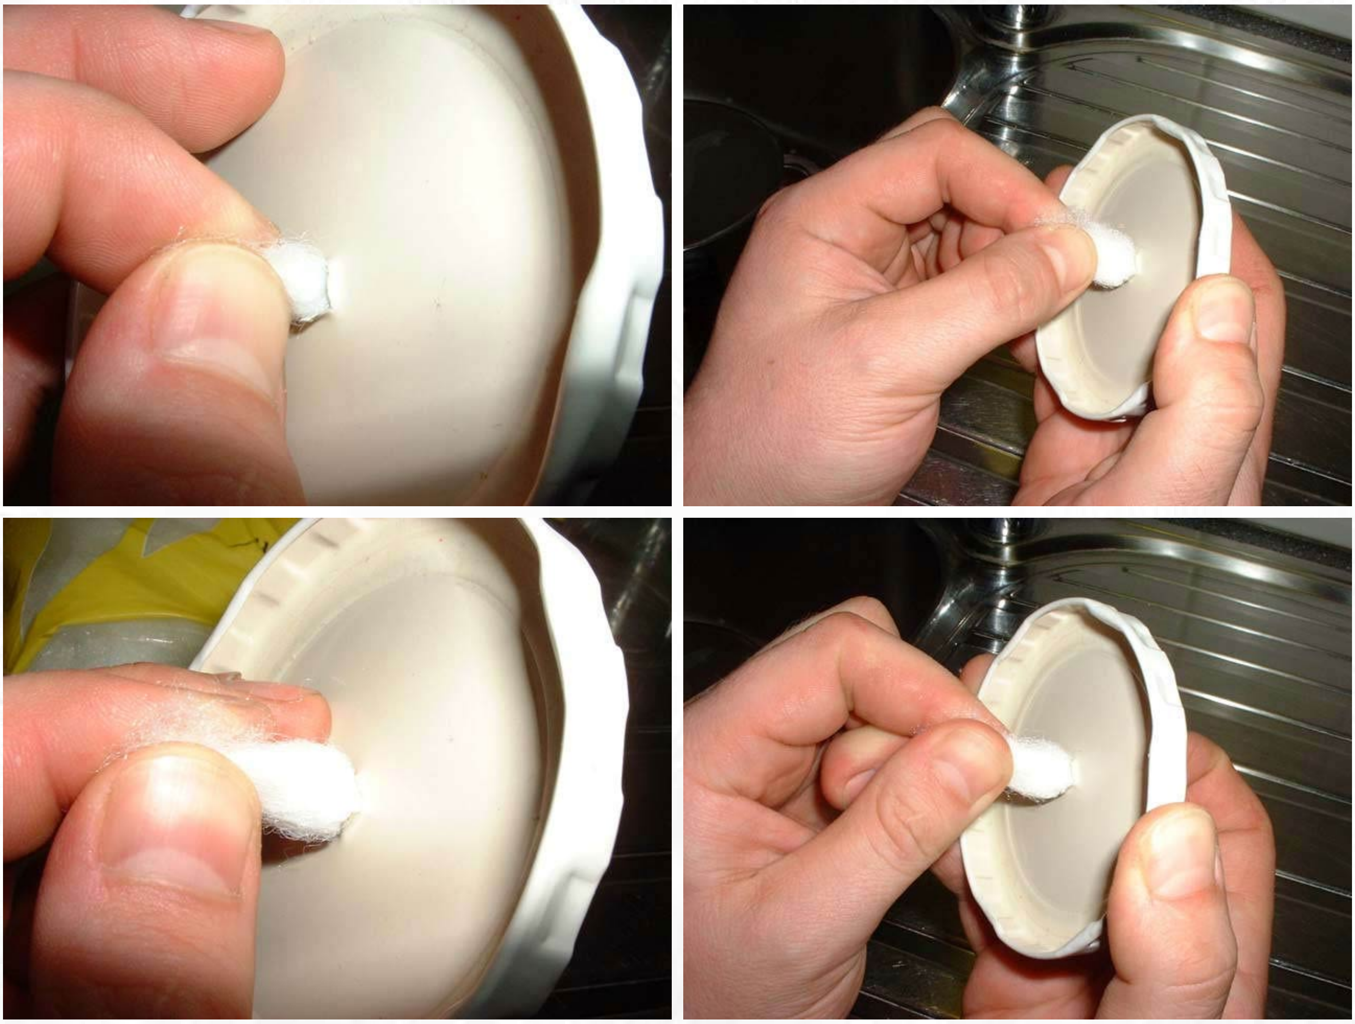
Take some floss and fold it to a small ball using both hands.

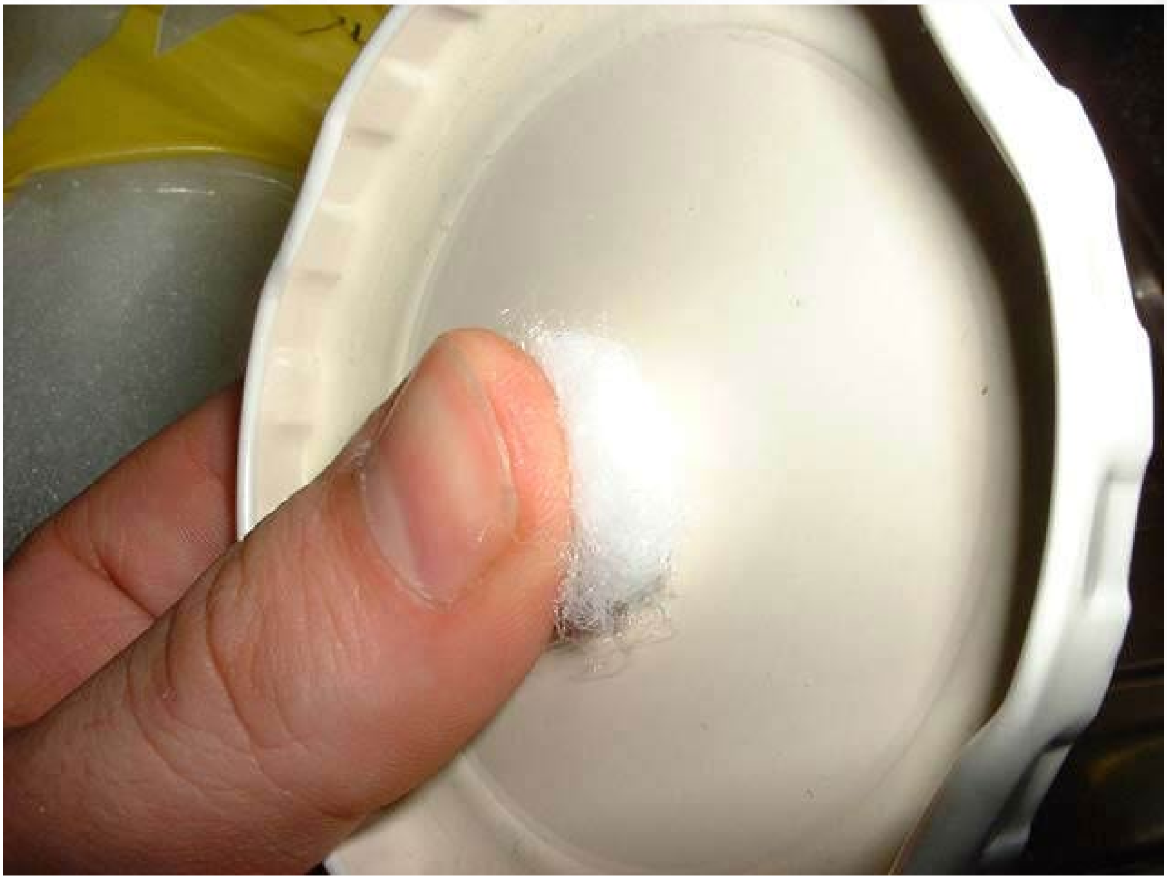


Make the ball having a tip at one end.

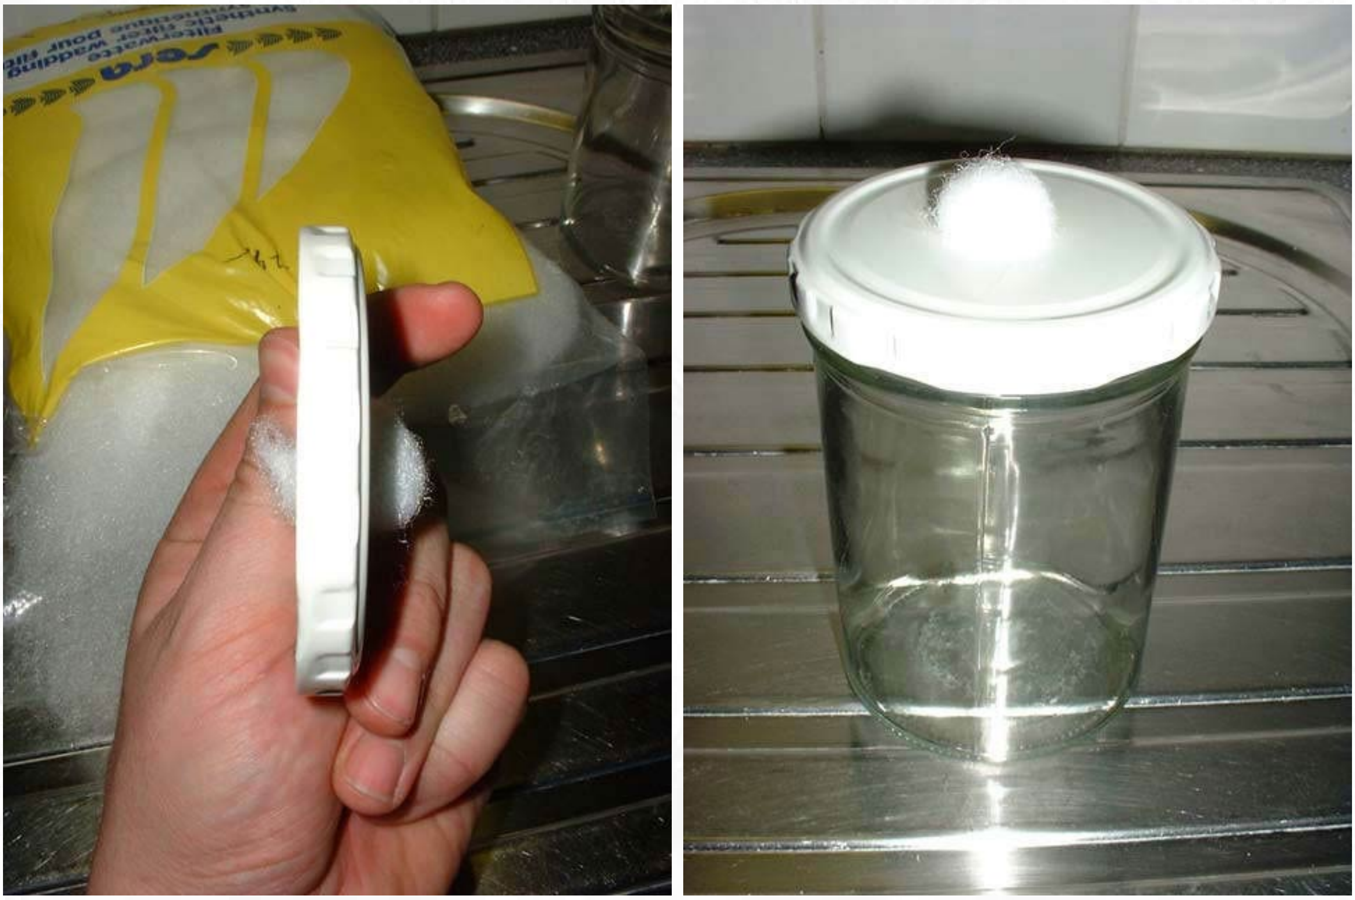


Put this end through the hole and pull it app. halfway through. It should form a relatively tight seat.
Be careful not to cut yourself on the sharp edges!





Push the floss back towards the edges. This will hold it in place.



sera
Filterwatte
synthetic filter wadding pour filtration

Ready.
You should replace the filter floss after using it 3-4 times just to make sure no substrate residuals collect on it which could support growth of contaminants.

Homemade Tyvek filter discs test

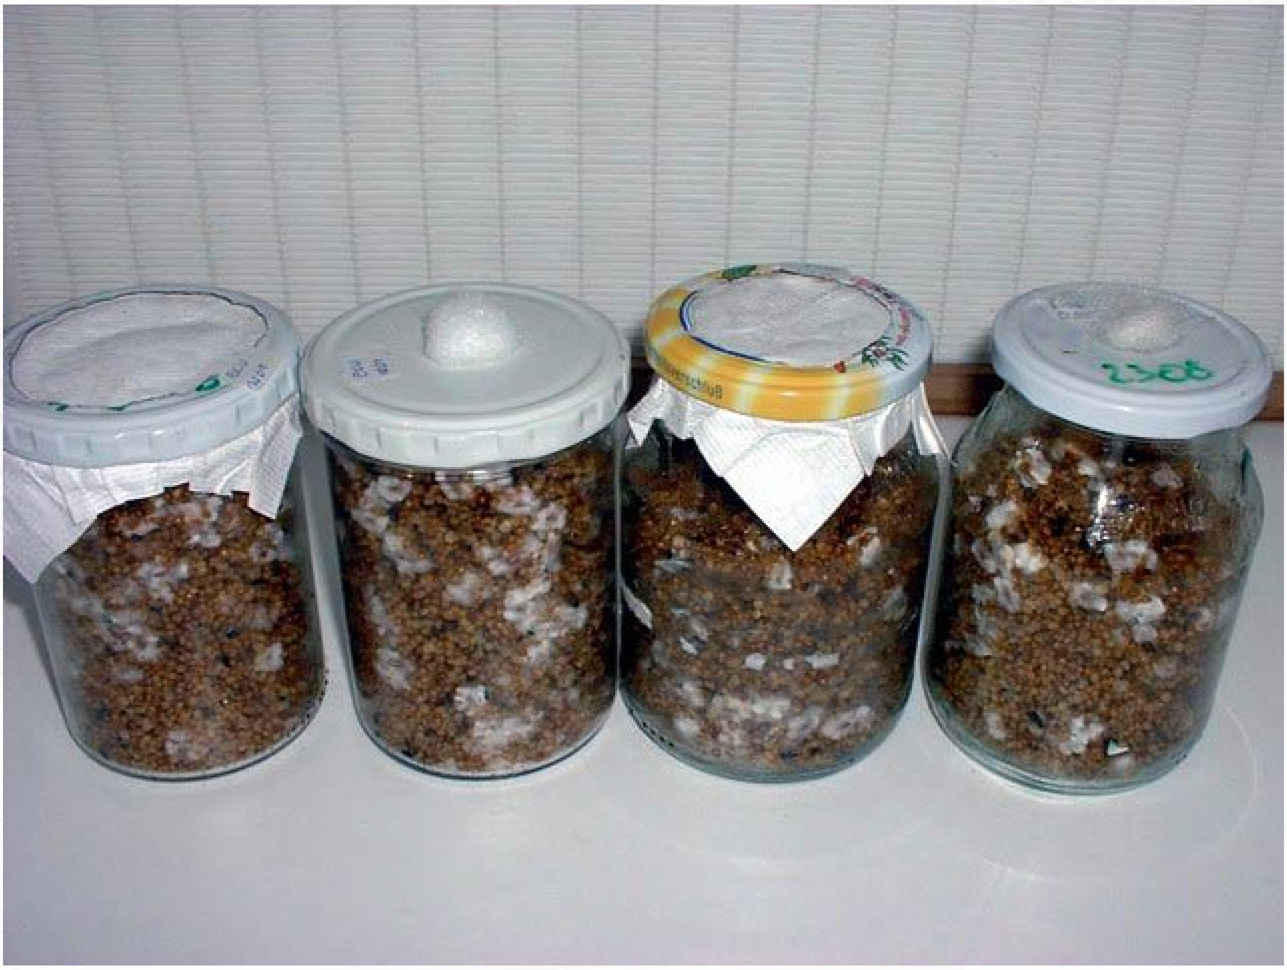
original source: http://www.fungifun.org/English/Tyvek

I conducted a test using filters made of Tyvek™ material.

I prepared 4 birdseed jars, 2 are covered with the polyfill lid like outlined in the Polyfil filter lid for Simple Minds, and 2 are covered with squares of Tyvek™ hold down by the rim of the lid. The variety of Tyvek was the thin Tyvek used in construction, "Tyvek house wrap".

I inoculated them with Ecuador rye grain spawn and incubate at 29°C.

After 2 days fresh growth was noticable both in polyfill filter jars and in Tyvek filter jars. I couldn't tell if the growth is faster in any of them.
The jars were shaken to distribute the newly colonized kernels and put back into the incubator.



After 3.5 days into colonisation the jars looked like this.

6 days after inoculation the jars were colonized.

If you look carefully you will notice, that the Tyvek filter jars have a thin layer of uncolonized, dry kernels on the top of the jar during the excessive gas exchange through the filter.

To counteract this one should make the hole in the lid smaller (about 1/2 inch in diamter) and thus only partially expose the filter surface.

No contamination problems were observed in jars with either kinds of filters.

All in all the test was a succes, proving that "Tyvek house wrap" is suitable for use as an filter in preparing of grain spawn.

Pressure Cooker Use

original source: http://www.fungifun.org/English/Pressure-Cooker-Use

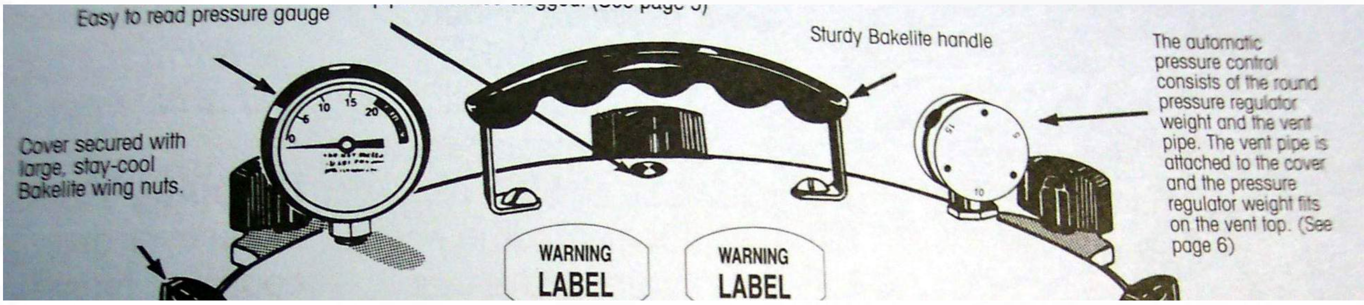
Pressure cookers and canner are important tools in mycological work. When used properly they guarantee the preparation of thoroughly sterilized mushroom growing substrates and tools.
In a pressure cooker the water reaches a higher temperature before boiling, and this higher temperature kills unwanted organisms more effectively and faster than normal cooking.

This document should give some answers on the correct use of pressure cookers.

Pressure cooker types

There are different ways of how a pressure cooker indicates and controls the operating pressure.

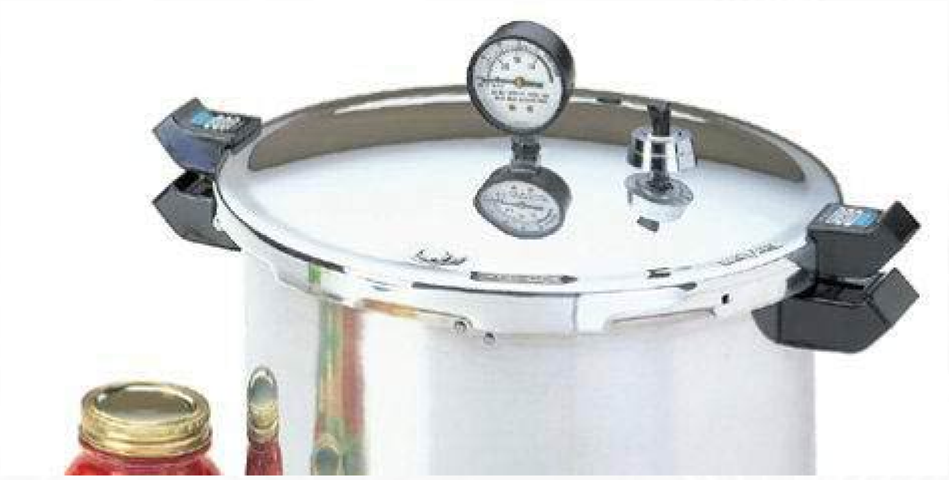
Pressure gauge + pressure regulator weight (All American Pressure Canner)



Easy to read pressure gauge
Sturdy Bakelite handle
The automatic pressure control consists of the round pressure regulator weight and the vent pipe. The vent pipe is attached to the cover and the pressure regulator weight fits on the vent top. (See page 6)
Cover secured with large, stay-cool Bakelite wing nuts.
5
10
15
20
WARNING LABEL
WARNING LABEL

The pressure regulator weight lets you select one of three pressure settings: 5, 10 and 15 PSI. You should select 15 PSI for mycological work. When the pressure cooker reaches the proper temperature, the pressure regulator weight will jiggle audibly, and you can see the steam being released. Additionally the pressure gauge will show that the pressure has been reached. It is normal that the pressure gauge shows 1-2 PSI less than what you selected on the pressure regulator weight. To maintain the proper temperature adjust heat lower to maintain a slow, steady rocking motion.

Pressure gauge + rocker (Presto Pressure Canner)



When the pressure cooker reaches the proper temperature, the rocker will jiggle audibly, and you can see the steam being released. Adjust heat lower to maintain a slow, steady rocking motion.

Rocker (Presto, Mirro, Hawkins....)

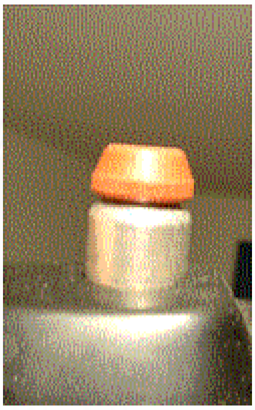
This is essentially the same as the above, just that they don't have a pressure gauge. When the pressure cooker reaches the proper temperature, the rocker will jiggle audibly, and you can see the steam being released. Adjust heat lower to maintain a slow, steady rocking motion.
To see if your pressure cooker reaches the desired temperature, you can do a pressure cooker test.

Spring system (T-Fal...)

Many new pressure cookers utilize a spring system.
A pin held by a spring is being forced out of the pressure cooker by the building pressure. The more the pin

comes out, the higher the pressure in the PC. After a certain point is reached steam is released with a hissing sound.
The operating point of those types of pressure cookers should be just before the steam is starting to get released, this means once you see the steam being released, you turn the heat down a bit.

In some types you can see the pin coming out:



(Gif animation not available in PDF version.)

WMF
PERFECT
PLUS
Made in Germany

In some types you don't:

In each case, the working point of those types of pressure cookers should be just before the steam is starting to get released.

Rack or trivet

Most pressure cookers come with a rack or trivet. Racks are made of aluminum of stainless steel. A rack keeps the jars from direct contact with the bottom of the pressure cooker. Some types of jars tend to crack if they are not on a rack.

More on racks at All About Pressure Cooker Racks and Trivets.

Pressure cooking step by step

1. Put 1 inch of cold water in the PC. Some pressure cooker manuals will tell you to use more water. You need to use as much water, that by the end of the pressure cooking there is still some water left at the bottom of the pressure cooker. If you are unsure, you can test drive the pressure cooker without jars first to see the 1 inch of water will fulfill this requirement or not. **Never let the pressure cooker run dry!** Place filled jars on the rack. Fasten PC lid securely.
2. Leave weight off vent port or open petcock. Turn the heat on at a setting from $^{2}/_{3}$ to the highest setting until steam flows from the petcock or vent port. You don't want the pressure cooker heat up too fast, since this can cause certain types of jars to break. Adjust the heat so that it takes around 15 minutes for the steam to begin to come out of the vent. The bigger the pressure cooker, and the more filled it is, the higher setting you can use.
3. Exhaust steam for 1 minute and then place weight on vent port or close petcock. The PC will pressurize during the next 5 to 15 minutes, depending on the size of the PC. (the bigger the PC, and the more jars are in it, the longer it will take).
4. Start timing the process, depending on the pressure cooker type
   - when the pressure reading on the dial gauge indicates that the recommended pressure has been reached **or**
   - when the weighted gauge begins to jiggle/rock **or**
   - when the valve comes up to the of second or third (last) ring **or**
   - when the steam is starting to get released from the pressure setting dial.
5. Adjust heat lower to maintain a slow, steady rocking motion, or the pressure indicator staying at the proper ring, or there is no steam coming from the pressure setting dial, depending on the pressure cooker type.
6. When timed processing is completed, turn off the heat, remove the PC from heat (if electric range), and let the PC de-pressurize at room temperature. (dial needle moves back to "0" or no steam escapes when weight is gently nudged). Do not force-cool the PC under water or force the steam out! The depressurazation can take anywhere from 5-20 minutes, depending on the size of the pressure cooker and the amounts of the jars in it.
7. After the PC is depressurized, remove the weight from the vent port or open the petcock.

If you are preparing whole grains (rye, millet, birdseed...), you will now want to wait around 30 minutes and then take the hot jars out and shake them to distribute the wetter and drier kernels.
If you are preparing PF jars it's best to leave them cool down in the pressure cooker over night.

Pressure cooker test

original source: http://www.fungifun.org/English/Pressure-Cooker-Test

A simple test to test if your pressure cooker is working properly:

Let a drop of water drop on the pressure cooker while sterilizing.
If the drop boils like underneath, the temperature is around 250°F (121°C) and the pressure cooker is working properly.

(Gif animation not available in PDF version.)

Why does this happen?

A pressure cooker operating under pressure is very hot, it is quite much hotter than the boiling point of water at 1 atmosphere (212°F=100°C). If the pressure cooker is of the "standard" kind, it will be at 250°F = 121°C.

If you put a small amount of water, a drop, on the surface of the lid of the pressure cooker while the pressure cooker is hot and under pressure, the drop of water will begin to boil vigorously and will evaporate in 2-3 seconds, since the surface of the pressure cooker is so much hotter than the boiling point of water at the atmospheric pressure.

If the pressure cooker doesn't work properly, i.e. if the pressure doesn't build up as it should, the pressure cooker temperature will be the same or only slightly above as the boiling point of water at atmospheric pressure. If you were to drop a drop of water on such a cooker, the drop would only sit there and slowly evaporate over the course of a longer time span.

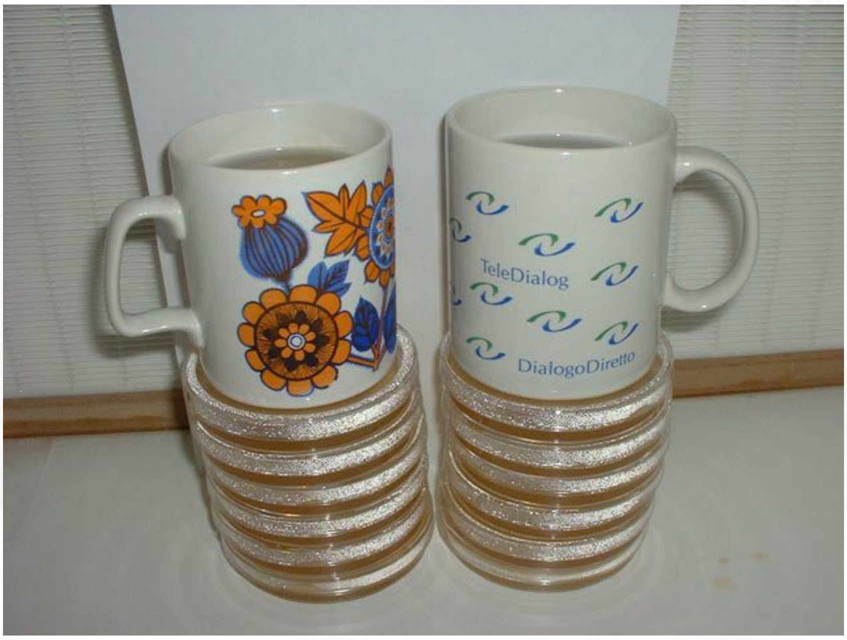
Pouring Agar for Simple Minds

original source: http://www.fungifun.org/English/Agar

These instructions will guide you through the process of pouring agar without having heavy condensation on the Petri dishes.

I stack the Petris in 5 or 6-piece stacks in front of the hood. Then I prepare some cups and boiling water.
I let the agar cool down to around 35°C, just before it solidifies. Then I pour the agar in the dishes, and immediately after a stack is finished I put a cup with the hot water on top of it.

What does this do? Water vapor condensates at cold surfaces. Now, when you stack the dishes, the top of each dish is kept warm by the bottom of the previous dish. Except the top one! Through the cold top one there is a temperature gradient and the top and to some extent also the dishes underneath get some condensation.



When you put a cup of hot water on the top dish, it prevents this condensation by heating the lid.
You will also notice I put a sheet of paper in front of the hood, so the dishes don't cool too fast from the side, which again contributes to less condensation.

I seal agar plates with a Glad Clingwrap, where I cut a small piece off the roll with a very sharp knife.
You can use any wrap, as long it's made from polyethylene. There are differences between brands though, some will work better than others.
Saran wrap is NOT suitable, since it's not made from polyethylene and is not gas permeable.
Sealing dishes prevents contaminants coming into the dish for whatever reasons, ads for easy handling since the both dish parts would otherwise come apart and allows gas exchange, since the polyethylene wrap is gas permeable.

Importance of Gas Exchange

original source: http://www.fungifun.org/English/Importance-Of-Gas-Exchange

When mushrooms digest a substrate, they produce carbon dioxide (CO_2), and consume oxygen (O_2).
This is a fairly important factor determining success or demise of a growth attempt.

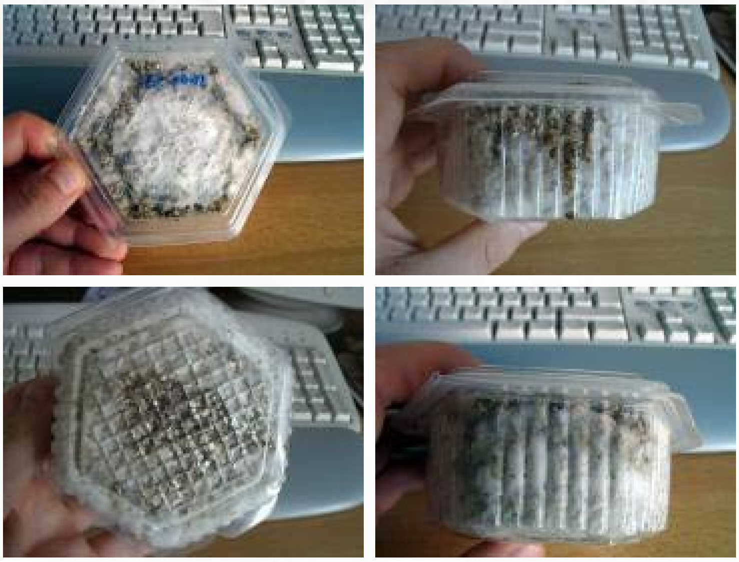
I prepared a few plastic containers with $^1/_2$ pint content with my standard substrate I use for PF tek jars. The plastic containers have a lid, that completely seals the container, so there is no gas exchange.

When I use the same substrate in jars with an aluminum foil lid, like described in the PF-Tek for Simple Minds I get full colonization in 8-12 days.

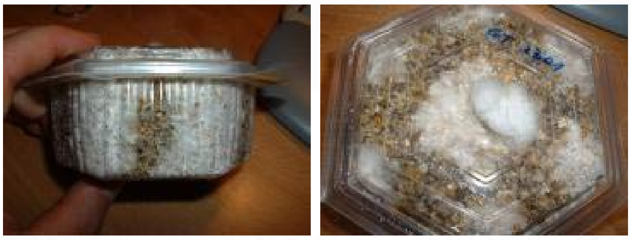
The spores germinated after 2 days and the colonization went fairly fast for another 3 days, then it suddenly stopped.

I left it then another week, and the colonization barely moved on.
Then I opened the container in front of a flow hood for a few seconds to provide some air.
The colonization again started, and again halted after a few days....
I repeated this another 2 times, and after 1 month into colonization, the substrate is still not completely colonized.
You can see at the pictures how the mycelium has a different appearance in some areas and it shows the different growth and stall phases.

The inoculation was at the sides and one inoculation point at the top of substrate. There is no vermiculite seal, but a thin vermiculite bottom layer.



TEST II :
This time I took the same plastic containers, but fitted them with a polyfill filter.
This is day 6 of colonization, look what a difference the air exchange makes!



One has to love polyfill!

Day 8:

I hereby declare this cake colonized.

FAQ

Why couldn't I put a few heat loving plants in my incubator at night to help with the exchange?
Plants convert CO_2 and water into oxygen and sugars....when they have light. This process is called photosynthesis.
The incubator shouldn't have light. So this woudn't really work well.
Plants need some oxygen for themselves too, btw.
Read
http://www.mcps.k12.md.us/departments/eventscience/EBS.OS1_RS~DF.html
http://www.hsv.k12.al.us/schools/middle/wtms/student/cell/cell_energy.html
http://www.saburchill.com/chapters/summary02.html

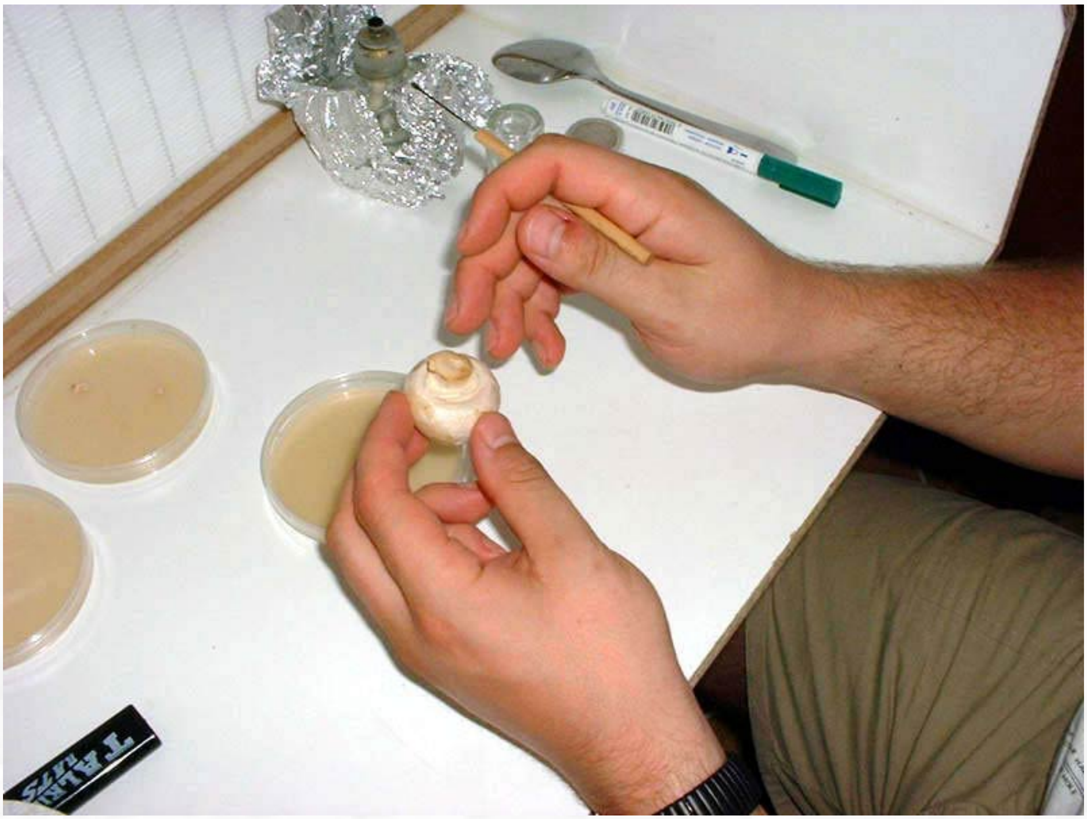
Besides, the point is not that the oxygen isn't available, it is there, in the normal air, to more than 20%, the problem is that it has to get to the mycelium, and it can't get there, if the jar is sealed.

I've found that the most tightly closed casings during regrow, turned out the best.
In the post casing - pre pinning phase the CO_2 levels should be high. This is best achieved by simply covering the casing container with aluminum foil or similar.
It will get some air exchange (same as the jars with the aluminum foil lid), but the CO_2 level will be high. That's what you want to achieve.

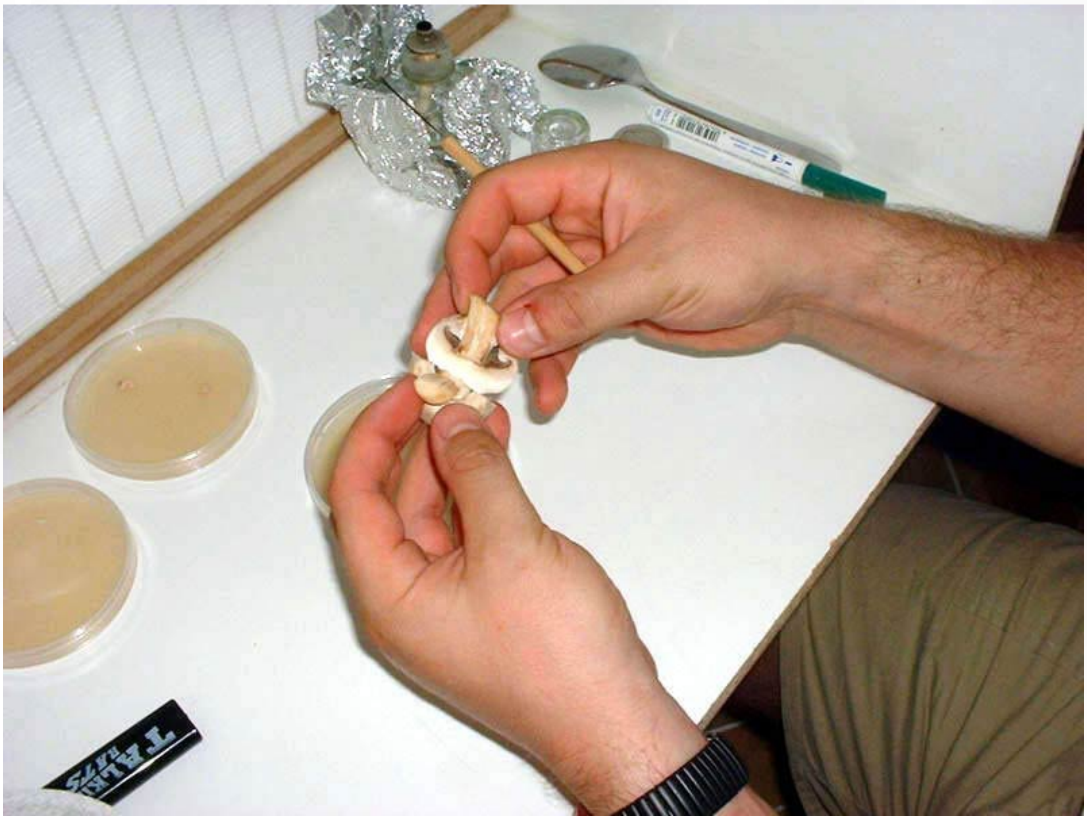
Cloning for Simple Minds

original source: http://www.fungifun.org/English/Cloning

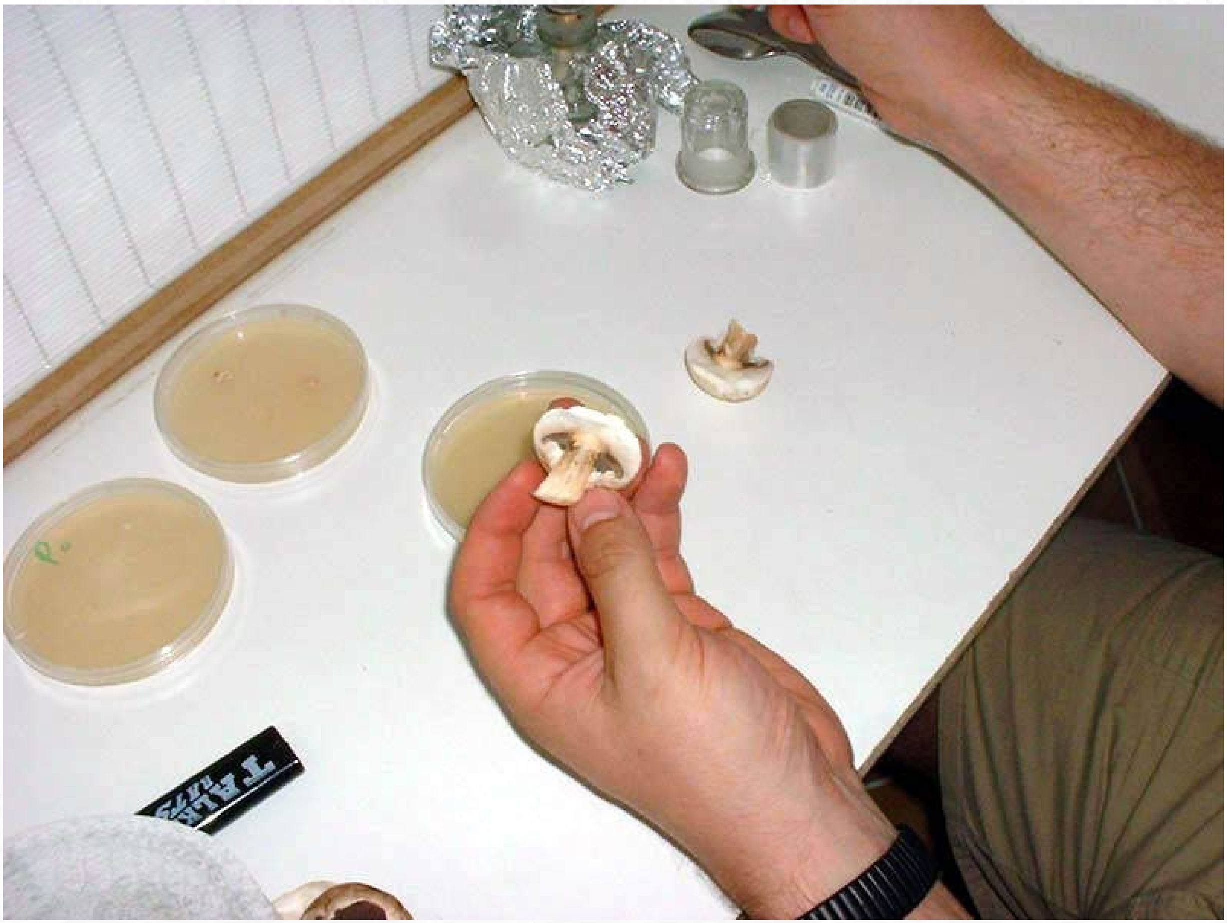
These instructions will guide you through the process of cloning a mushroom on agar.



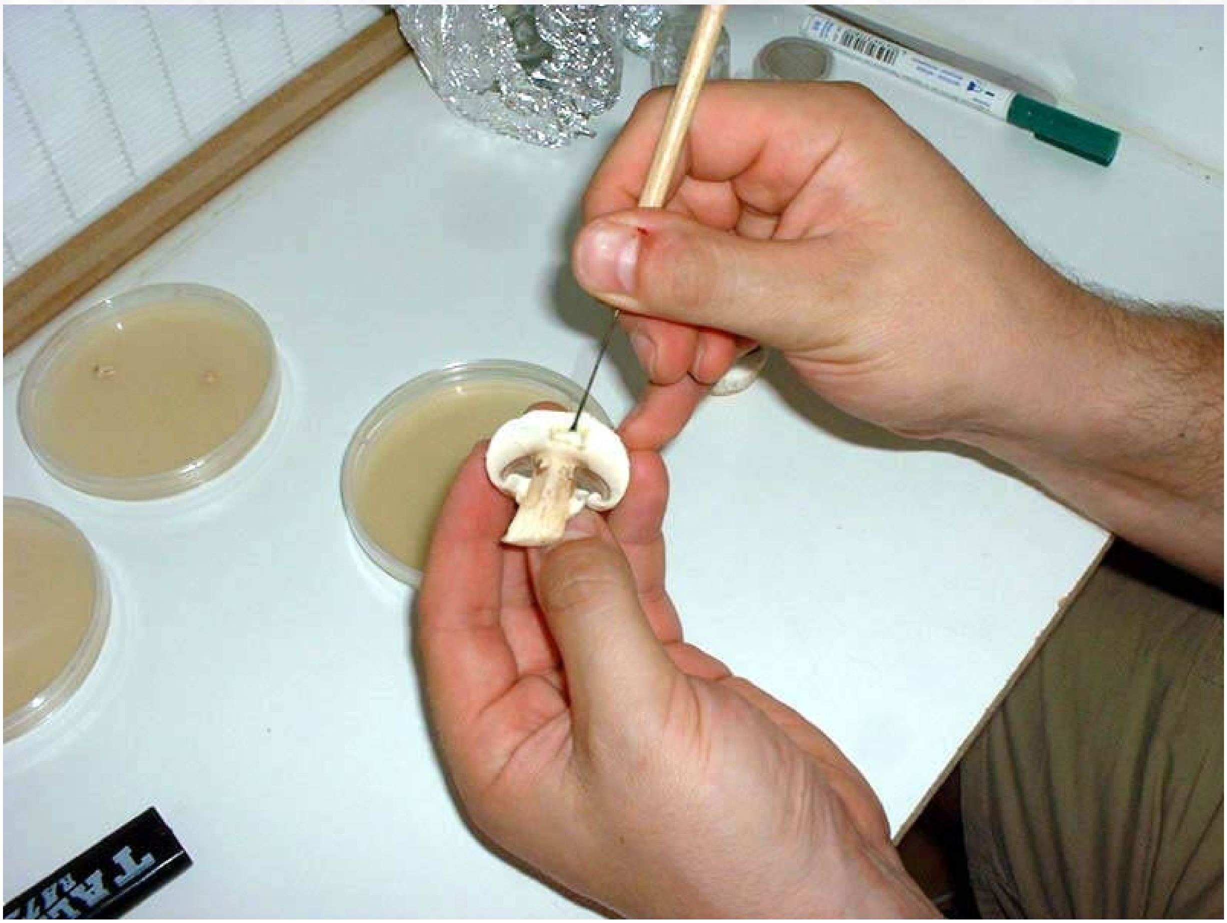
Take a nice, healthy mushroom.



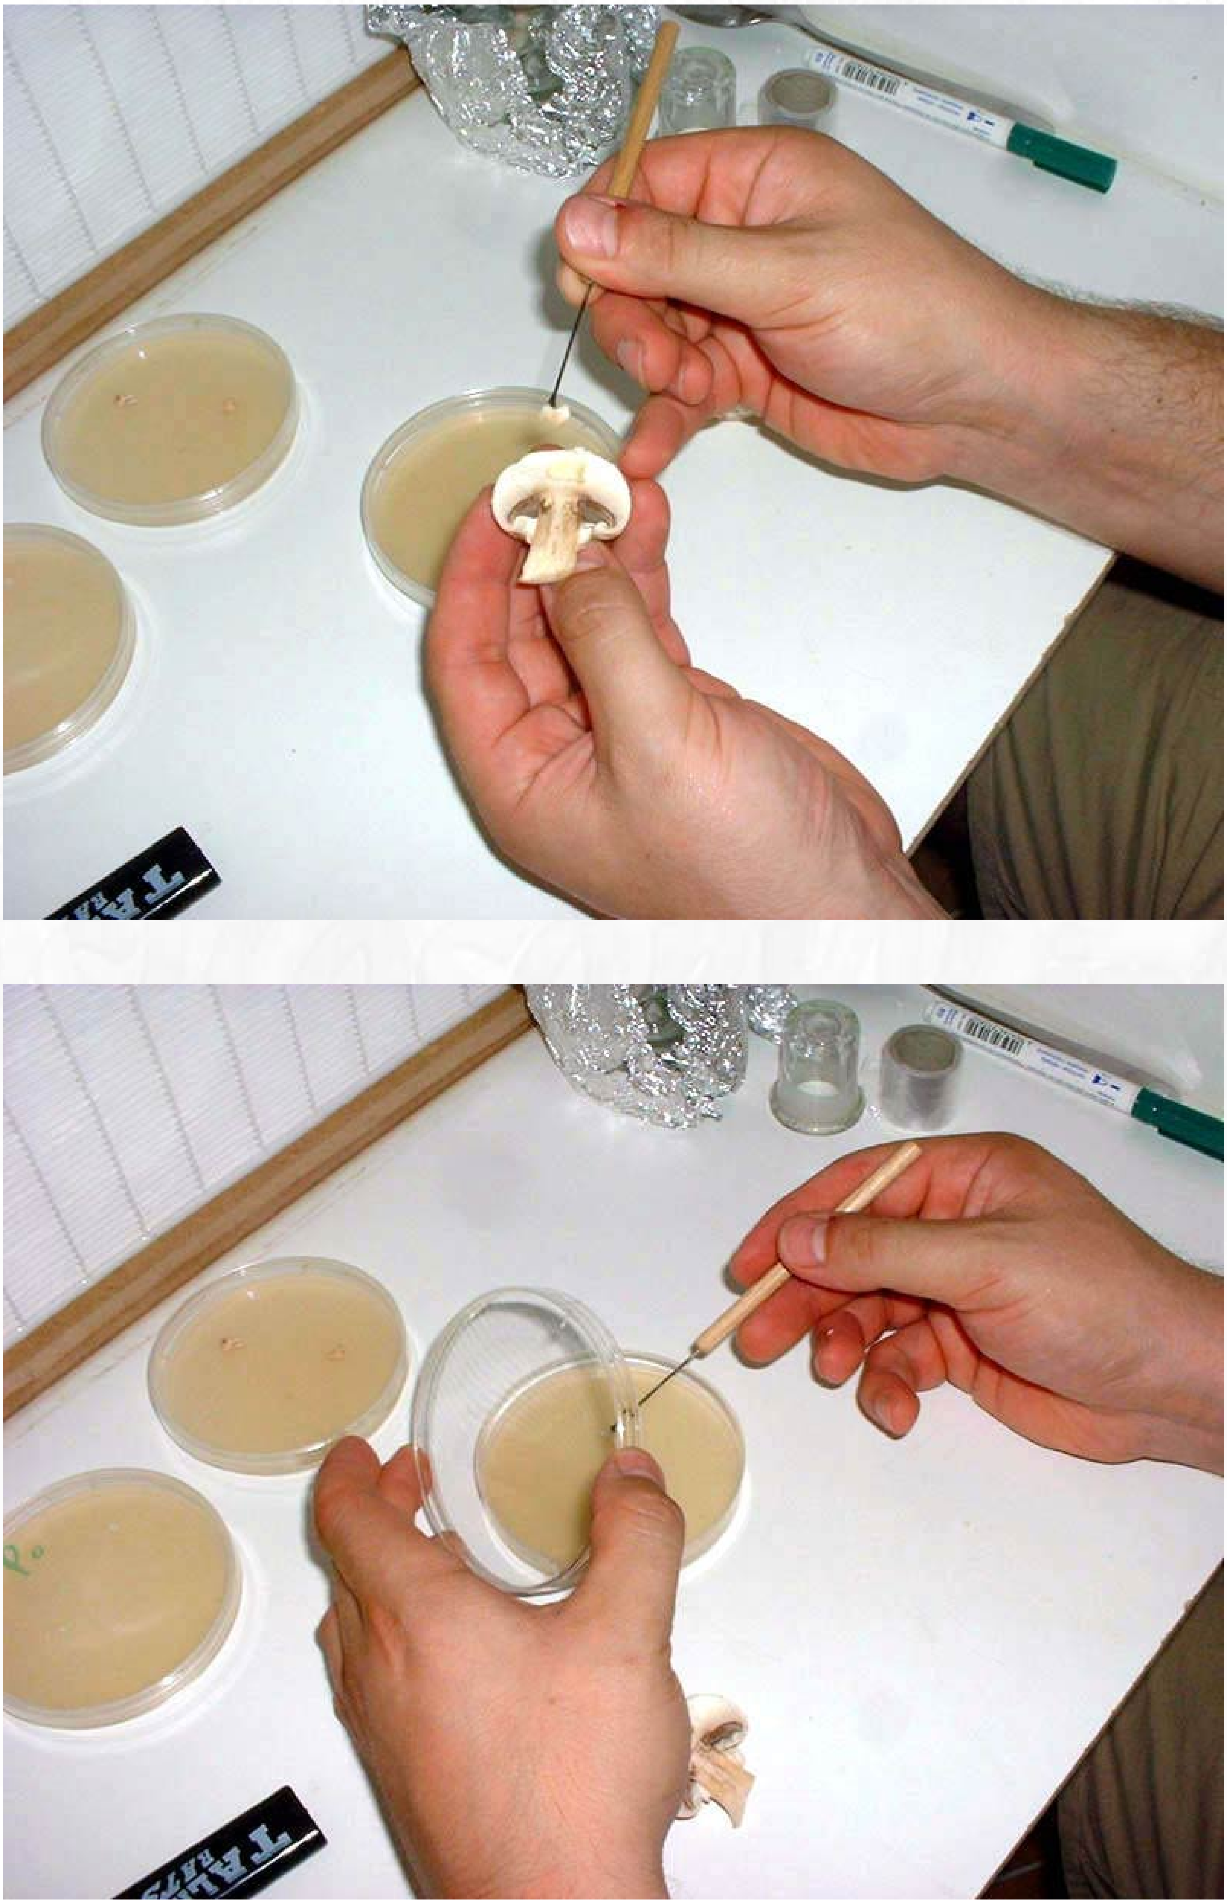
Tear the mushroom apart in the middle lenghtwise.



Flame the scalpell untill glowing red.
Let cool for a few seconds.



Cut a small chunk from the cap base, measuring around 2 x 2 x 2 mm.



Transfer to agar.

Mycelium Inoculation Technique

original source: http://www.fungifun.org/English/Mycelium

This is a significant add-on of the PF-Tek which enables you to grow virtually hundreds of PF-cakes with only one spore syringe! Also the primordia will appear in as little as 16 days after inoculation! The key is first to colonize a sterilized rye jar and then use this mycelium to make a mycelium syringe.

For the first part I basically use the The Foolproof Psilocybe cubensis Mycelial Culture Technique.

I use 100 g (3,2 ounces) rye + 105 g water + a knife tip of gypsum (optional) in a 450 ml (1 pint) jar.
For more detail on grain preparation read Grain for Simple Minds.

There is way to prevent airborne contamination entering the jars. Take a clean plastic bag and spray the inner side with Lysol or alcohol. Rub it from outside so the Lysol is evenly dispersed on the inner surface of the bag. When the sterilization time is over, wait a few minutes for the pressure to build down to ambient. Then take a clean, folded cloth or thick gloves, open the cooker and transfer the (careful, burning hot!) jars to the bag (shake the rye jars at this stage to distribute the dryer and wetter kernels!).

Roll the rest of the bag together, so you get it pretty airtight.
As the hot air in the jars is cooling down and its volume decreases, fresh (contaminated!) air from outside is drawn in. This setup will accomplish that the contaminants from the air set down on the wet bag surface and don't come into the jars!

The sterilization time should be 1 hour to assure complete sterilization. You should shake the rye jars immediately after spore inoculation and than once after 3-4 days and optionally again after 8 days. The optimum room temperature for incubation is about 27°C (80°F).

Now comes the best part!
After the rye jars are completely colonized you will need:

- At least one empty plastic syringe with needle, 10ml or more
- A small (app. 200 ml) jar with a screw lid (I take one from a spaghetti sauce)
- Tin foil
- Alcohol lamp
- A tea spoon

Punch a hole with a small nail into the middle of the lid. It has to be big enough for the needle of the syringe fits through. Fill the jar with app. twice the amount of water you will need to fill the syringes. (for instance when you have three syringes with each 10 ml to fill, use app. 60 ml water). Screw the lid on and cover with a double layer of tin foil, sterilize in a pressure cooker for 30 minutes and then handle according to the above tips.

After the water jar has cooled down to room temperature prepare everything for the transfer of the colonized rye to the water filled jar.
Wash your hands, clean the working surface, take the colonized rye jar, loosen the lid of the water jar, but don't take it off yet. Sterilize the already washed and Lysol-sprayed spoon over the flame of the alcohol lamp. I use to cool the hot spoon by dipping it in a small glass of alcohol, but you can also wait a few moments the spoon cools down. Then open the rye jar, the water jar and transfer 2 spoon full of colonized rye to the water jar. This should obviously best be done under sterile conditions (in front of a HEPA filter or in a glove box), but if you work fast and in a draft free room you should accomplish this without contaminating the whole jar. Replace the lids back and screw them tight. The rye jar can be kept in a fridge at least three months and be used over and over again.

Take the water jar, put a finger on the tin foil where the hole is and shake it vigorously at least 3 minutes until you see many tiny mycelium pieces swimming in the water. Take a clean, sterilized syringe, sterilize the tip of the needle over the flame and pull (holding the needle still in the flame) the plunger back 4 millimeters ($^1/_5$ inch). This will give you a little air bubble so later on you can shake the mycelium water prior to inoculation of the PF jars.

Remove the tin cover, hold the jar at an angle, insert the needle into water and pull the plunger until the syringe is full. Be careful the syringe needle is clean and sterilized or you will contaminate the mycelium water.

That's it! You can now use this syringe like you would use the spore-water one. You can keep the mycelium syringes in the fridge at least 2 months.

Spore printing

original source: http://www.fungifun.org/English/SporePrinting

Wash your hands and work in a clean environment to perform the following steps:

- take a clean material you want to print on (fresh typing paper, index cards, wax paper, tin foil, glass slides....)
- cut a opened, clean, mature cap off the stem as near to the gills as possible with a clean scalpel or knife
- place the cap on the printing material gills down
- cover the cap with a jar or glass or place the printing material in a plastic container (Tupperware...) with lid on.
- let sit for 12-24 hours at room temperature
- pick up the cap, cover again and let the print dry for around 24 hours
- when the print is dry fold the print and tape the edges or leave it as is and put into a clean plastic zip bag.
- label and store in a dark, cold and dry place.

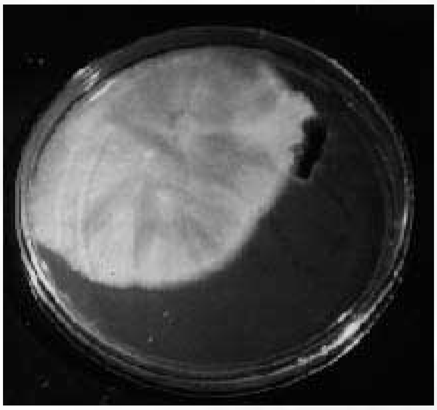
The Illustrated Mushroom Grower's Guide

original source: http://www.shroomery.org/8437/The-Illustrated-Mushroom-Growers-Guide

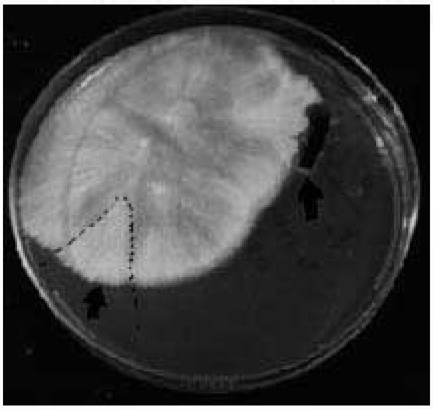
Not for the beginner, this cubensis cultivation method requires you to be fairly experienced with mushroom cultivation...and to have access to some basic laboratory equipment. It's got helpful illustrations.

Hey folks. Here is a detailed description of the method I use to grow Psilocybe cubensis. I have had very good success and have worked out most of the bugs so this method is guaranteed to produce lots of our little, happy friends. Unfortunately for most of you, I have access to laboratory equipment including an autoclave (for sterilization) and an incubator (for growing at constant temperatures) but I think you can substitute your own homemade stuff like a pressure cooker.
I start with Psilocybe cubensis mycelium which has been grown on an agar plate. The agar media I use is Potato dextrose agar (PDA) from Difco. This contains Potato dextrose broth and regular agar at 1.5 g/l. I am sure Malt extract agar would be just as good or even some home made version of PDA. The agar was autoclaved at 121°C, 15 psi for 30 min and was then cooled to 50°C. At this temperature, the agar was aseptically poured into Petri plates and allowed to cool and solidify. These plates can now be stored in a plastic bag in a cool location for as long as you want. If there was any contamination, it should show up after about 3-4 days at room temperature. If there is none, then the plates are good to use.

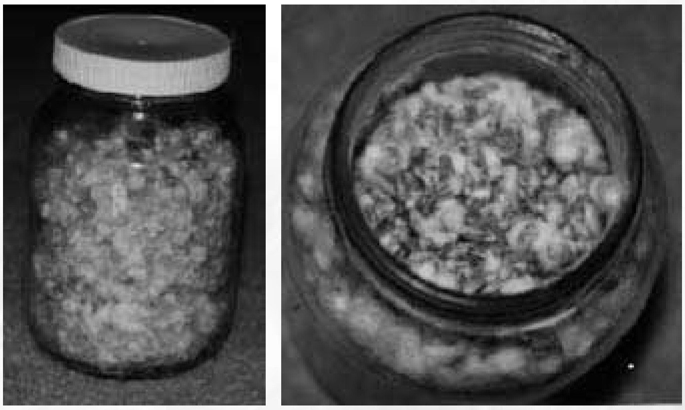
The Psilocybe cubensis strain I use was obtained from a local store and I was assured that it was a good one. Basically, the strain is dikaryotic and can be used directly to inoculate jars. I first aseptically transferred a small piece of mycelium containing agar to a few plates and grew them at 30°C for 1 week. Two of these plates were set aside as my stock cultures so that I did not have to go back to the original (and risk contamination) and were stored at 4°C (in the fridge) with some plastic wrap around them to keep in the moisture. They were also stored upside down so that any condensed water would collect on the lid and not on the surface of the agar. The other plate was used to inoculate a bunch of new plates with small pieces of mycelium containing agar. These new plates were grown at 30°C for one week. After this time, a nice white, kite string-like mycelium had grown. The kite string-like mycelium was actually only found in sectors on the plate and it was these areas that were used to inoculate jars of rye substrate.



Rye substrate was prepared using 130 g of rye seed combined with 100 ml's of water in a 500 ml (pint) jar. The jars I used had plastic screw-top lids which could be left partially unscrewed to allow air to enter. Also, mineral supplements like $CaCO_3$ could be added to the water but this was not found to be necessary. Once the rye and water was combined in the jar, the jars were autoclaved at 121°C, 15 psi for 1 hour. These were then allowed to cool to room temperature with the lids partially unscrewed in a sterile area overnight. The next day, two small pieces of mycelium containing agar (from a kite string-like sector), approximately 0.5 cm by 0.5 cm in size, were added to each jar aseptically and the jars were shaken. These jars were then incubated at 30°C in the dark for 2 weeks with shaking every 3-4 days to evenly distribute the mycelium. It is crucial that the lids of the jars be very loose at this stage so that air can get in to the growing mycelium.

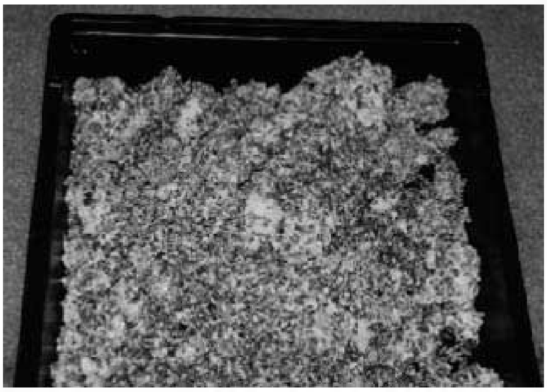


After 2 weeks of incubation and occasional shaking, the jars of rye were found to be fully colonized with white mycelium.

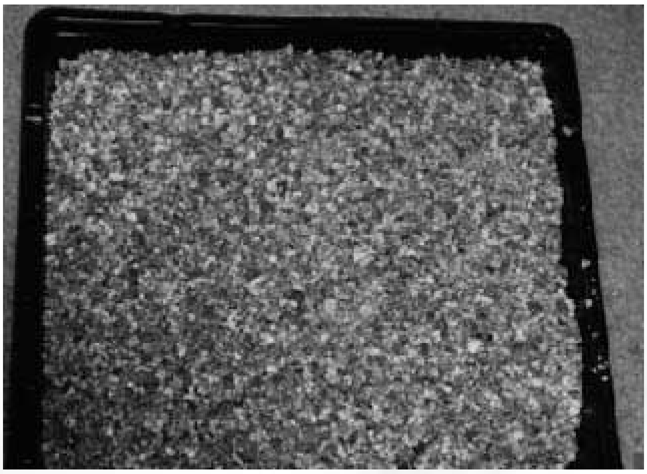


At this time, they have a very distinctive mushroomy smell. I have **never** had a jar contaminated and this is likely due to use of aseptic technique (sterile conditions). Five or six jars are dumped into plastic containers (about 2 ft by 1 ft by 5 inches) that also have clear plastic lids.

Small air holes should be punched into the lids to allow air into the container. No aseptic technique is required at this time as the rye should be fully colonized. The mycelium containing rye should be leveled off at the top to give a fairly flat surface.

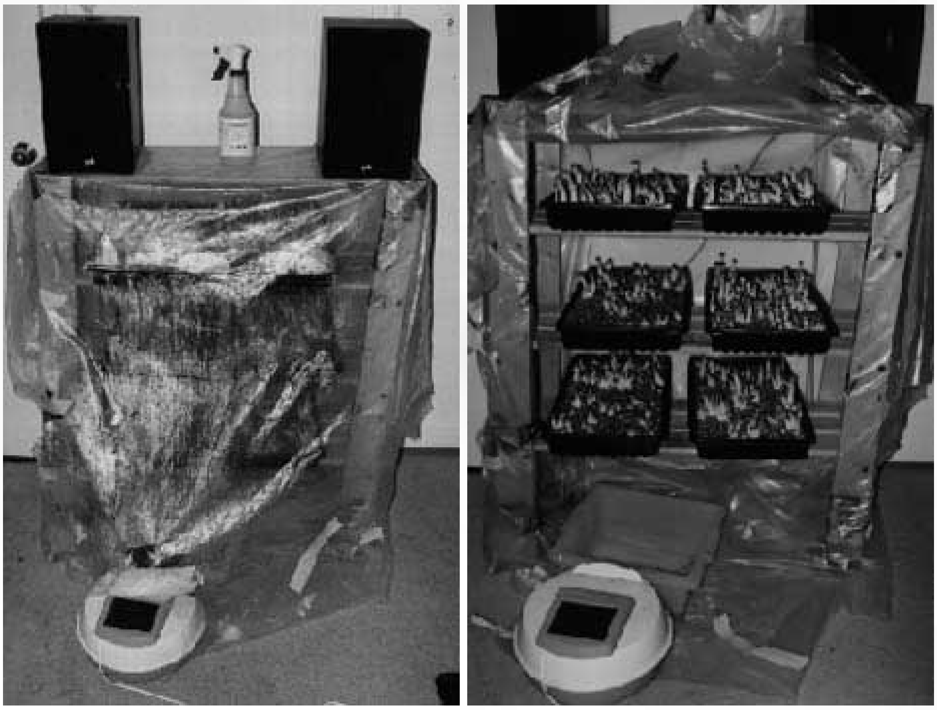


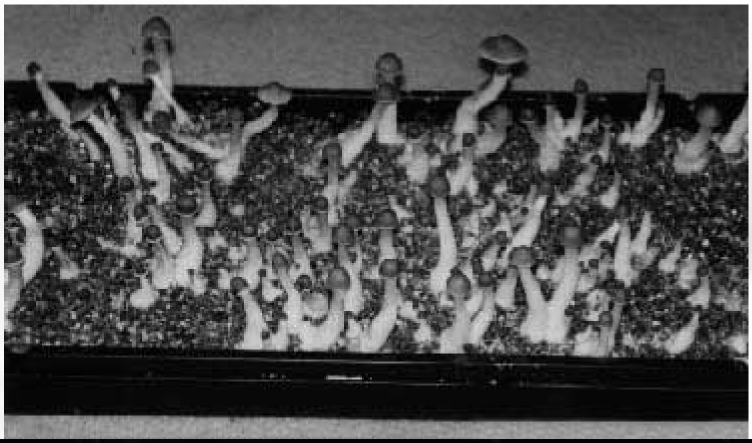
Now the rye should be cased with vermiculite. I have tried peat moss and a combination of vermiculite with peat moss but have found that vermiculite by far works the best. The vermiculite should be fully soaked in water and then the excess water wrung out. This is applied to the rye to a level of about 1-2 inches and then is leveled out.



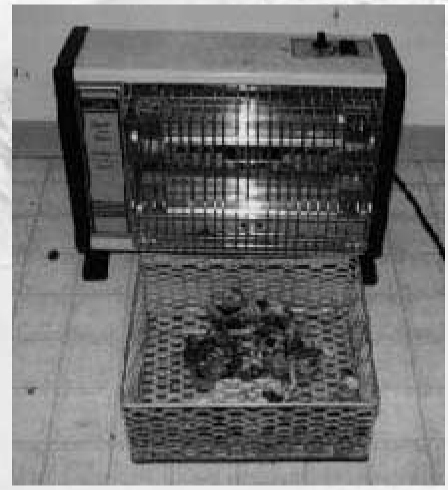
These trays of cased substrate should now be incubated in a humid environment, in the dark at 24-30°C for about 3-5 days. The trays can be kept moist by gentle misting with water at this time. Too much water is not good so don't overspray. During this time, I keep my trays in a plastic tent with no extra humidification. The tent is basically a small wooden shelving unit from IKEA which has been covered with clear plastic. A lot of water collects on the lids of the tray and this indicates that a very nice humid environment exists inside. Remember, at this stage nohumidification is required. Don't over water. After 3-5 days, white mycelium should be poking up through the vermiculite casing.

Once quite a bit of mycelium has poked up, but not too much, the temperature should be lowered to 20-24°C and the trays should be exposed to regular bursts of sunlight (i.e. open the curtains). At this time, mistings should be ended and the inside of the tent should be kept very humid using a humidifier. Be careful because over humidification can be a problem. This should continue for about 2 weeks. Small shrooms begin to appear in about 1 week and continue to grow over the remaining week.





Keep humidifying as the shrooms grow but not too much. Once the veils of the shrooms have broken, they should be carefully picked and dried immediately. For drying, I basically just use a heater that has a fan attached and I blow warm (not hot), dry air over the shrooms for about 2 days. At this time, the little guys are nice and dry and ready to be bagged and stored.



I usually get about 2-3 flushes and afterwards, I put the leftover substrate out in the garden. I found that in the late summer, many more mushrooms will grow in the garden from the spent substrate and these are very large with a more dark golden color. These garden grown shrooms are also **very** potent!

That's about it. Happy growing.

Indoor mushroom growing technique for the boil a bag

by

D.H Jarrold

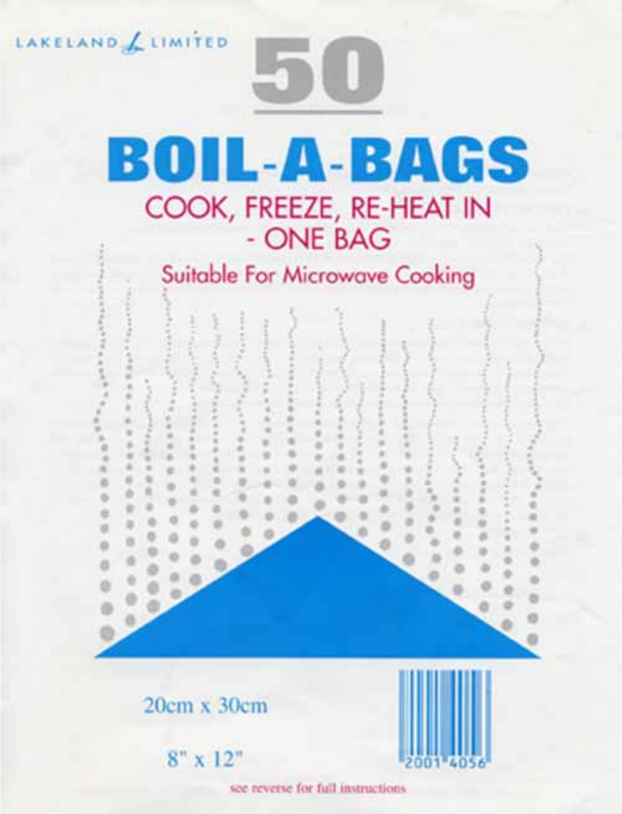
Introduction

Firstly: Getting some "Boil a Bags" is all important in using this technique to grow your mushrooms. Boil a bags are plastic bags that can go in the pressure cooker or microwave without melting. the brand i use are made by a company called Lakeland Plastics, in packs of 50 at a size of 8 x 12 or that's 20cm by 30cm: cost is about £2.50p per pack of 50.



LAKELAND LIMITED

Barcode number : 2001 4056

Instruments you will need

Here are some essential instruments you will need to grow your mushrooms.

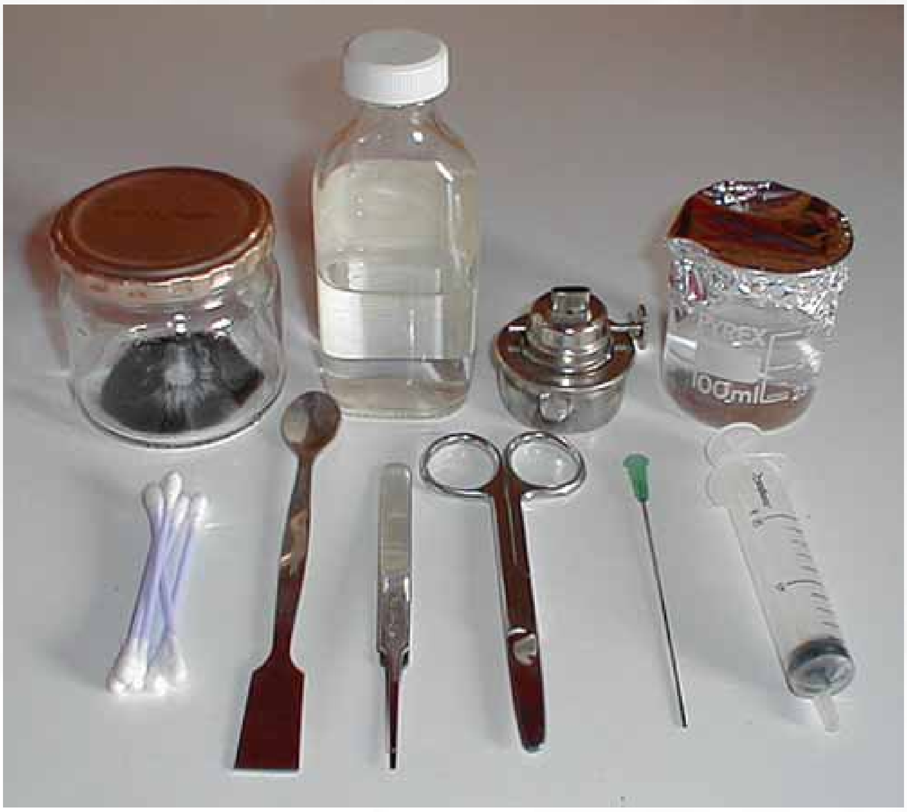
Top row left to right:

1. a spore print in a jar
2. propyl alcohol
3. spirit burner
4. glass pyrex container

Bottom row left to right:

1. some cotton wool buds
2. a flat edged metal scraper
3. metal tweezers
4. metal scissors
5. syringe needle
6. syringe

A long syringe needle can be easily made by removing the original needle from its green plastic holder with the use of a pair of grips & replacing with a thin piece of stainless steel tubing, obtainable from model and craft shops, or metal engineering companies. You may find it easier if you heat the tip of the steel tube before you insert it into the holder.



Making The filter can

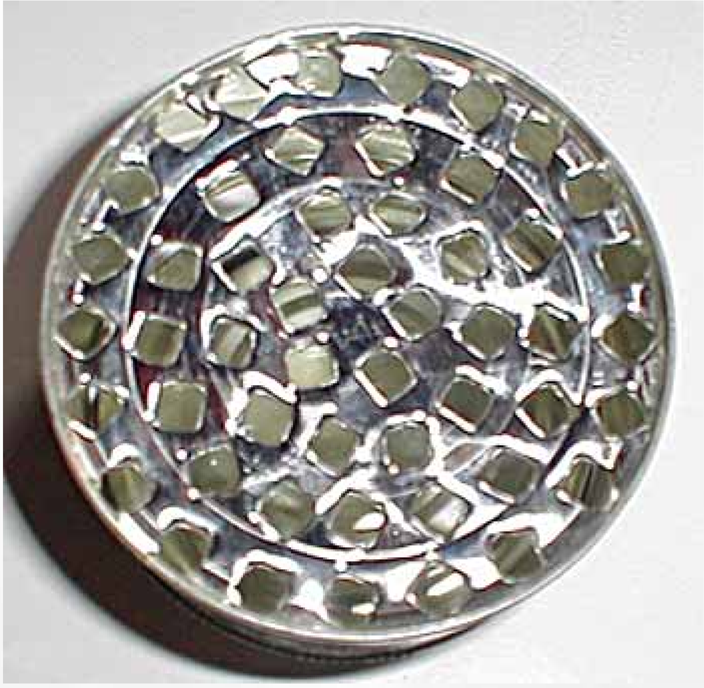


Fig 3. Get an empty cleaned 3 to 4 inch round food can "*when you first open the can, don't open all the way, leave the lid connected by an inch or so this will serve as an attached lid*". Now with a hammer and nail, make holes all over the bottom of the can, so that is has lots of breath holes.

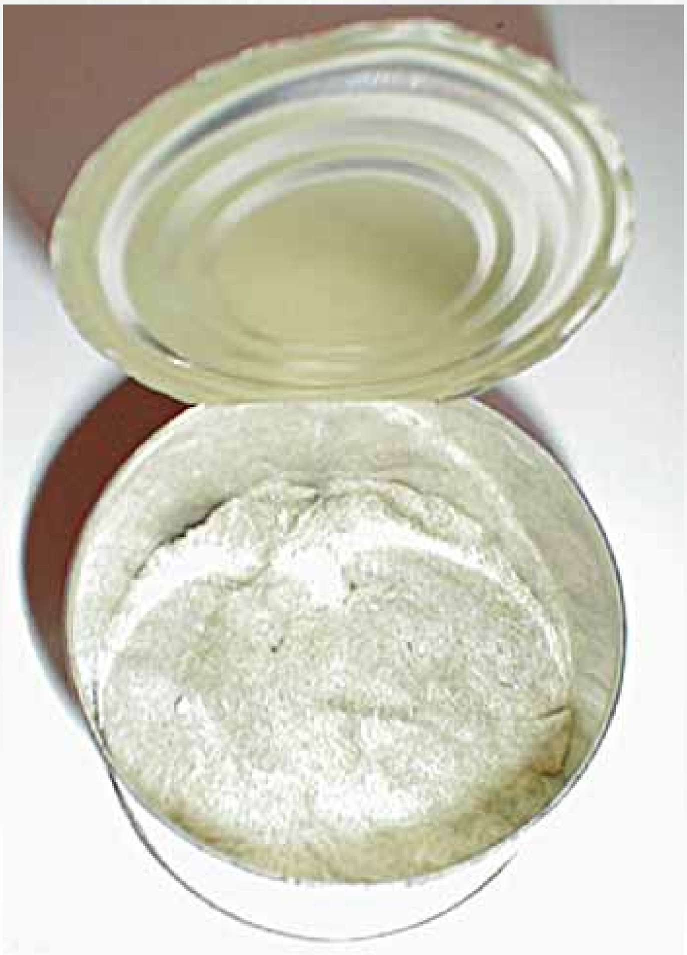

Fig 4. Line the bottom inside of the can with about 1cm of rock wool, or ordinary loft insulation fiber glass,

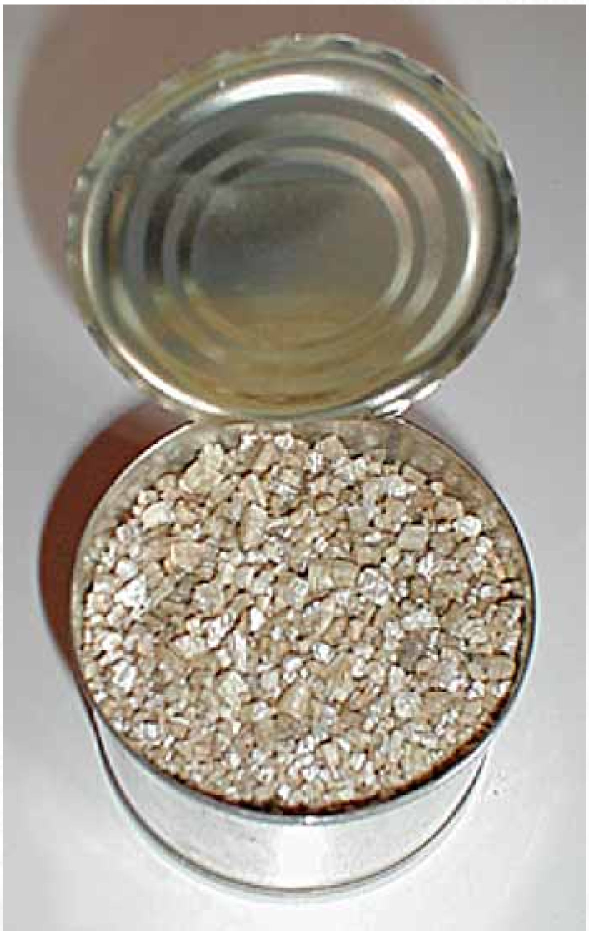

Fig 5. Fill the can with Vermiculite until you are 1cm from the top. Alternatively, instead of using vermiculite, Simply fill the can with small pieces of rockwool.

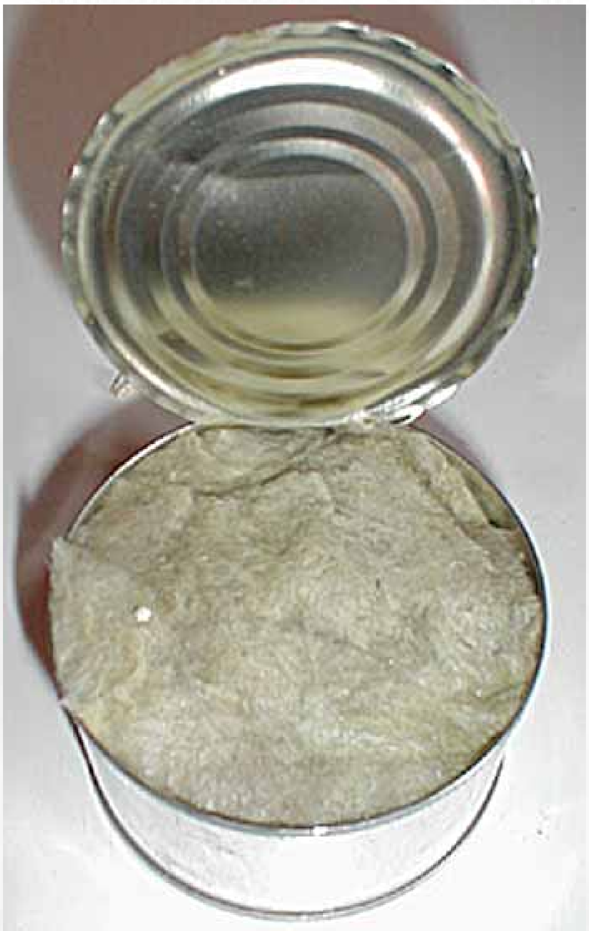

Fig 6. Top with a little more rock wool to hold in place. The filter is now completed & with the lid closed down is ready to be used.

Preparing the Straw

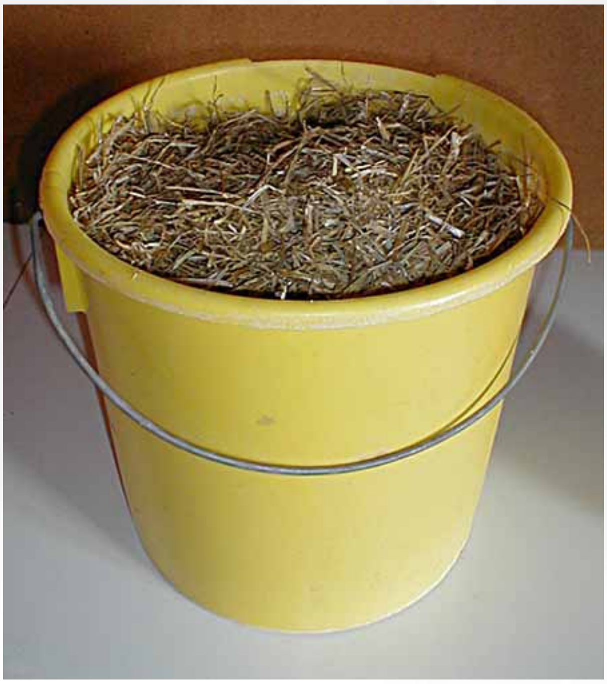

Fig 7. Chop some straw to be at 3 to 10cm lengths " you can buy straw pre cut to this length from many pet stores". Place as much of the straw as you need into a large water tight container.

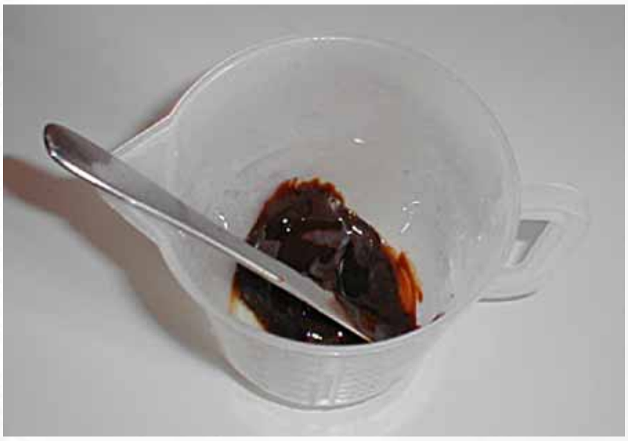

Fig 8. A heaped table spoon of marmite is added to a pouring jug. *Marmite, vegimite, or yeast extract is used to help quicken the germination time of the spores.*

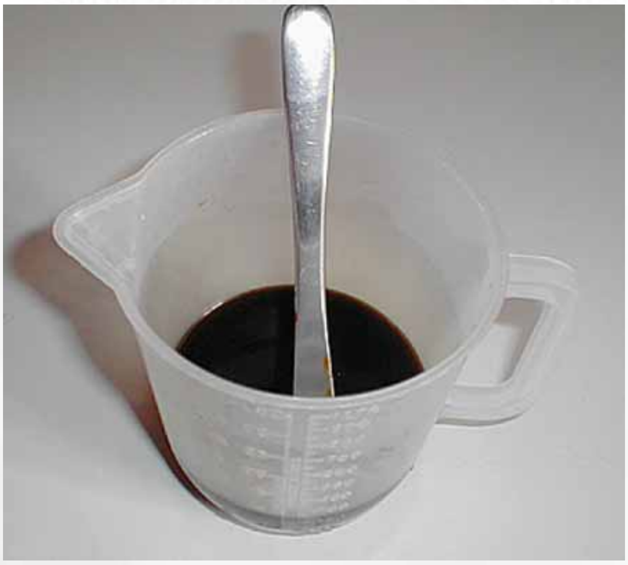

Fig 9. The marmite is dissolved in some boiling water. This is then poured into a bucket & an additional 6'ltrs of of boiling water is added.

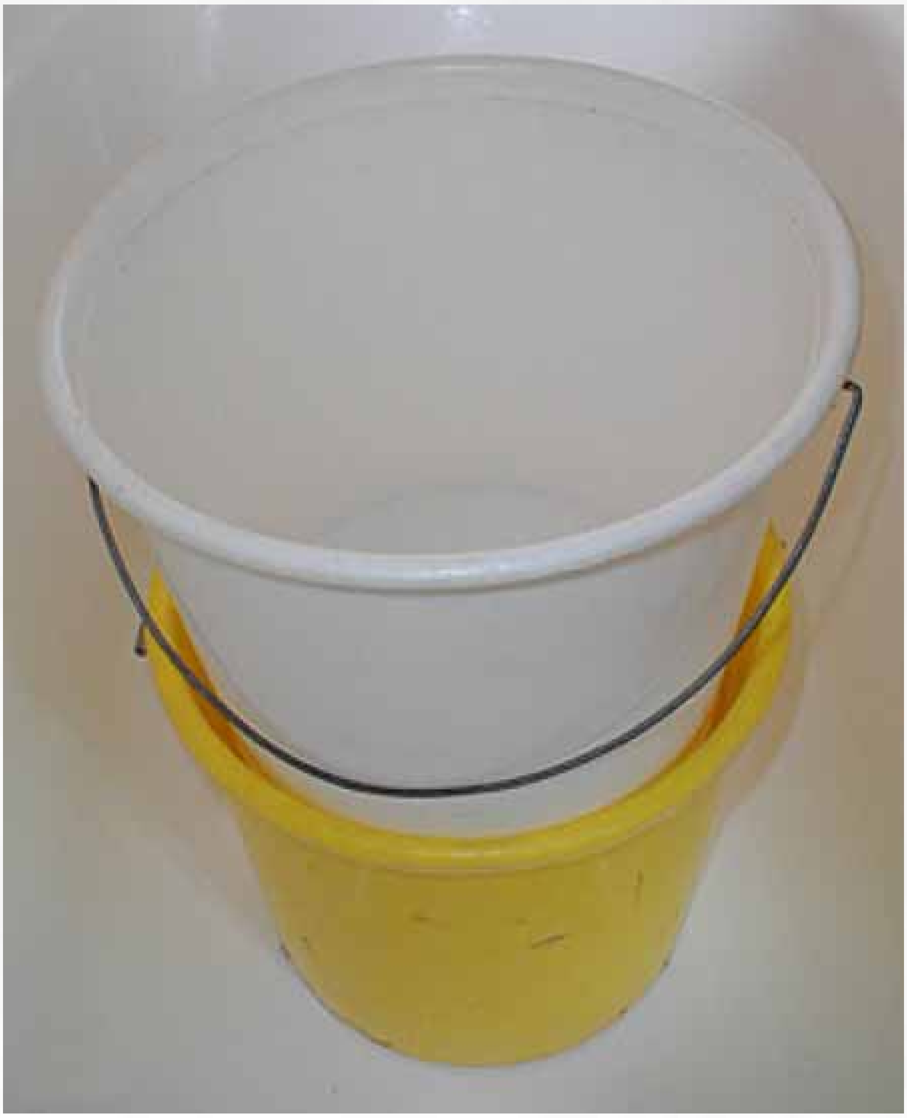

Fig 10. The marmite mixed boiling water is poured over the straw in the yellow bucket, the straw will now be weighed down by filling the white bucket with water. After an hour check to see how far the straw has been pushed down into the bucket & that the water level is still covering the straw. If needed add more boiling water & leave to soak for 1 more hour.

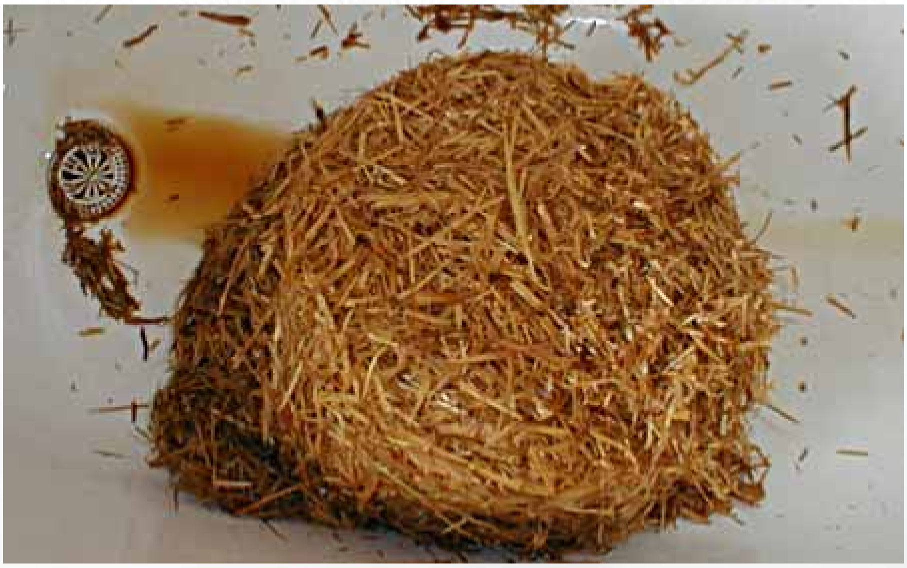

Fig 11. After the straw has been soaked, it is turned out in the bath tub & left for 1 hour to thoroughly drain.

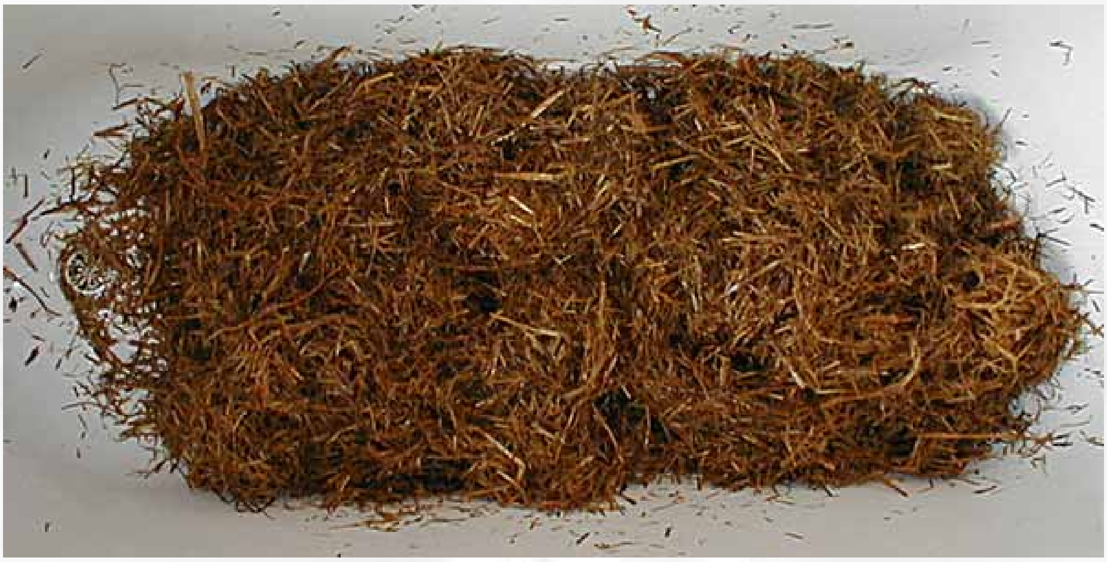

Fig 12. Evenly spread out the straw in the bath tub, if you find the straw is still to wet, then use your hands to squeeze out the surplus water.

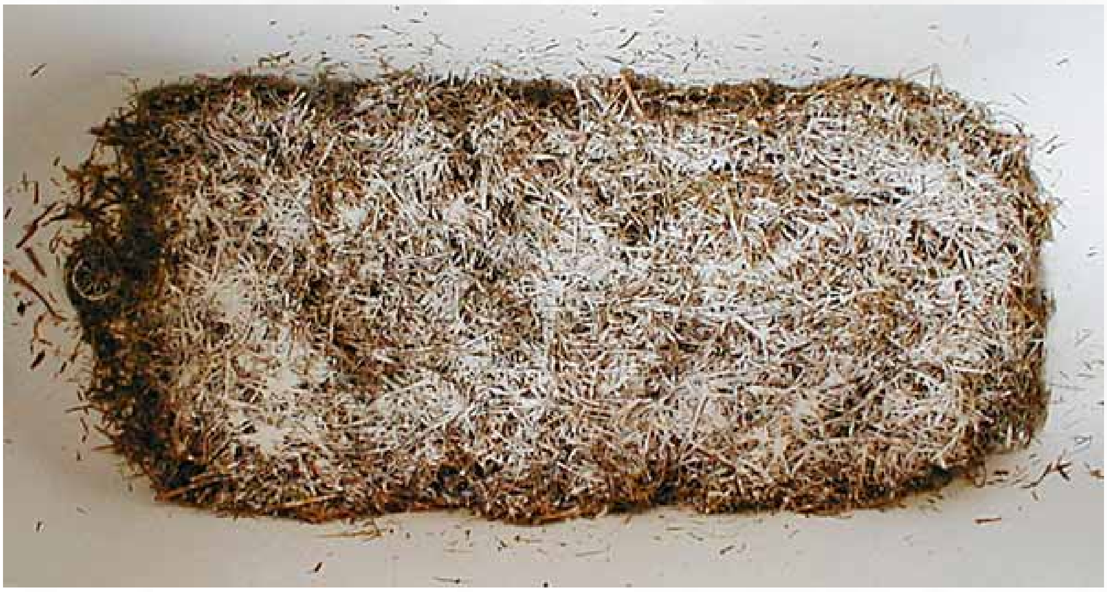

Fig 13. Some brown rice flour for extra food is sprinkled over the straw "*for 6 bags worth, Sprinkle around 3 to 4 handfuls*" then thoroughly mix in using your hands.

Filling the bags

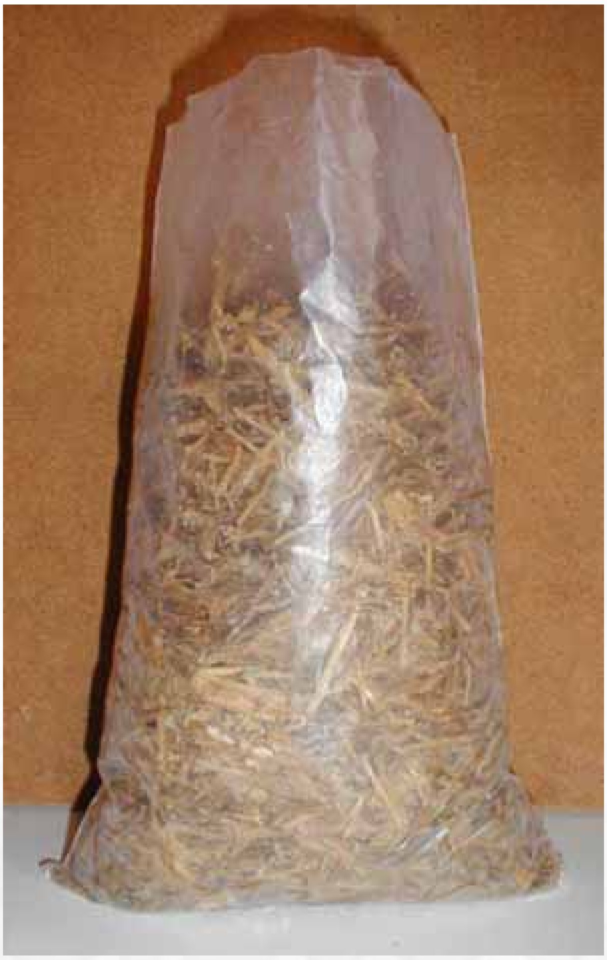

Fig 14. Firmly pack some straw mixture into the bags until they are almost full, leaving enough room to fit the filter can into the top of the bag.

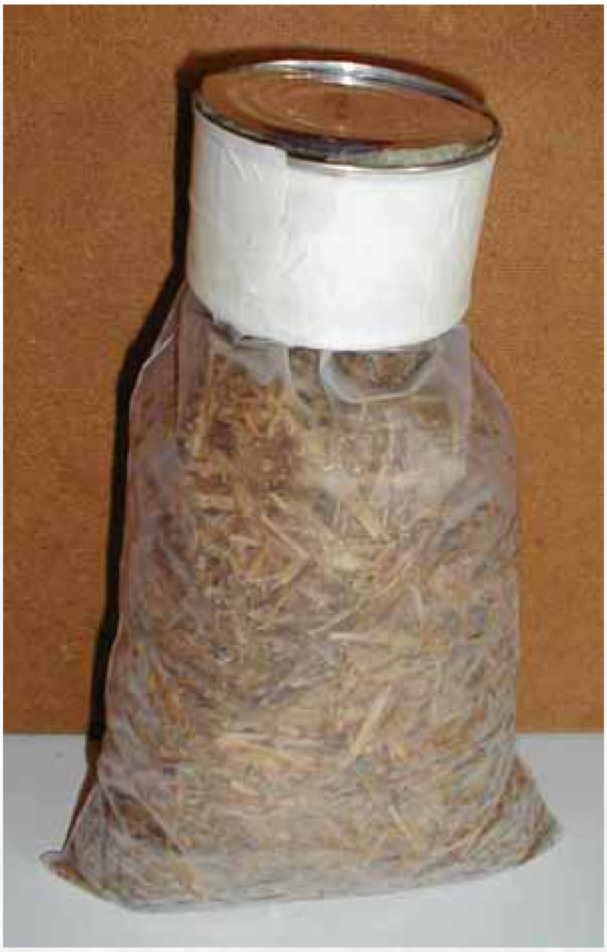

Fig 15. The filter can is fitted into the top of the bag & secured by going around the neck of the bag 3 times with wide masking tape, then firmly push the tape onto the can & bag.

Sterilizing the bags

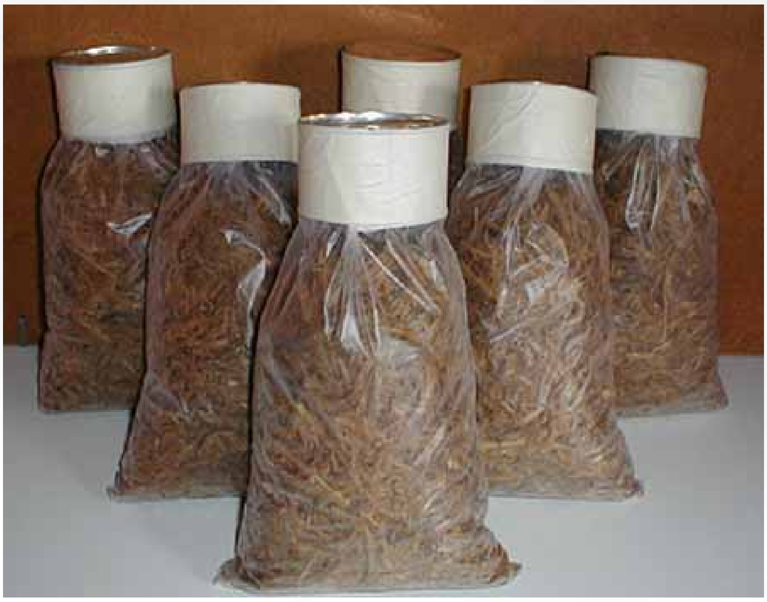

Fig 16. All 6 bags are now ready to be sterilized.

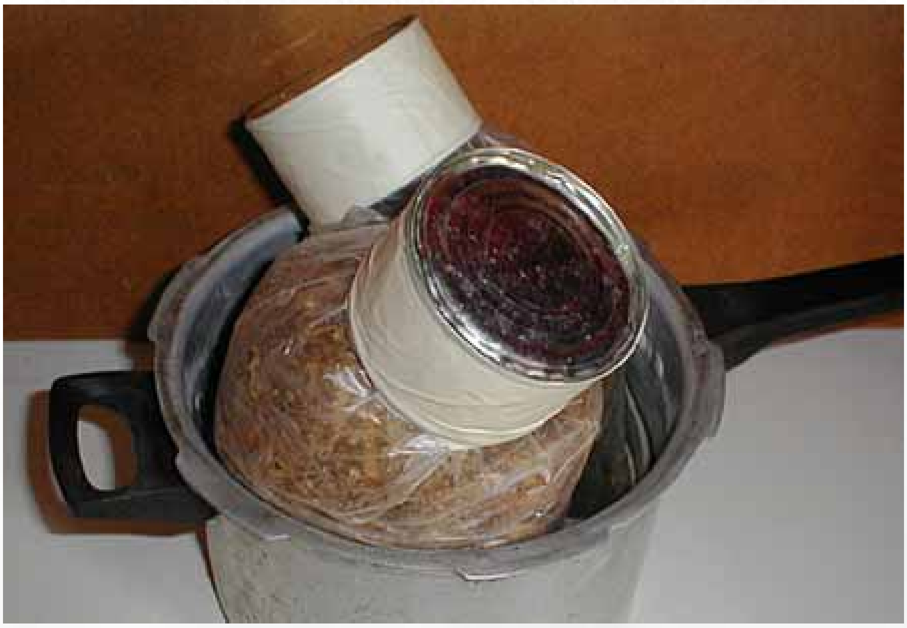

Fig 17. Two bags are placed into the pressure cooker "*Maybe only one, depending on the size of your cooker*" water is added & with the lid on, the bags are brought up to maximum pressure "15psi" for 60 minutes, You May find it favorable to do this in two' 30 minute stages.

Preparing bags for inoculation

If you are planning on using a standard 4cm long needle, then please follow this method for short needle inoculation.

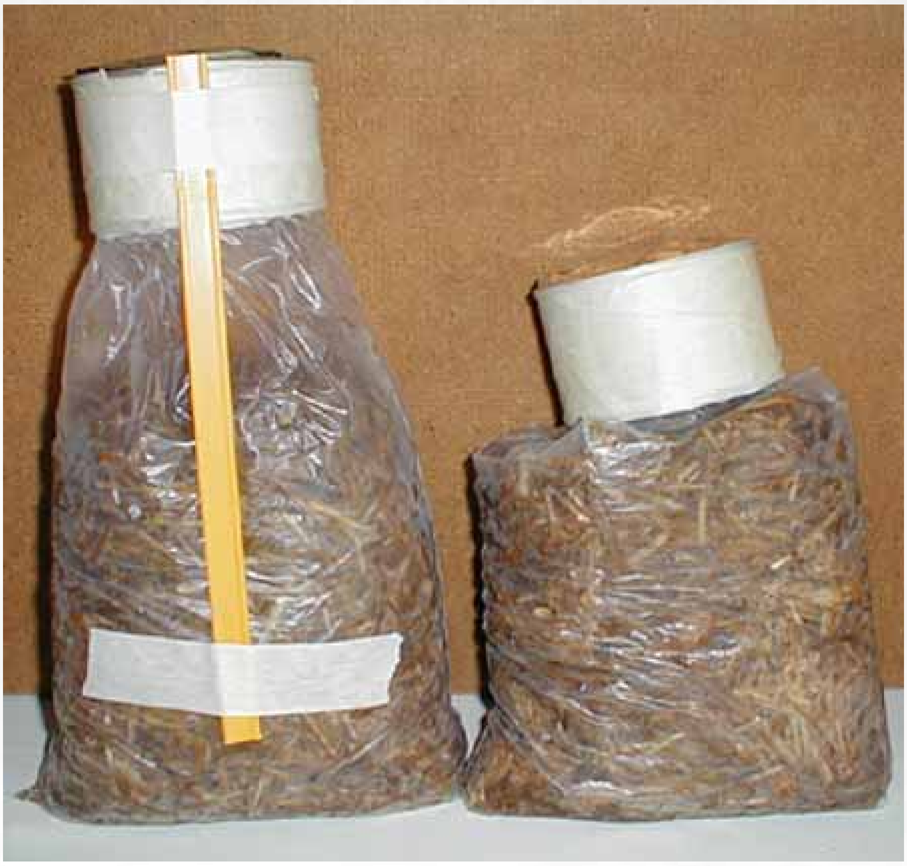

Fig 18. These 2 bags have just been sterilized & have thoroughly cooled down. Tape 2 supports, "*1 each side of the bag*" from can to bag base' as illustrated on the bag to the left.

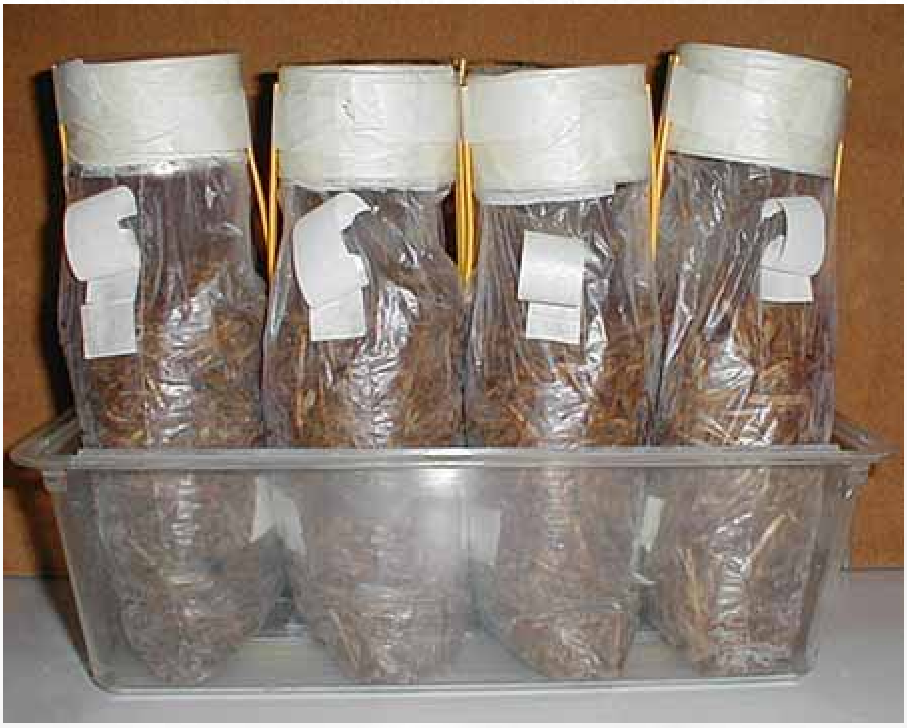

Fig 19. Here we see 4 bags that have had their supports added, it can be helpful to stand them in some kind of container, this will make things easier for you to prepare & inoculate them, it also makes sense at this point to add tape to the inoculation points, 1 on each side of the bag "2 inoculation Points per bag" "*this piece of tape stops the hole from enlarging upon inoculation*" an additional piece of tape is placed & looped back, so that when you have inoculated the bag, you can quickly roll the tape down over the hole as you remove the needle from the bag.

Preparing the spore syringe

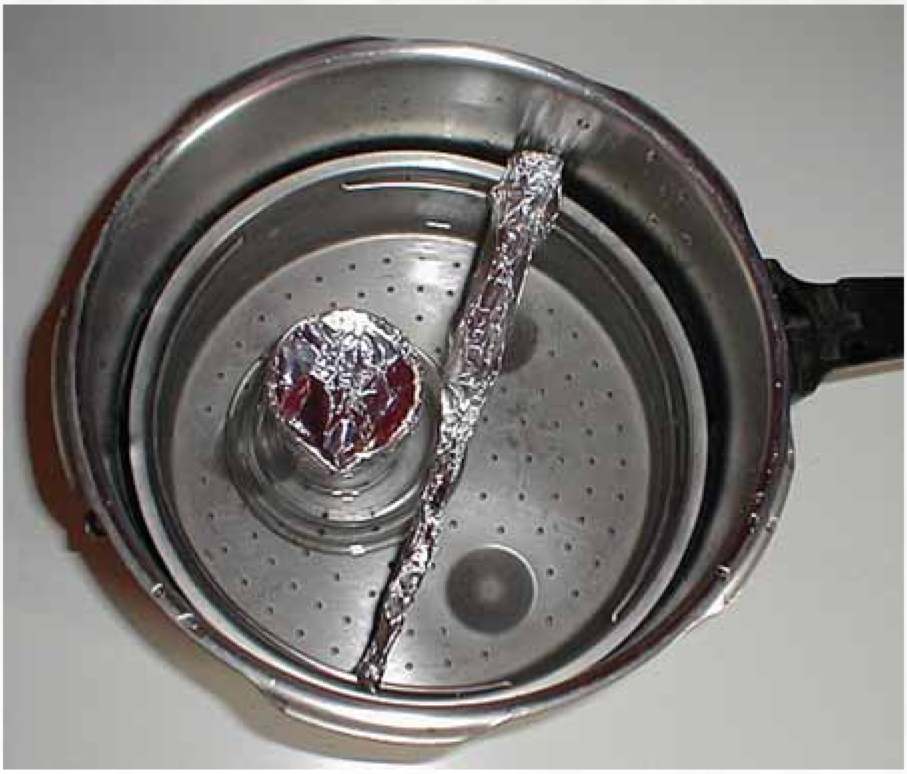

Fig 20. The syringe & its needle are connected & wrapped in tin foil, The pyrex jug in filled with 80ml of water & has a tin foil lid placed on top, The contents of the cooker is now brought up to full steam "15psi" for 20mins.

WARNING !

THE REST OF THE PROCESS WILL REQUIRE YOU TO WEAR A PROTECTIVE BREATHING MASK, OR A CLEAN HANKICHIEF COVERING YOUR NOSE & MOUTH.

THIS IS NOT FOR YOUR SAFETY, IT IS' SO THAT YOUR BREATH DOES NOT DIRECTLY INFECT THE SPORE SOLUTION.

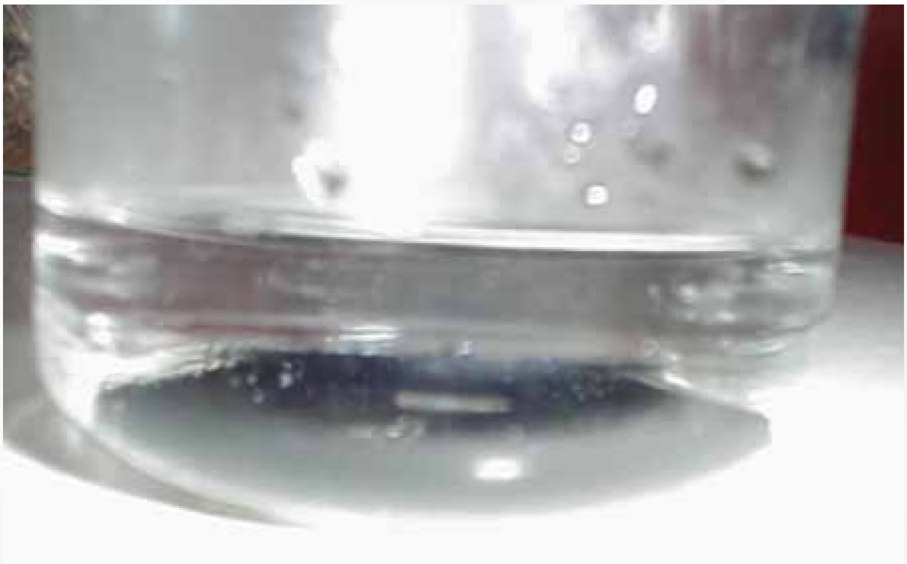

Fig 21. Now that the water has cooled, it can be added to the spore jar, But as you can see the spores do not readily mix with the water.

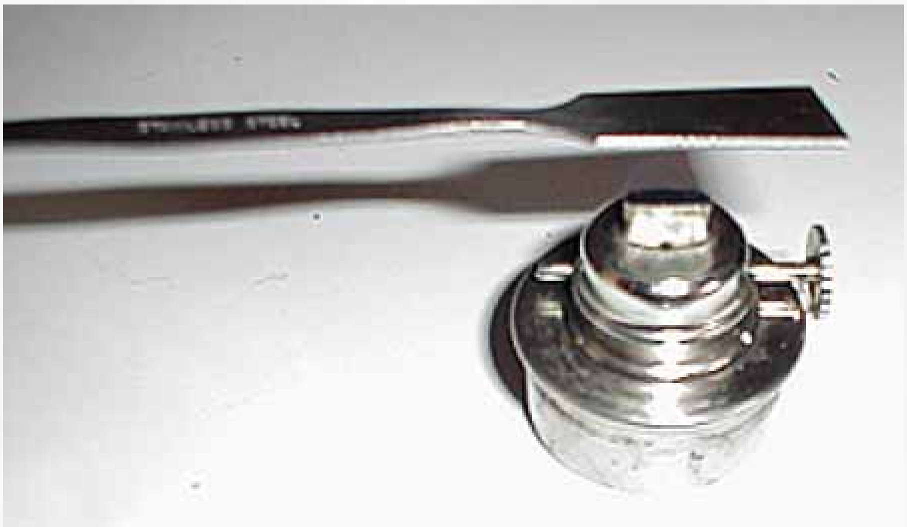

Fig 22. Add some methylated spirits to burner & flame sterilize the flat ended scraper.

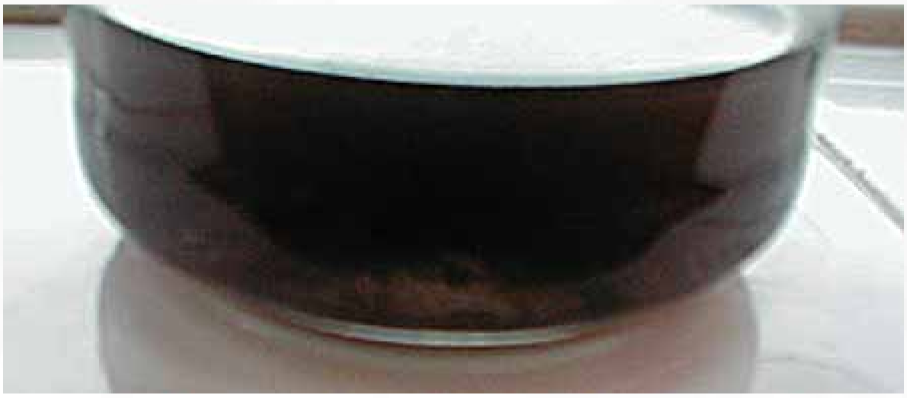

Fig 23. The scraper is then used to loosen the spores from the bottom of the jar, so that they disperse into the water & can then be easily loaded into the syringe.

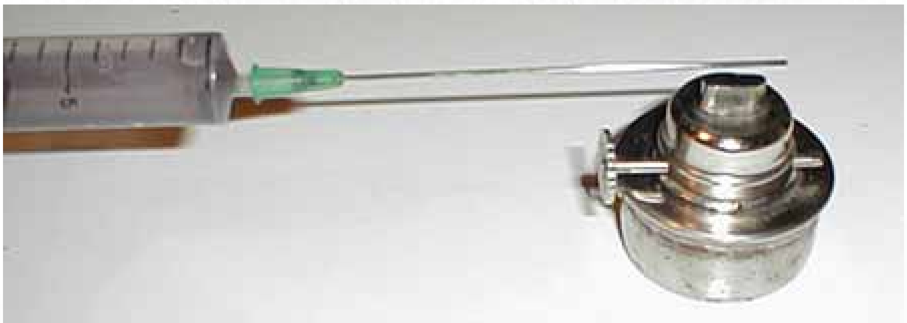

Fig 24. The syringe is passed through the flame to sterilize it, "*this is done every time before you refill from the spore jar or inoculate a bag ! And remember to replace the lid on the spore jar each time you refill the syringe !*"

Inoculating the bags

Short Needle Method

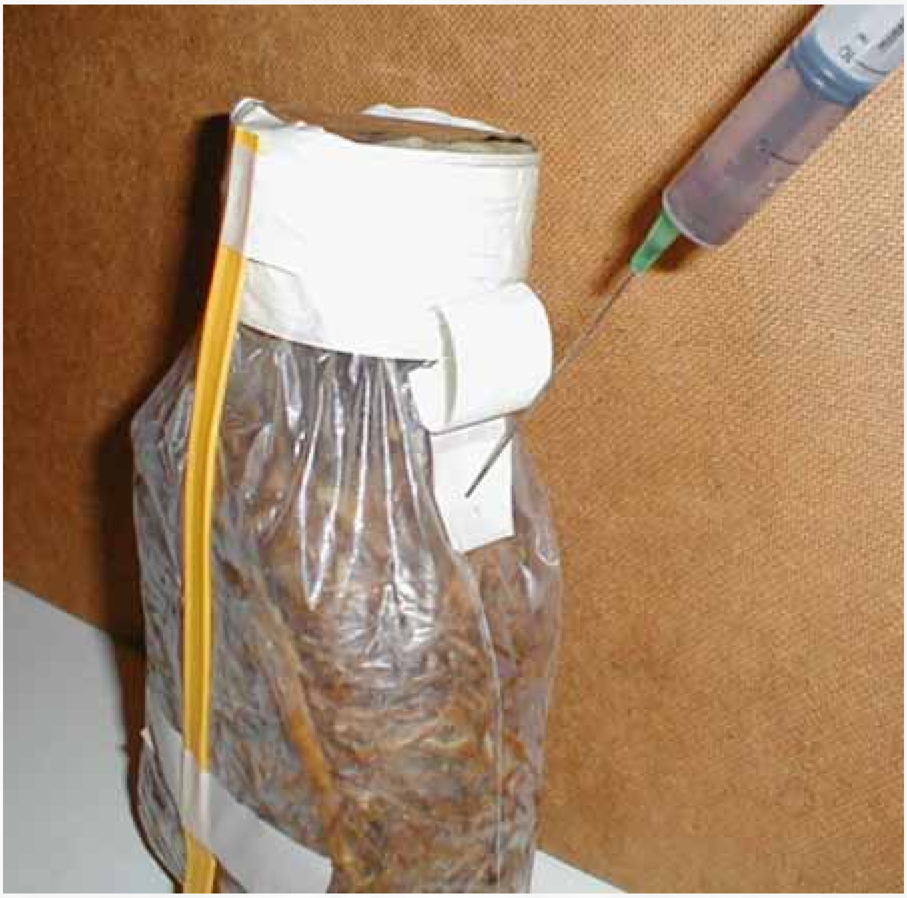

Fig 25. Here we see a bag about to be inoculated through the bag & bellow the filter level, this method is for short needles that cannot be passed all the way through the filter can for inoculation, there has also been a little preparation before this is done "see Fig 19". Using a cotton wool bud swab both inoculation points with propyl alcohol, now that the needle is fully flame sterilized.

"Again heat the needle tip only! Until it is Red, this will allow you to easily penetrate the bag".

Insert the needle all the way into the bag & release 5cc of the spores into each inoculation area, swiftly rolling down the tape as you remove the needle from the bag.

Long Needle Method

This Method is much easier, quicker & more trouble free than the short needle method.

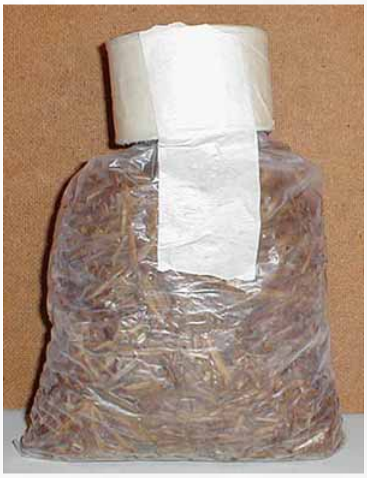

Fig 26. To secure it a sterilized & cooled bag has its filter can taped on both sides of the bag.

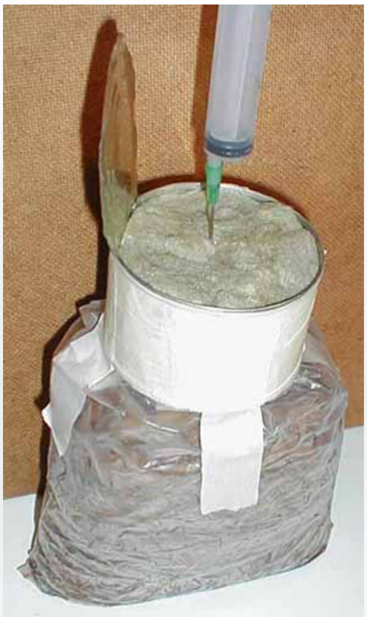

Fig 27. The lid of the filter can is lifted, the needle has been flame sterilized & is passed all the way through the can, & 10cc of spore solution is inoculated into the Straw, The needle is then removed & the lid of the can is closed down, if the lid keeps tending to lift up, then secure it with a small piece of tape. The bags can now be placed in a cardboard box & kept in a warm place for spore germination & mycelium growth.

Keeping an eye on things

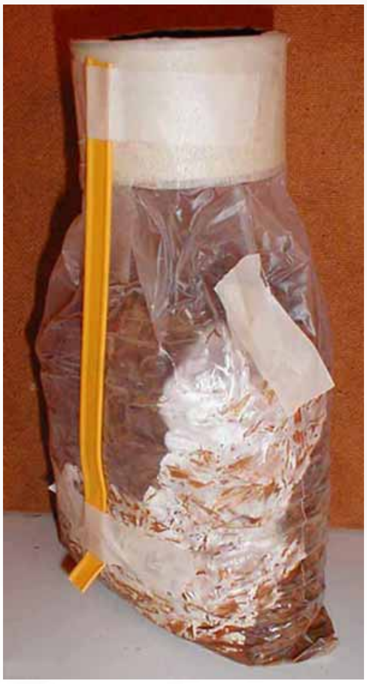

Fig 28. A few days after inoculation the mycelium growth is easily visible.

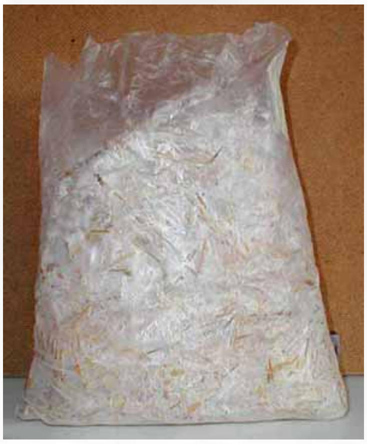

Fig 29. The Mycelium has totally colonized the bag, It is time to remove the filter & place them in the humidity chamber.

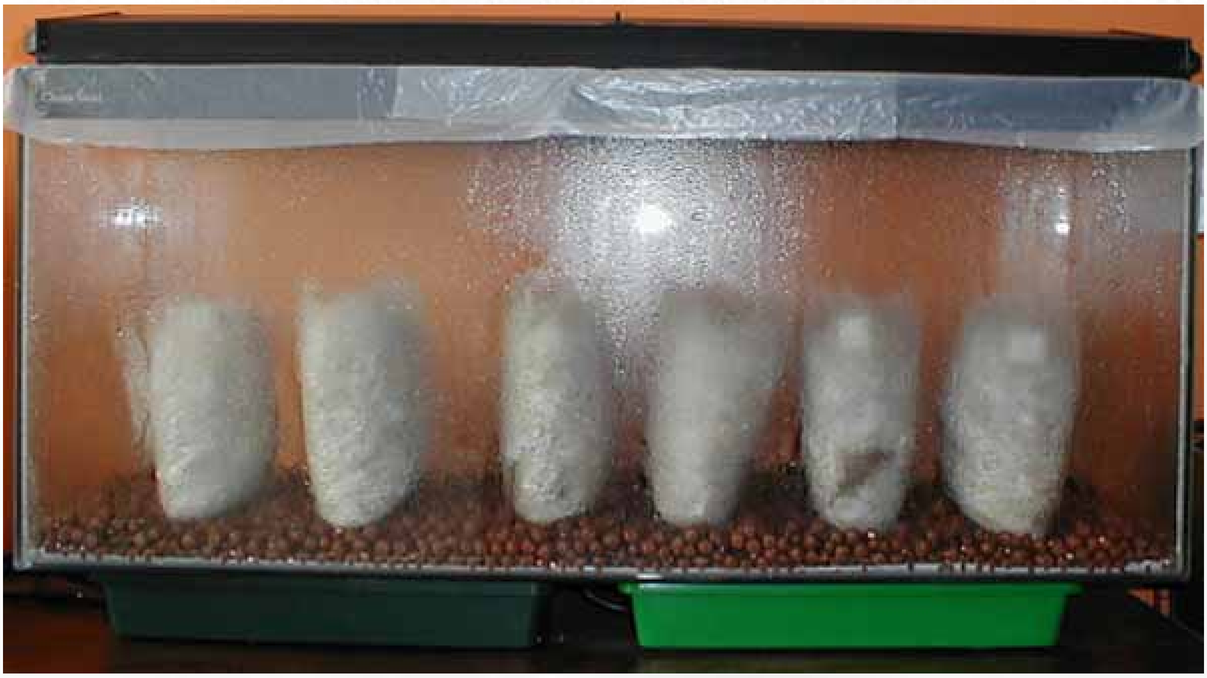

Fig 30. Place the bags into a humidity chamber, this is simply a 4ft by 2ft fish tank, also note that I have added a layer of soaked hydro pellets to the bottom of the tank, this will keep the interior nice & humid, there has also been a layer of plastic placed over the top of the tank to create a seal, so that none of the humidity escapes & no fly's can get in. All that needs to be done for the next few days is to fan some fresh air into the tank twice a day & keep an eye out for signs of forming mushrooms.

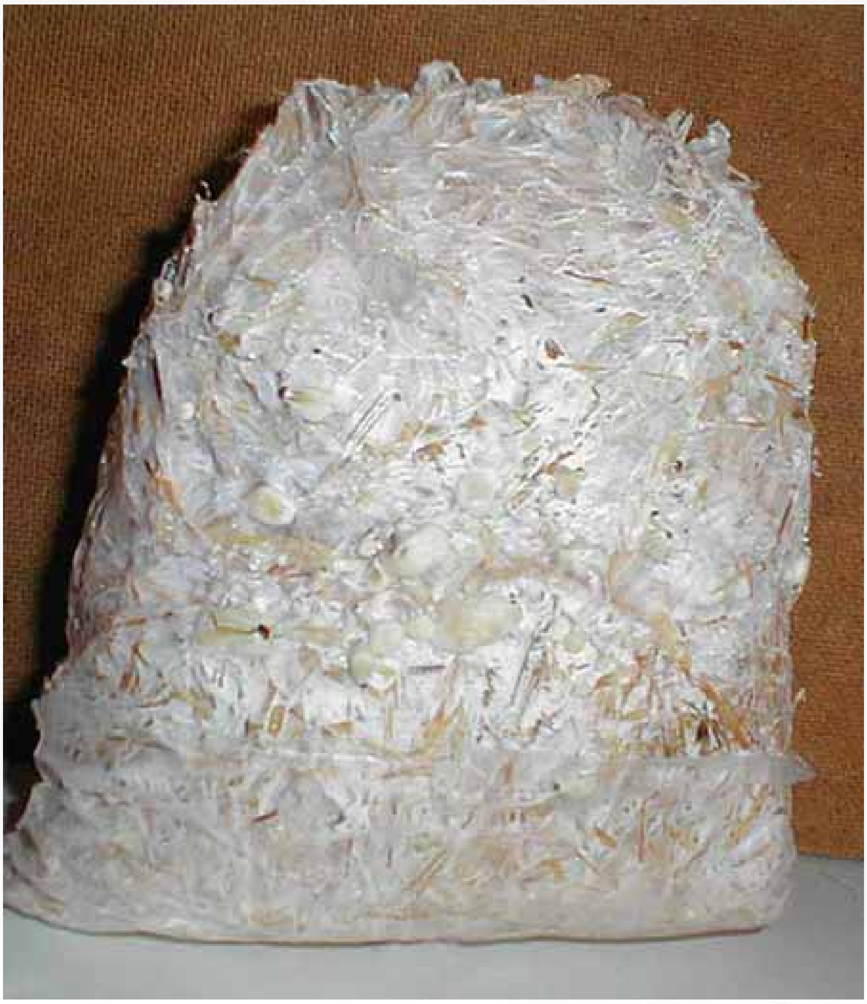

Fig 31. Here we see the first signs of mushrooms starting to form, it is time to cut the bag down the sides & remove as much of the bag as needed, I like to leave at least 2cm of the bottom of the bag intact, this allows me to stand the bags anywhere I like, without the worry of them getting to wet when they are standing in the humidity chamber.

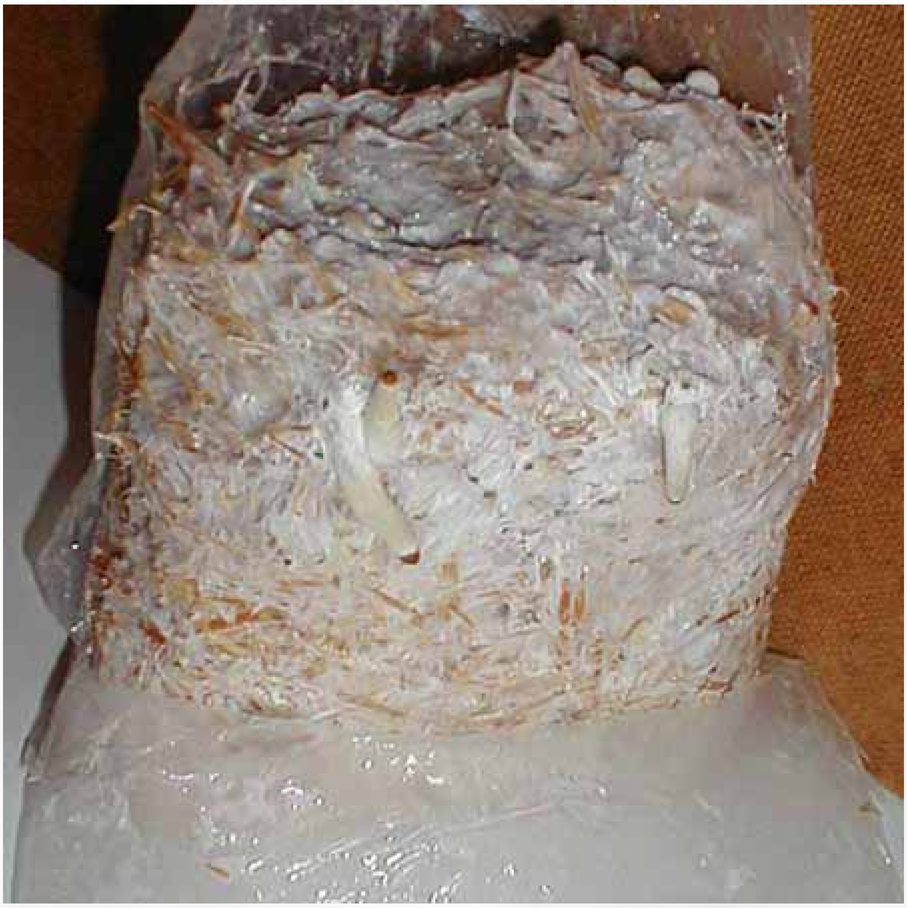

Fig 32. Here again we see the first signs of small mushrooms starting to form.

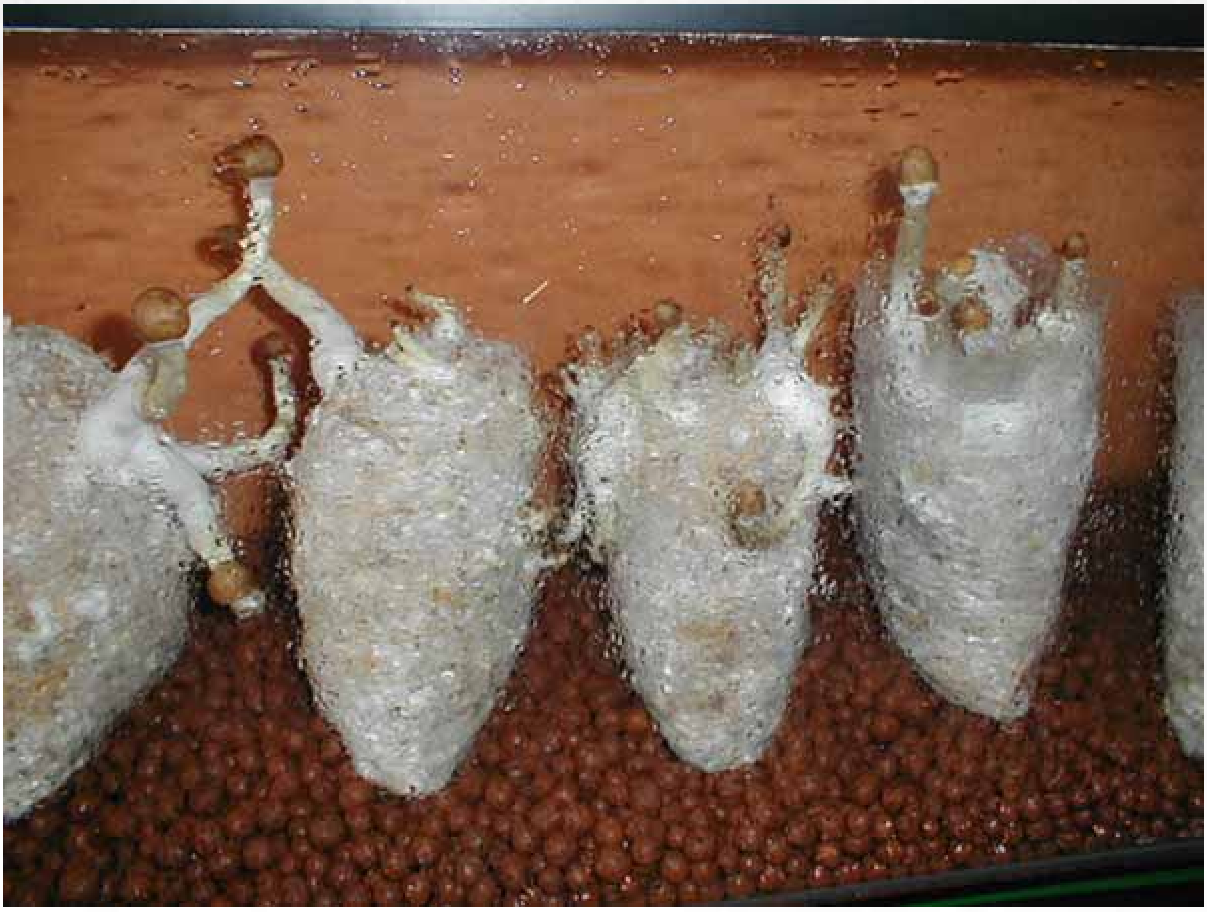

Fig 33. Mushroooms around halfway grown ! keep up the fresh air change of the tank twice a day !

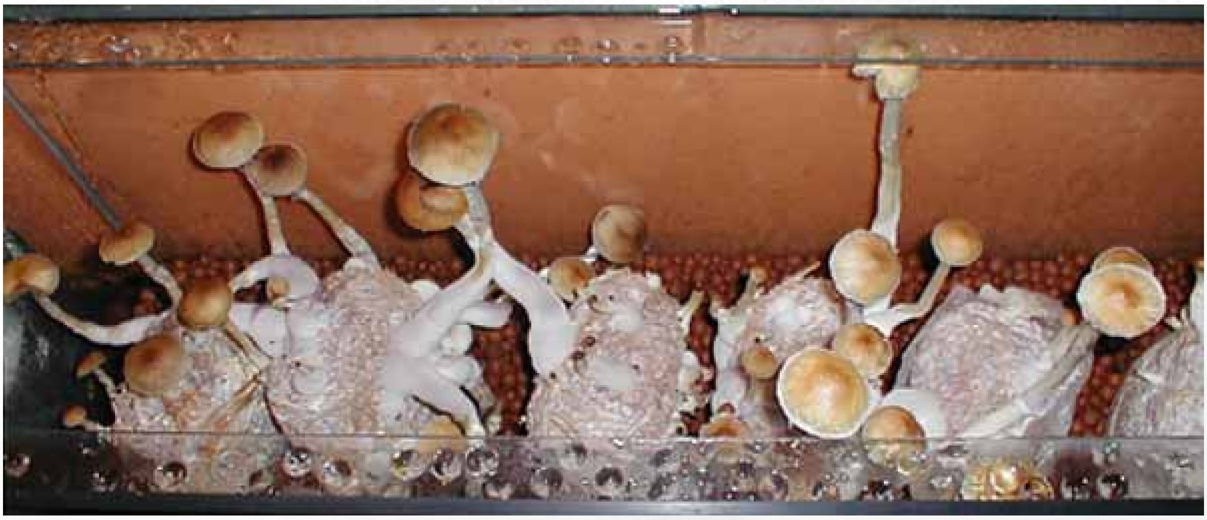

Fig 34. Mushrooms are now ready to pick ! or to take spore prints from.

Taking a spore print

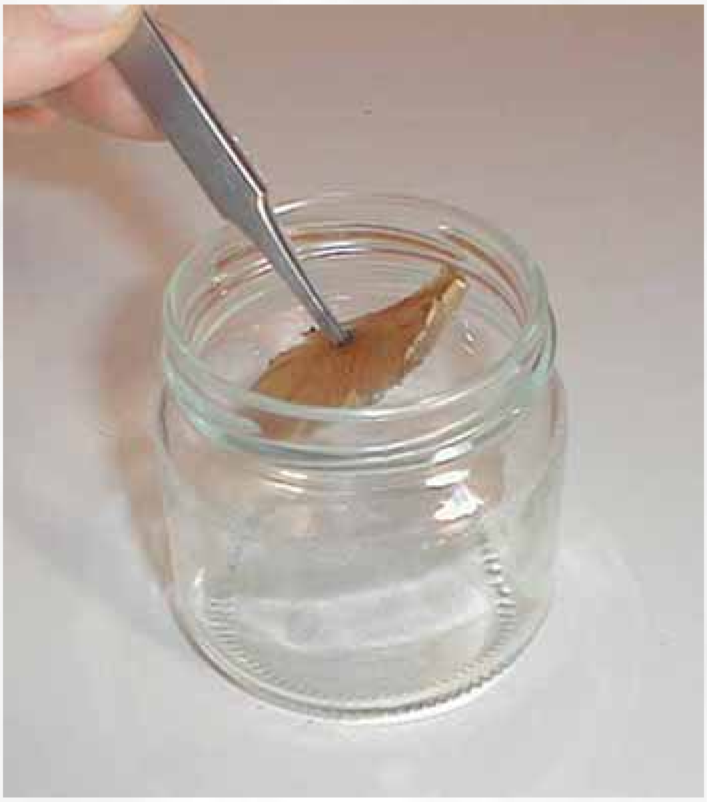

Fig 35. Now that you have grown some mushrooms, you will need to take some spore prints so that you can grow your next crops. First of all get some small clean glass jars with metal screw lids, take the lids off and lean them aside the jars & on a metal baking tray put them under the grill of your oven for 30mins at half the maximum heat so that they can be sterilized. When the jars have cooled, carefully go into the grill & place a lid loosely on each of the jars, now remove the tray from the grill & tighten the lids onto each of the jars.

Take your jars, tweezers, scissors & meths burner, to your mushroom growing tank !

FOR THIS PART OF SPORE PRINT TAKING WEAR YOUR BREATHING MASK.

Get one of the jars and unscrew its lid "but leave it on" Flame sterilize your tweezers & scissors. Gently push the tweezers into the top of an opened spore loaded cap & cut it from the stem with your scissors, now carefully place the cap gills down into the jar & immediately replace the lid ! but do not ! tighten it all the way, as any moisture in the jars or on the spores will need to naturally evaporate. see Fig 37.

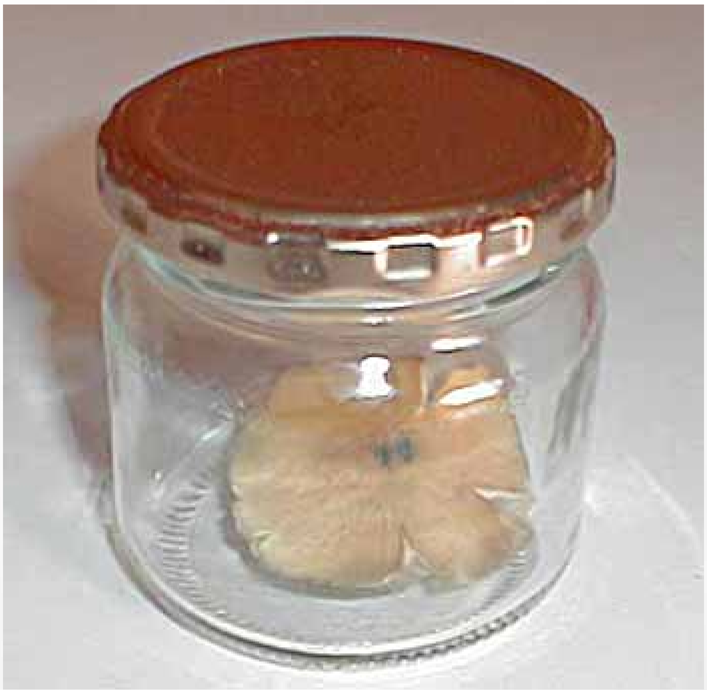

Fig 36. The cap has been carefully placed into the sterile jar & with the lid loose is left for at least 24 hours' for the spores to settle on the bottom of the jar.

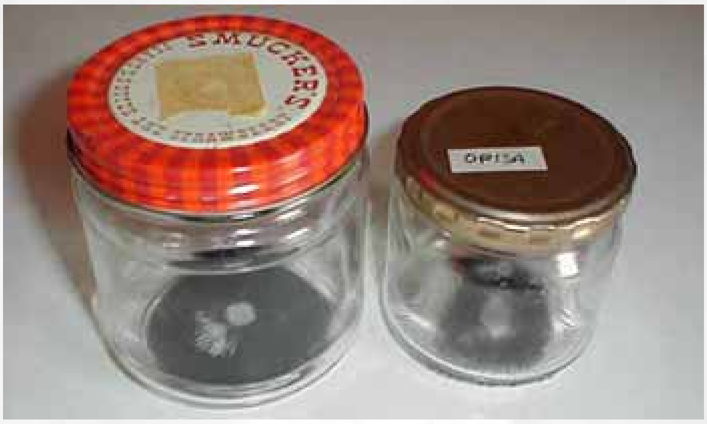

Fig 37. In this picture, using the tweezers the caps have been removed from the jars & for a further 24 hours have stood in a clean draught free area, so that the spores can loose their moisture, now this has been achieved the lids of the jars can be firmly tightened for later use.
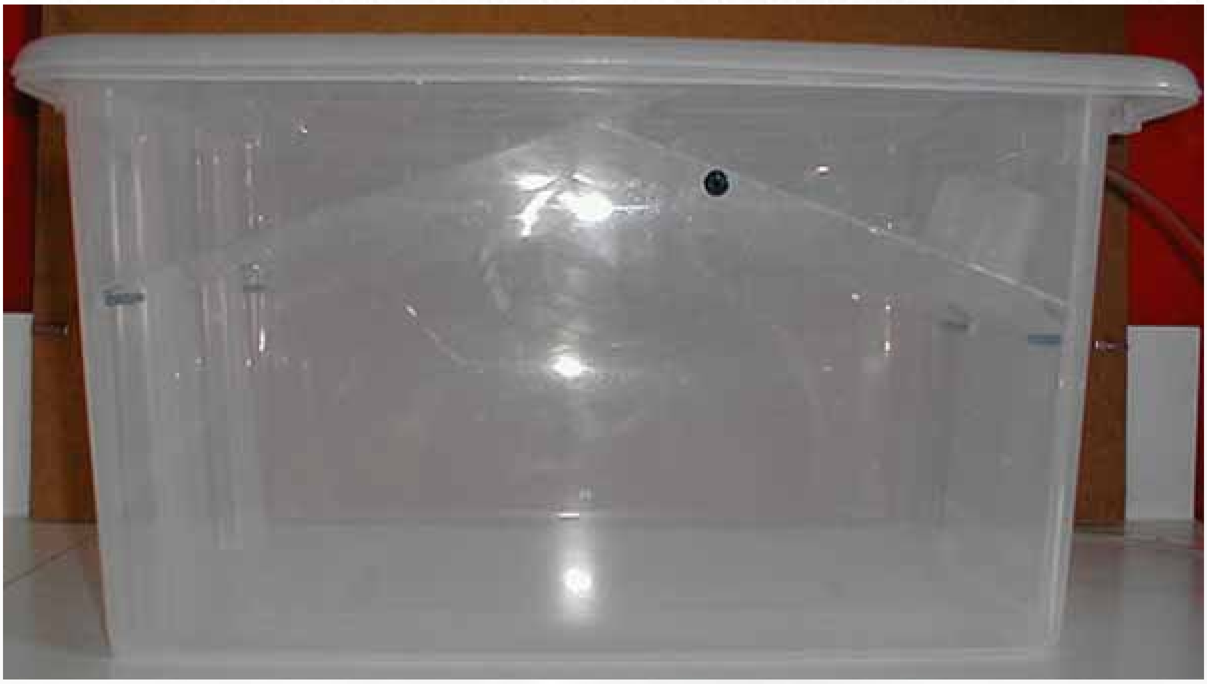
The Circle Is Now Complete !



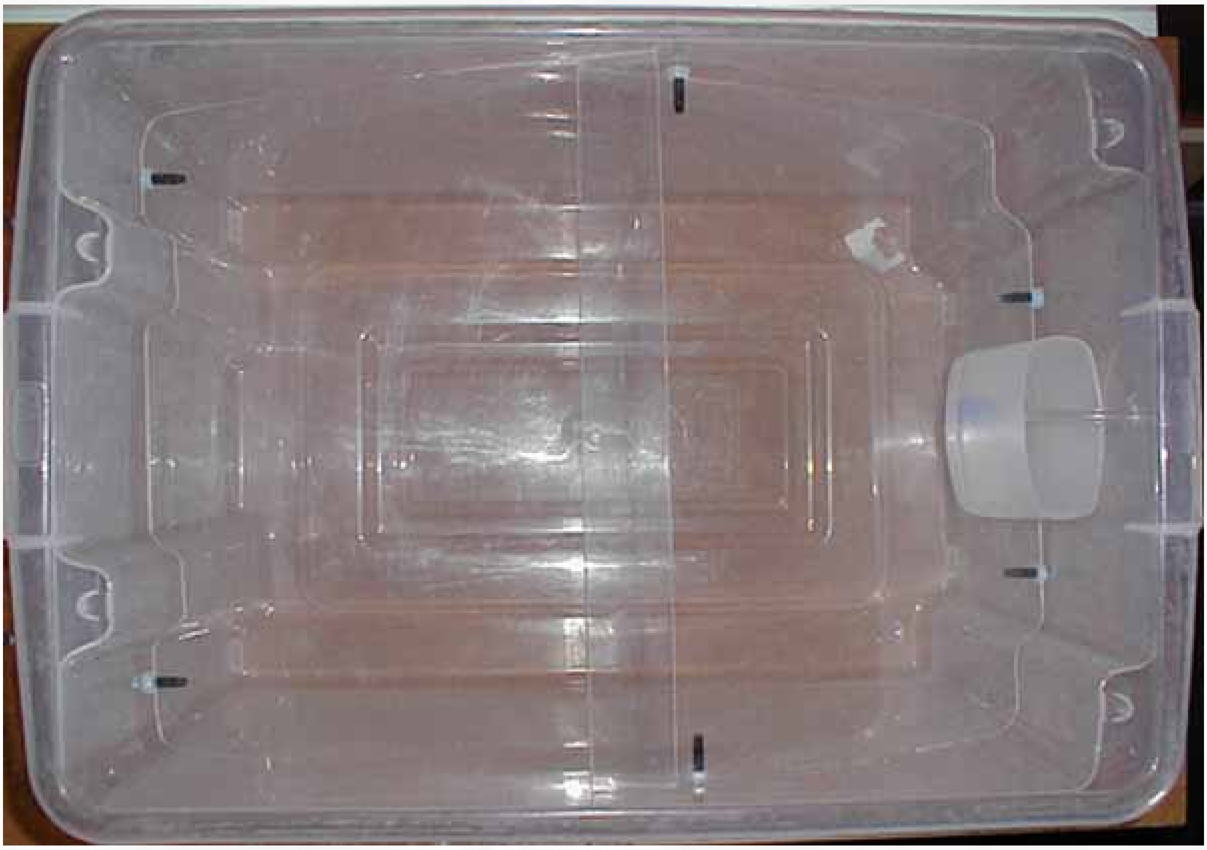


Fig 38 & 39. Here are some pictures to help you make an easy self humidifying chamber, most things to make the chamber can be obtained from local hardware shops & the plastic car registration plate nuts & bolts from car accessory shops. All that is needed to keep the tank humid is an air stone some tube & a small aquarium air pump, Simply make a small hole near the top of the tank & feed the pipe through to the water container, attach the air brick & pump. The inner angled drip lids are simply shaped 2mm plastic sheet.

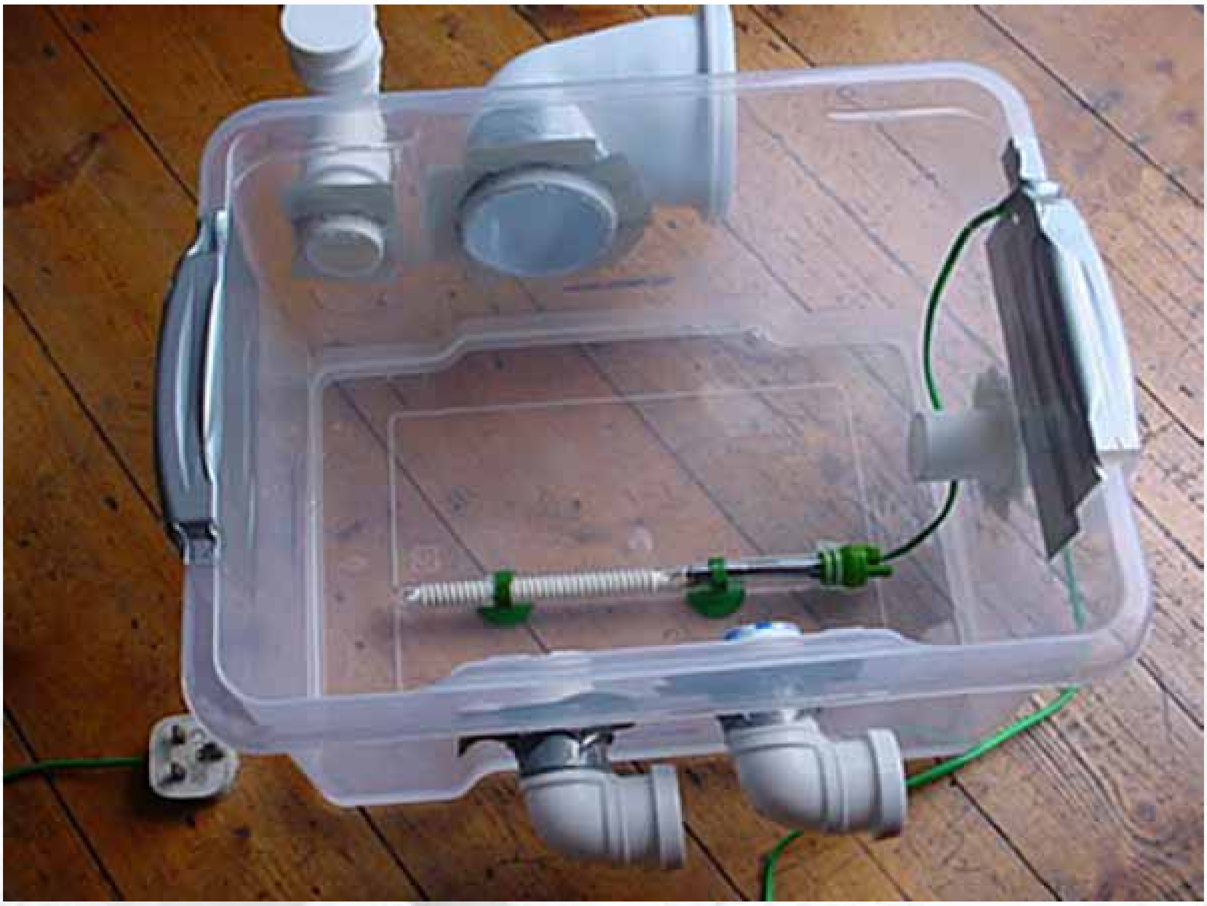

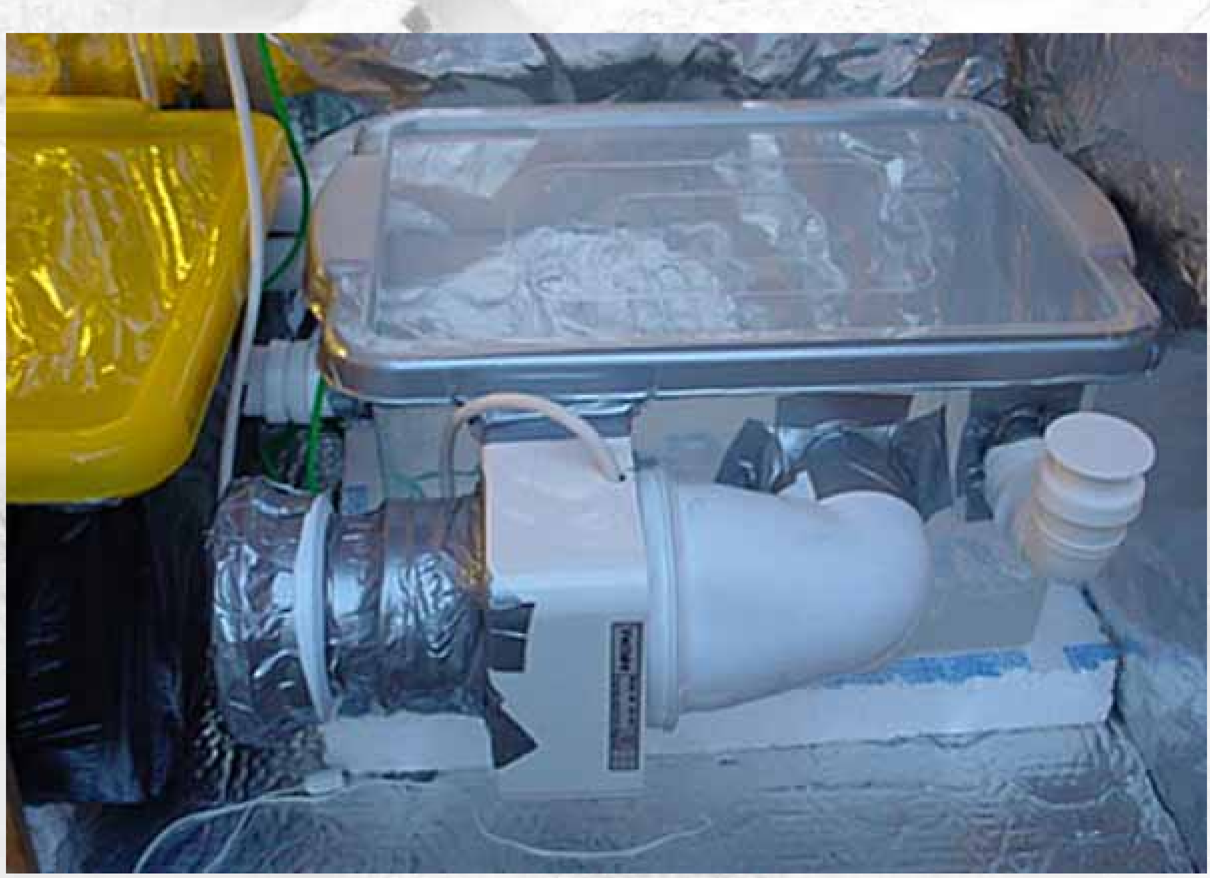

Fig 40 & 41. These two pictures show how to make a warm humid air delivery chamber, this is very useful for those who live in a cold climate, or want to grow at cold times of the year. All of the small connection ducts are potential outlets & the one large duct is the main input. The container is filled with a few Inches of water & with the lid & input fan fitted is ready to use, it may take you a few hours to set the water heaters timer to get the desired humidity temperature, when you have achieved this, plumb in the growing chambers & away you go !

Pasteurized Wheat Straw Prep TEK

Pasteurizing of wheat straw

Introduction

The following procedure is a simple method for pasteurizing wheat straw and is ideal for the small-scale home cultivator. The number one benefit of working with a bulk substrate like Pasteurized Wheat Straw (as far as the small-scale cultivator is concerned) is the impressive boost that it offers in terms of overall performance and cropping yields. Fruitbodies grown out on WS are typically much larger than ones that are grown out on grain or flour. Colonization (or Spawn Run) times are also decreased which means that the mycelium grows more rapidly in straw than it does in grain or flour.

Wheat straw is an ideal substrate for these particular mushrooms and for this particular application. In fact, given its cleanliness, ease of preparation, and nutritional benefits; it may be the best alternative for any indoor cultivation app where these (or other similar mushrooms) are concerned.

The type of straw that we will be using is known as **Wheat Straw** and is commonly used amongst commercial grow-ops for creating composts to be used with edible mushrooms that require it. For small-scale apps, straw can be used as a primary substrate for this particular kind of mushroom.

Wheat straw can be purchased at any feed store for approximately $5 for 1 bale. One Bale weighs approximately 40 lbs dried. That is a lot of substrate for the price! Other places that are likely to carry wheat straw are; gardening centers or nurseries (frequently used for landscaping). You should be able to find straw at any one of these places with little effort.

Note: *Be sure not to use an Oat or Barley type straw. Make sure that you are purchasing "wheat" straw!*

Overview

Below is a list of all the items you will need to carry out this procedure:

Large pot for boiling water (5-7 Qt.)
2 lbs or more of wheat straw
A metal grate or a heavy weight (for holding the straw under water during pasteurization.)
1 Meat probe Thermometer
A pair of scissors for cutting up straw.
A large container (for holding the chopped straw)

Wheat Straw Preparation

Place the following items in your workspace:

Bag of Wheat Straw
2 large bowls or pans

Procedure

Before you begin, you will want to fill the large pot with water (about 1/2 - 3/4 full) with tap water like so.

Place the pot of water on the stove top and turn the stove on to begin the boiling process.

The water water should be allowed to boil for 20-30 minutes before adding straw. (This gives us plenty of time to chop the straw down to size in preparation of the pasteurization process).

Chopping the straw

The straw needs to be chopped down to a reasonable size so that it is easier to work with for our particular application. Generally, wheat straw should always be chopped down to 1-3 inch lengths which allows for a better substrate medium for both the cultivator and the mushrooms. The idea is to compact as much substrate mass as possible into a given area which increases your cropping efficiency while offering the mycelium a more ideal medium to colonize over. Cropping efficiency, in this case, is determined by how much substrate can be packed into a given area. This is essentially what determines the yield for a given substrate mass or "cake". In other words; a substrate/cake that is more compact or dense will produce greater yields than one that is less dense or compact.

Since we will be using such a small container to house our substrate/cakes, we will need to chop the straw down to the minimum possible length desirable. 1 inch is a good length for this particular application.

Start by grabbing a hand full of straw, and while working over your tray or bowl, begin cutting the loose pieces of straw off the end of the bushel like so.

Work your way down, one inch at a time, until you're able to get an even edge to work from (see pic above).

Continue to cut the bushel down to 1 inch lengths and repeat this procedure until you have at least 2.5 to 3 times the amount of mass that you plan to fill. Above is a picture of the final batch of straw ready for pasteurization.

NOTE: I FOUND A REGULAR BLENDER QUITE EFFECTIVE AT CHOPPING DRY STRAW, I USED A PLASTIC CUP AS A 'PUSH STICK' TO FEED THE STRAW TO THE BLADES.

Pasteurization

In order for pasteurization to be completed, Wheat straw is bathed in a pot of water at 160-170°F for a total of 30-45 minutes.

The pot of water should have had plenty of time to come to a boil and remain for 20-30 minutes.

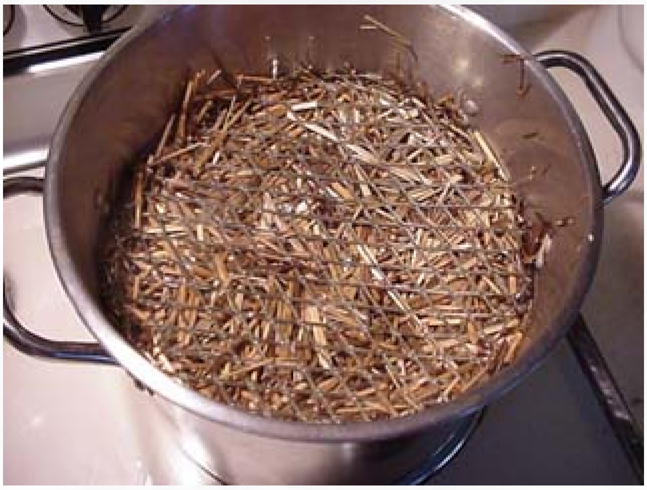
F

Before we can add the straw to the pot of water, we need to lower the temperature of the water to a point below boiling that is ideal for pasteurization to proceed. To do this; simply turn the stove dial down by 1/3 or 1/2. Using the Meat Thermometer Probe; periodically check the temperature of the water until it nears the ideal range for pasteurization (160-170°F).

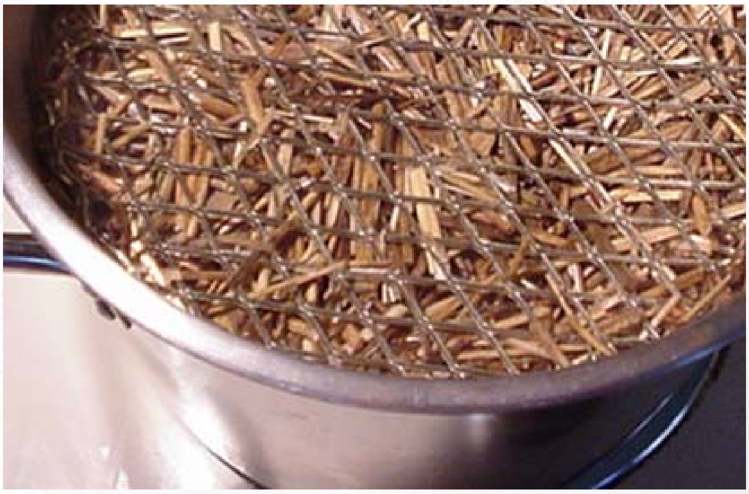
Once the water temperature is down within range; you can begin to add the straw into the water. This is the point where you should start your 30-45 minute countdown.

After filling the pot with a portion of dry straw, force the floating straw down under the water with a heavy-duty utensil for total submersion

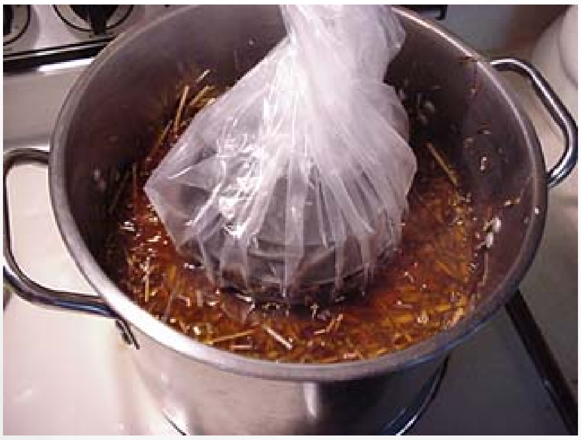
Repeat this procedure of filling and submerging the straw into the pot of water until you have added as much straw as necessary for your application (or as much as can possibly be contained in the pot your working with).



Using a grate (or some form of heavy-duty material that will allow you to hold the straw submerged under the water for the duration of the pasteurization process), force the straw down into the pot of water like so.



Here is a close up view of the type of grating that was modified to fit this pot for this particular purpose.



Now, you will need a heavy weight of some kind to place on top of the grate in order to keep the straw forced down into the pot of water. I used a couple of weights from a weight-lifting set and wrapped them in a heavy-duty plastic bag, like so.

Be sure to use the thermometer probe to gauge the temperature of the water. It's important to keep an eye on the gauge to make sure that the straw remains within the ideal range for the duration of the pasteurization process.

Draining water from straw

Once the straw has been fully submerged and pasteurized for the 30-45 minute time period, the stove should be turned off and allowed to cool down for about 10 minutes before draining the water out of the pot.

In the pic above, you can see how the leftover water from the pasteurization process was drained (and strained) into a 1 QT jar where it will be saved for another batch of grain.

Above is a picture of the final product of the drained wheat straw juice that will be used on the next batch of grain jars in place of bottled water, which will provide the spawn jar with a nutritional boost that will help to speed up the colonization cycle considerably.

Once the water has been drained from the pot, it's time to move the freshly pasteurized straw into a heavy-duty plastic bag where it can be allowed to cool down to room temperature before being spawned.

I recommend tying the bag up and poking about 20-30 holes into it with a clean nail or similar poking device and allowing it to hang for a 4-6 hour time period until it has had plenty of time to cool back down to room temperature. (see pic above).

Above is a picture of the final product after pasteurization and draining is completed.

Once the straw has cooled down to room temperature, you can proceed to the following TEK where you will find the necessary information for spawning the freshly pasteurized wheat straw with a pre-colonized jar of grain spawn.

Table of Contents

Spawning Pasteurized Wheat Straw

original source: http://mycotopia.net/archives/discus/messages/5/6734.html

Overview of spawning

Below is a list of all the items you will need to carry out this procedure:

Pasteurized Wheat Straw (cooled to room temp)
1 QT Jar of Grain Spawn (or colonized BRF)

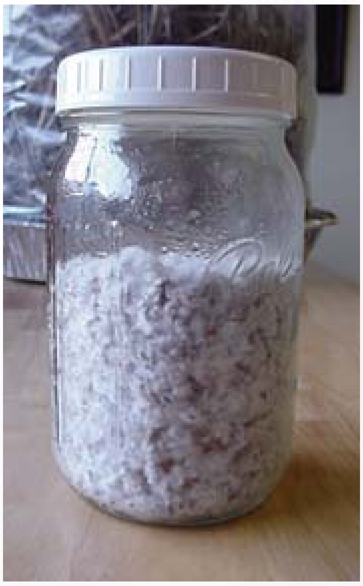
Initial Preparation

Before we begin, it's always a good idea to wash your hands and clean the work space that you will be working in before you get started. I recommend saturating a paper towel with rubbing alcohol and wiping your hands down thoroughly with it, paying close attention to your finger tips and nails where dirt can be easily trapped.

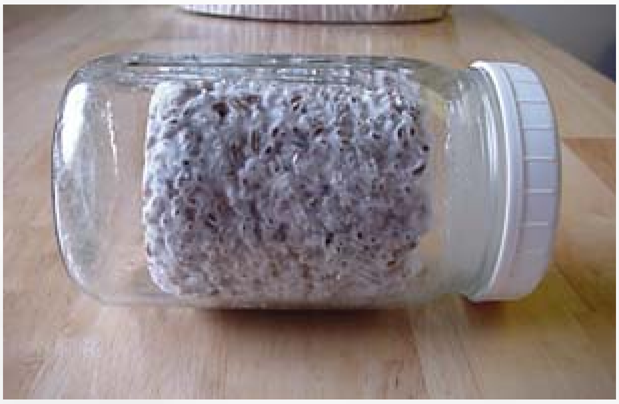
Spawn Preparation

The jar of grain spawn that you will be using to spawn the PWS with will need to be shaken first before applying to the prepared substrate. However, it is important that the grain is allowed to recover from the shaking for a 24 hour period before spawning takes place. The best time to shake the spawn jar is the day before pasteurization takes place. After 24 hours, the mycelium has had a chance to re-colonize and should be checked very closely for contamination before being used as spawn.

By doing this, you are allowing the mycelium to recover from the transitional state into an active state that will ensure rapid colonization of the wheat straw... which is very important. The mycelium needs to colonize the pasteurized wheat straw as rapidly as possible in order to beat the contaminations from taking over the substrate first. Once the mycelium has established itself in the substrate, it can easily fight off the contaminations that may be present. However, in it's transitional state, the mycelium is very vulnerable and has no way to protect itself from the competing contams that are present in the bulk substrate.

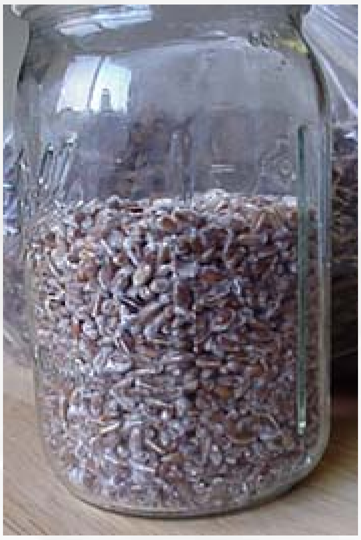


In the picture above, you can see the jar of colonized grain spawn ready to be shaken so it can be used to spawn our soon-to-be pasteurized wheat straw.



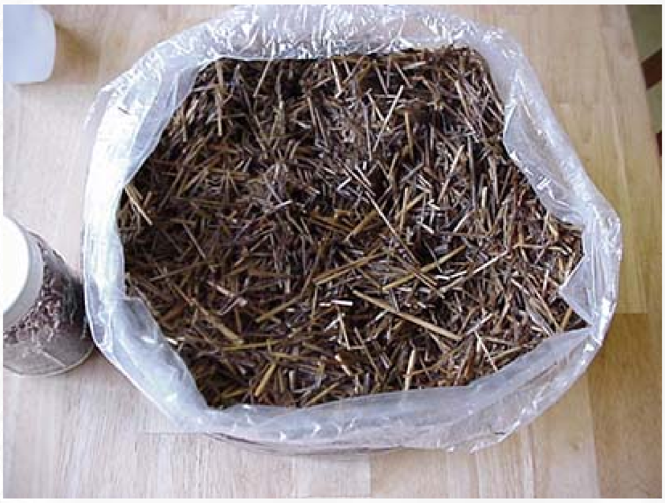
Above you can see how the colonized grain has bonded together so that when it is shaken considerably, it still remains in tact. It's important not to let a grain jar colonize much further beyond this point or you will likely never break it apart!

But, this spawn jar is right on schedule and as you can tell by the pic above, it gave in after a few good shakes.

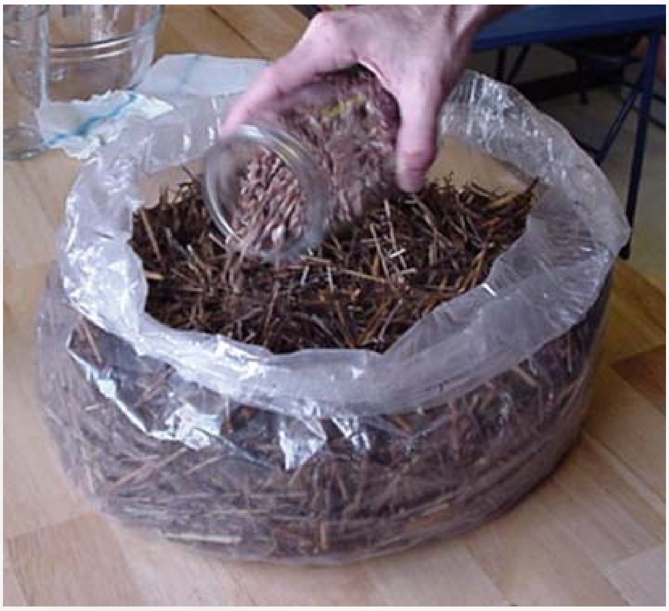


The picture above was taken directly after the spawn jar was shaken and is not ready to be transferred to the Wheat straw yet. It needs to be placed back into incubation for another 24 hour period so it can recover a little before it can be used as spawn for the wheat straw. Above is a picture of the spawn jar 24 hours after shaking and directly before being used as spawn for the wheat straw. As you can tell by the picture above, the jar of grain has had a chance to recover from the shaking that took place the day before and appears to be ready for spawning.

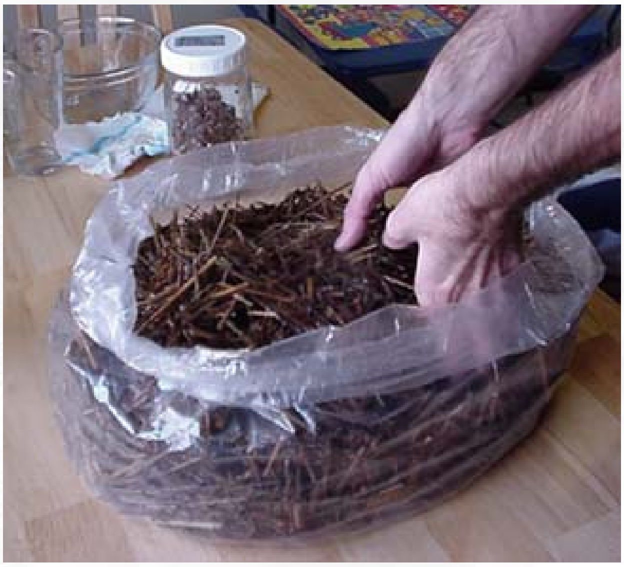
Spawning Procedure



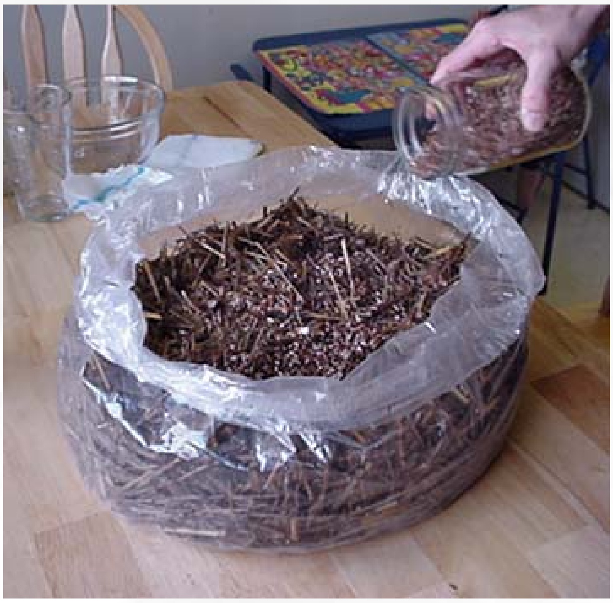
First, you will want to shake the bag of pasteurized straw and then open it up as wide as possible, like so.



Next, very lightly shake the recovering spawn jar just enough to break the kernels apart (being careful not to disturb the recovering mycelium anymore than necessary). Now open the jar up and pour about 1/5th of the grain spawn out over the surface of the straw, like so.



With clean hands (as described above); work the grain into the straw by turning it over so that the grain mixes well with the straw, like so.



Repeat the process of adding grain to the straw and mixing the two together until the entire jar of grain spawn has been added to the substrate, like so.

Once all the grain spawn has been added to the bag of straw, the bag should be tied and shaken thoroughly to ensure proper distribution of the grain kernels throughout the bag of straw.
Once this has been completed, the freshly spawned bag of Pasteurized Wheat Straw is now ready to make Wheat Straw Cakes which can be used in the terrarium.

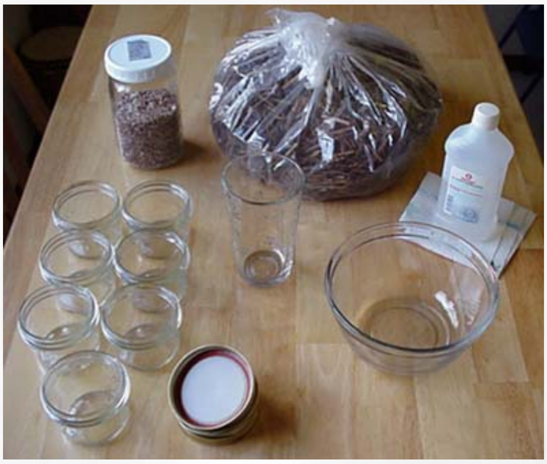
Table of Contents

Small Wheat Straw Cake Preparation

original source: http://mycotopia.net/archives/discus/messages/5/6767.html

Overview of small cake preparation

Below is a list of all the items you will need to carry out this procedure:



Spawned Wheat Straw
7 half-pint canning jars w/ lids
A bottle of Rubbing Alcohol
A paper towel
A drinking glass (optional)

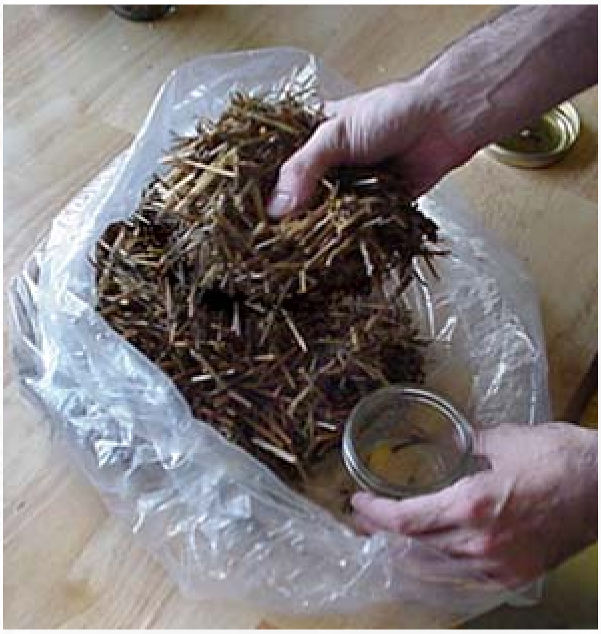
Note: The following items pictured above are not required for this TEK:
Jar of Grain Spawn
Large Glass Bowl

Initial Preparation of small cake

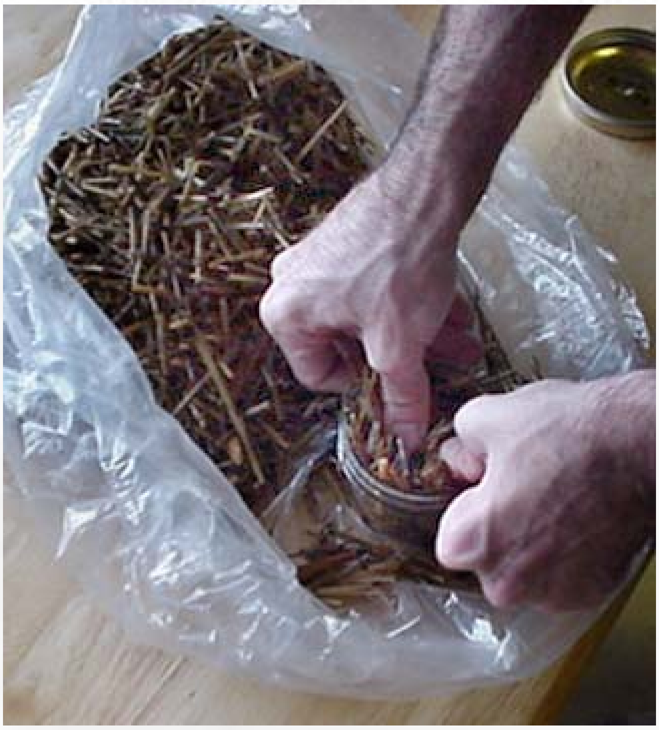
Before we begin; it's always a good idea to wash your hands and clean the work space that you will be working in before you get started. I recommend saturating a paper towel with rubbing alcohol and wiping your hands down thoroughly with it, paying close attention to your finger tips and nails where dirt can be easily trapped.

Start by saturating the paper towel with alcohol, like so.

Using the alcohol-saturated towel; wipe the glass jar clean (starting on the inside and continuing to the outside), like so.



Once the jar has had a moment to dry; it's time to begin adding the straw to it. Working over the bag of straw; start by adding a very large handful, like so.



After a large handful of straw is added; using both of your thumbs and working around the jar in a circular manner; press firmly down on the straw in order to compact it, like so.

Continue repeating this procedure of adding straw to the jar and compacting it with your hands, like so.

You'd be surprised at how much one of these half-pint jars can hold when you pack the #### out of one!
Note: A drinking glass can also be used to compress the straw down into the jar. (I prefer using my hands).

Continue adding and packing the straw until you end up over-filling the jar with straw to the point that it can't possible hold anymore. Now, it's time to add the lid to the jar. To do this, you will want to apply a lot of pressure to the lid as you tighten it to a close.

After the lid is tightened onto the jar, it's time to wipe it clean with the alcohol-saturated towel like so.

That's it! Just repeat the process until all the jars are filled, like so.

Once all the jars are filled and cleaned, they are now ready to be placed back into the incubation chamber so the mycelium can colonize them in preparation for the pinning/fruiting stage.

Note: *It's a good idea to shake the bag of straw and grain spawn up after each jar is prepared to help re-distribute the grain kernels back into the straw because the grain tends to fall through to the bottom of the pile as it gets handled.*

Table of Contents

Large Wheat Straw Cake Preparation

original source: http://mycotopia.net/archives/discus/messages/5/6744.html

Overview of large cake preparation

Below is a list of all the items you will need to carry out this procedure:

Spawned Wheat Straw
A 1.5 Qt capacity Glass Bowl
A bottle of Rubbing Alcohol
A paper towel

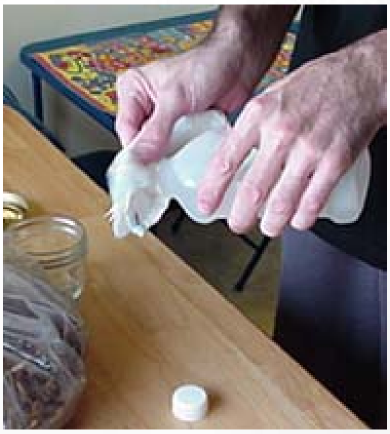
Additional Items required: (not pictured above)

A small sheet of Tin Foil
A small plate
A weight of some kind (needed to compress the straw down into the bowl)

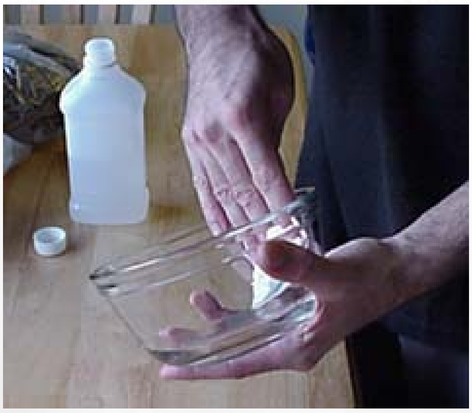
Note: The following items pictured above are ***not required*** *for this TEK:*
Jar of Grain Spawn
7 half-pint canning jars w/ lids
A drinking glass

Initial Preparation of large cake

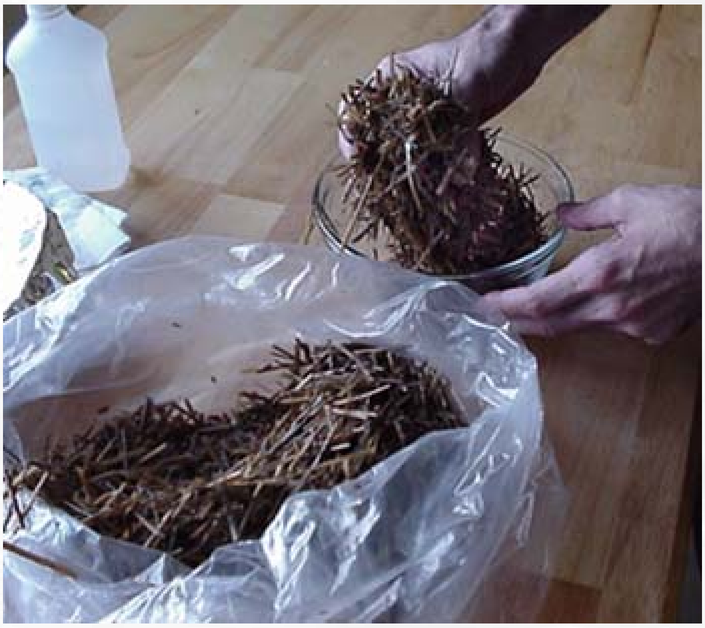
Before we begin; it's always a good idea to wash your hands and clean the work space that you will be working in before you get started. I recommend saturating a paper towel with rubbing alcohol and wiping your hands down thoroughly with it, paying close attention to your finger tips and nails where dirt can be easily trapped.



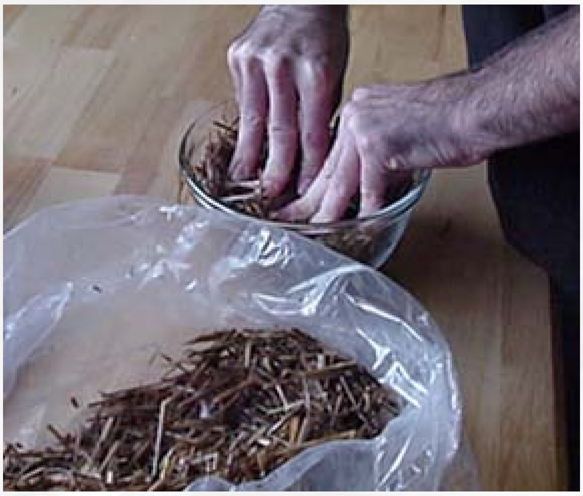
Start by saturating the paper towel with alcohol, like so.



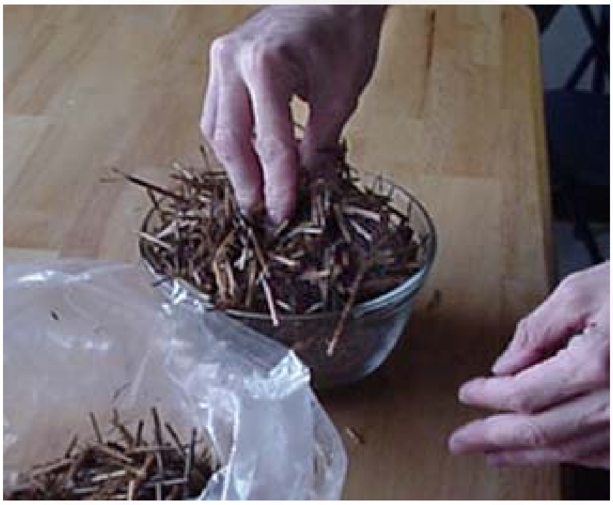
Using the alcohol-saturated towel; wipe the glass bowl clean (starting on the inside and continuing to the outside), like so.



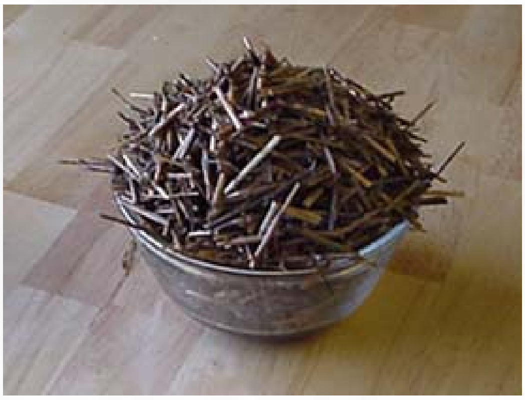
Once the bowl has had a moment to dry; it's time to begin adding the straw to the bowl. Start by adding a large handful, like so.



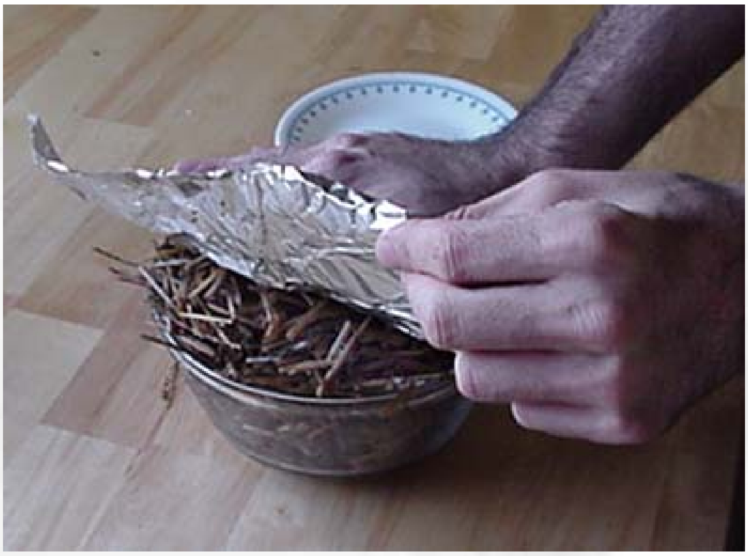
After a large handful of straw is added; use your fingers to press firmly down on the straw in order to compact it, like so.



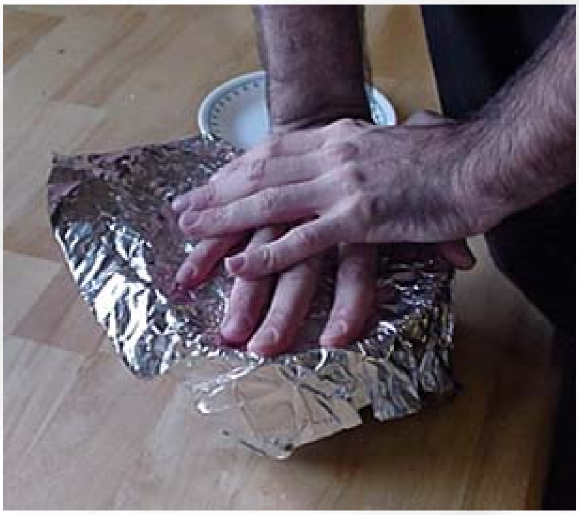
Continue repeating this procedure of adding straw to the bowl and compacting it with your hands, like so.



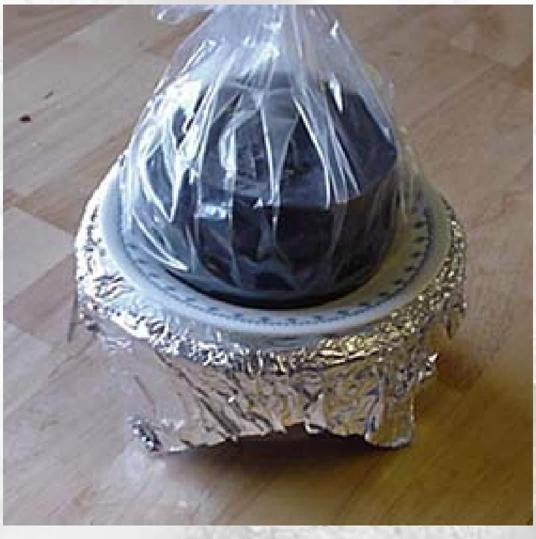
Continue adding and packing the straw until you end up overfilling the bowl with straw to the point that it can't possible hold anymore, like so.



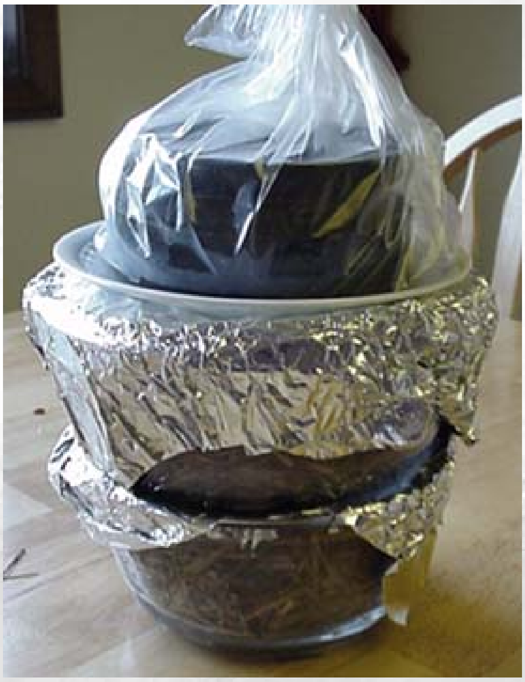
Now it's time to cover the straw with foil, like so.



After you have covered the straw with a sheet of tin foil; you will now want to press firmly down on the bowl of straw with both of your hands as best you can to compress the straw down into the bowl, like so.



Using a small plate like the one pictured above; place the plate over the tin foil-covered bowl of straw and place a weight over the top to help compress the straw down during the incubation phase.



If you are working with more than one bowl of straw, then you can stack them for efficiency, like so.

That's it! The cake is now ready to be placed back into the incubation chamber so the mycelium can colonize it in preparation for the pinning/fruiting stage.

Cold Water Lime Pasteurization For Growing Mushrooms

Using lime and cold water to pasteurize substrates without heat

Intro

I'll admit, pasteurizing straw in hot water with a propane burner can be a bit of a pain.

You need a large burner, a full propane tank, and plenty of time to make sure the whole process goes smooth. Even more of a pain, it needs to be done outside or in a large shop - because you can't set up a propane burner in your living room!

Which leaves many new growers wondering...

"Isn't there another way to pasteurize large amounts of straw?"

Yes!

It's called **Cold Water Lime Pasteurization**, and it's a cheap and effective *low-tech* way to prepare substrates for growing mushrooms.

The process is simple. You basically just **soak straw for 12-24 hours in a bath of cold water** that has been treated with **hydrated lime**.

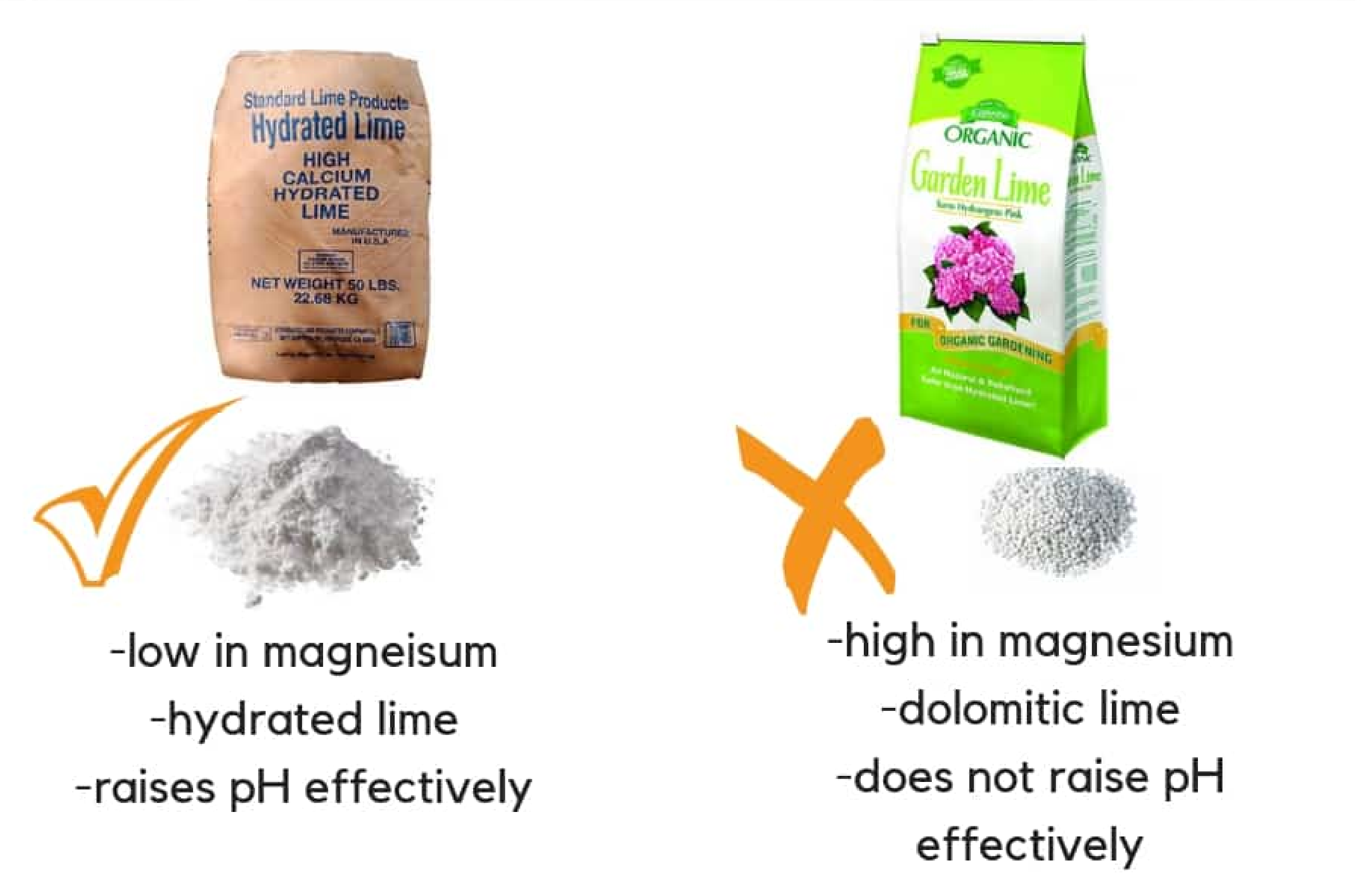
The lime will rapidly and *dramatically* increase the pH of the water, causing the mold spores, bacteria, and other contaminates in the straw to be killed off.

Once drained, the substrate can be inoculated with your mushroom spawn. The mycelium will then be able to grow in squeaky clean straw, unhindered by other competing organisms - for at least a little while!

What Is Hydrated Lime?

Hydrated Lime is basically just Calcium Hydroxide, chemically known as $Ca(OH)_2$, and is often used in industry for a whole whack of different reasons, from pickling cucumbers to treating sewage water.

This white powder is known by a many different names. BUT - not all Lime is created equal, and **some types will *not* work** for growing mushrooms.



Standard Lime Products
Hydrated Lime
HIGH CALCIUM HYDRATED LIME
NET WEIGHT 50 LBS. 22.68 KG
ORGANIC
Garden Lime
FOR ORGANIC GARDENING
-low in magneisum
-hydrated lime
-raises pH effectively
-high in magnesium
-dolomitic lime
-does not raise pH effectively

✘ What Type of Lime WON'T Work?

Make sure you don't get the type of lime that is used for treating garden soils, or buffering substrates. This is too weak! It is typically found at garden centers in pellet form or crushed stone.

This is **Calcium Carbonate Lime**. You might see it called a bunch of different names including dolomitic lime, garden lime, quicklime, limestone, chalk, and many more. This will not be effective in raising the pH high enough, or fast enough to kill the contamination. (check out wikipedia for a quick primer ('limer?) on pH)

Also, you want to make sure that the lime you use is **low in magnesium**, and high in calcium.

This type of lime is typically WAY high in magnesium. High concentrations of magnesium will retard the growth of mycelium, even after the substrate is drained and inoculated.

✓ What Type of Lime WILL Work?

The type lime you want is **Hydrated Lime** that is **low in magnesium**.

This white fluffy powder is manufactured by a process that treats "quicklime" with water, changing the chemical structure by converting *oxides* to *hydroxides*.

Keep in mind that it is possible to find garden variety "hydrated lime" that is high in magnesium. This will not work. Chances are, you'll need to go to an agricultural supply store or similar to find the correct type of lime. It isn't always easy to find, so if you have trouble trying to get some, don't be surprised!

The lime I used was picked up at a local UFA, and is the type typically used to treat drinking water on acreages.

How Does Lime Work?

Lime works by rapidly altering the pH of the water, making it extremely alkaline and killing off the contaminates in the substrate.

Once drained off, the substrate has a low concentration of living contaminates, giving mushrooms the upper hand.

I haven't tested it, but I'm guessing it's a combination between the substrate pH coming back down to earth after being drained AND the mycelium's natural ability to be resilient in high pH environments. Either way it works pretty well!

> **SAFETY FIRST**
> Hydrated Lime is potentially hazardous - so be careful when handling it.
>
> I like to wear gloves, safety glasses and a mask. Getting it on your skin can cause rashes and

burns, breathing it into your lungs can cause respiratory issues, and getting it in your eyes can be especially dangerous.

Always use protective equipment and don't say I didn't warn you!

Cold Lime Step By Step

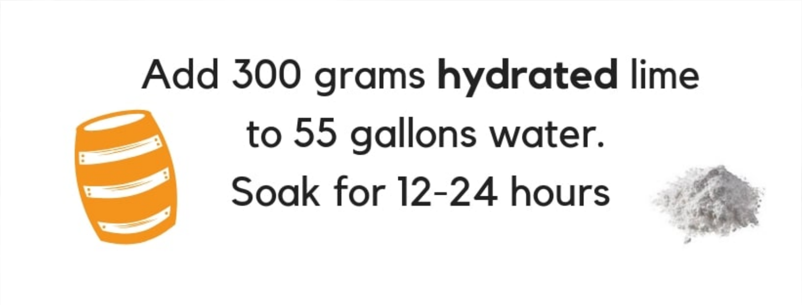
This type of substrate treatment is easy for most people to do at home.

It's even used by some small-scale commercial mushroom growing operations that want a low-tech, cheap and effective way to pasteurize straw.

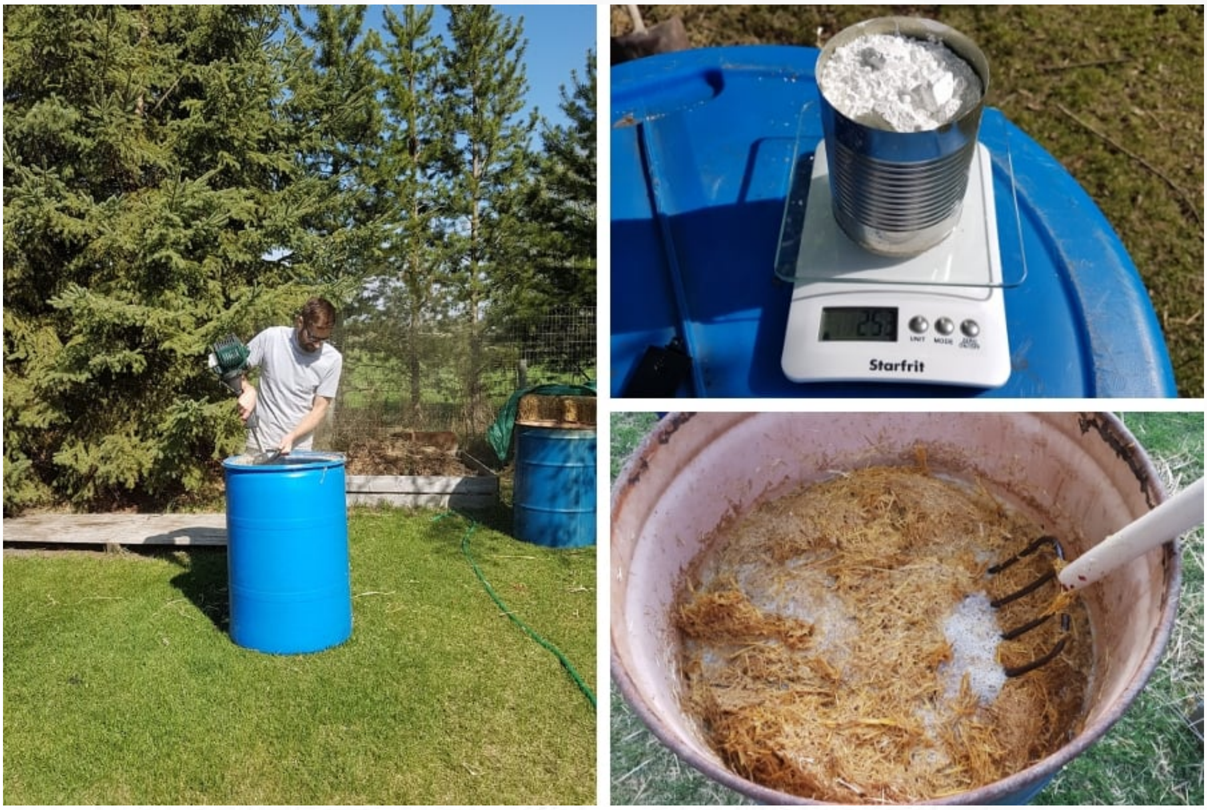
The overall process is very similar to growing mushrooms on straw with heat pasteurization, the only difference is to replace heat with lime.

What You Need

- Hydrated Lime (about 6 grams per gallon of water used)
- Water
- A 55 gallon drum, or large tote
- Straw (wheat straw or oat straw)
- Poly Tubing or Other Suitable Cropping Container
- Spawn, about 2.5lbs per 25 lbs wet substrate.



Add 300 grams **hydrated** lime
to 55 gallons water.
Soak for 12-24 hours



STEP 1: PREPARE STRAW

Chop your straw into 2-3" pieces. You can do this with shears if you have a small amount, or by whipping it up with a weed-whacker in a large drum.

This is not 100% necessary, but chopping the straw impacts how easily the mycelium can work it's way through the straw, and makes the nutrients in the straw more accessible.

The result of chopping is faster colonization, and very likely a **much bigger yield**.

STEP 2: PREPARE WATER BATH

Add the hydrated lime to the water in a large drum or tote.

A good rule of thumb is to use about **6 grams of hydrated lime for every 1 gallon of water**.

If you have a 55 gallon drum of water almost full (50-55 gallons of water), this equates to about 300-330 grams of lime. (*doesn't have to be exact*)

If you don't have a scale, you can estimate with volume and use about 1-1.5 cups lime per 55 gallons of water.

STEP 3: ADD STRAW AND SOAK

Add your straw and soak in the lime bath for 12-24 hours.

Ensure that the straw is evenly mixed though the water bath so that it is all treated equally. Straw floats, so you might want to place something heavy on top to ensure full submersion. I like to use a cinder block and a metal grate on top of the straw to hold it down.

STEP 4: DRAIN AND INOCULATE

After 12-24 hours of soaking, remove the straw and let it drain for 20 minutes of so. You don't want to leave it so long that new contaminates have a chance to settle in the substrate, but you also want to ensure that most of the water drains off so that the straw is not overly wet.

Inoculated the straw at a rate of 10-15%. You can either mix it all together, or place it down in layers. One of the best options for cropping container is poly-tubing. I like to use 14" lay flat diameter tubing, which makes straw logs that are about 9" in diameter.

Make sure that you cut holes in the poly tubing to allow for the mycelium to breath while colonizing. I like to use an arrow head and stab holes all around the log, every 4 inches or so. Make sure you also place holes in the bottom of the log so that any excess water can drain off.

STEP 5: COLONIZE AND FRUIT

The straw should colonize relatively quick, depending on the species and the spawn rate. The mycelium should start growing right away. Place the log in a room temperature environment away from direct sunlight. In 10-14 days, the log should be fully colonized and ready to be placed in fruiting conditions.

That's it! Again, it's very similar to the process for heat treated straw. Takes a little longer, but requires less work overall.

A Recent Grow With Hydrated Lime

I just finished up a grow using Cold Pasteurization of straw and had some pretty good results!

For this grow, I chose Blue Oyster (*Pleurotus columbinus*) and Yellow Oyster (*Pleurotus citrinopileatus*) because they're both fast growing, high yielding strains that typically do well on straw substrates.

I decided to fruit them outside, because the conditions were right, and because growing these species outside can produce some nice large fruits without too much hassle!

First step, I chopped the straw using a weed whacker in a large decommissioned rain barrel. I then soaked the straw for about **18 hours** in a **55 gallon drum** full of cold hose water and about **300 grams hydrated lime**.

The straw was then piled up on a large mesh screen for about 20 minutes to drain. It's surprising how much the color of the straw changes after the lime water bath!

It appears *so* much more yellow/gold from the treatment. At first, I thought the straw might have been fried in some way... but it turned out to be no problem at all!

Once drained, I stuffed the straw into poly tubing and inoculated it with grain spawn. Instead of mixing the spawn and straw *before* loading the tubes, I decided to add the spawn to the log in layers.

This involves grabbing handfuls of straw, stuffing it into the log, sprinkling a thin layer of spawn, and then repeating until you run out of straw or spawn. The result is a kind of "layer cake" of spawn and straw - which, believe it or not, will colonize just about as fast as if it were thoroughly mixed.

Keep in mind - If you decide to use this method, make sure that you really press down each layer as you are making it, so that there are no large air pockets or areas of loosely packed material.

Once the logs were stuffed, I stabbed the outside of the log with an arrowhead, about once every 4 inches or so. This included perforating the bottom of the log so that any excess water can drain off as the log colonized.

BLUE / PAST
05/14 w LIME

The logs were brought into a cool storage area, inside, so that they could colonize. After about a 7-10 days, the logs were fully colonized, and ready to be brought outside.

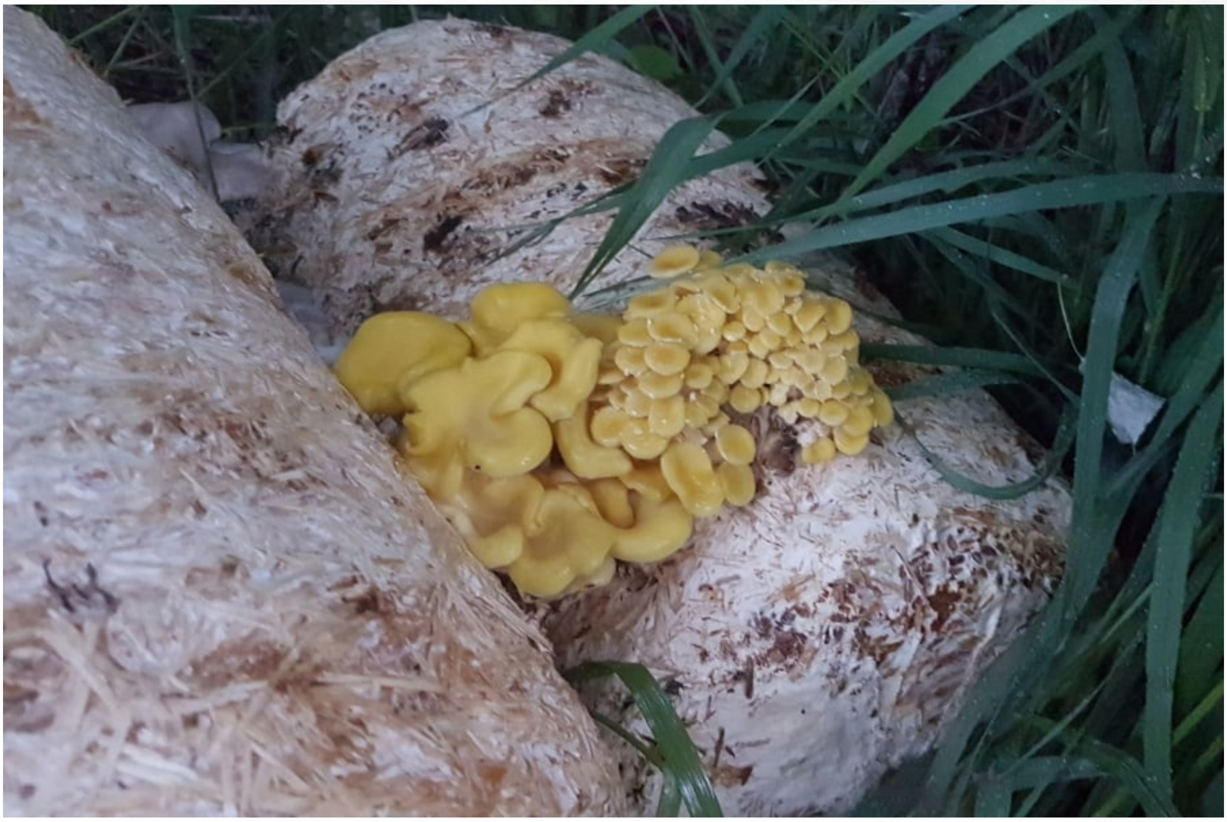
I hung these logs in a custom-made arbor, complete with a poly windscreen to help prevent the fruits from drying out. Oysters definitely need LOTS of fresh air, but if there is a constant wind, even just a slight breeze, the fruits will inevitably dry out and abort. You can usually remedy this by placing the log near the ground, deep enough into the trees, or simply draping it in poly sheeting.

The two logs fruited nicely!

The Blue Oyster, of course, had no problems producing some nice large cluster. I did however have to get 'em pretty early so that the bugs didn't take over.

The Yellow Oyster also fruited nice, although I didn't manage to snag any pictures.

That being said, once I thought the log was totally done, I stripped off the poly tubing and threw it in the compost pile... where it decided it wasn't done yet! This happens often, especially with Oysters, who just like to keep fruiting and fruiting and fruiting.



Other Low-Tech Methods

Of course, both heat pasteurization and lime pasteurization are effective, but they aren't the only way to treat your substrate. There are some other methods that are cheap and effective, that you might want to try for yourself.

Anaerobic Pasteurization

Although there are a million different types of bacteria and other contaminates that can affect your grow, you can divide them into two groups - **aerobic** (oxygen loving) and **anaerobic** (oxygen hating). Basically, some contaminates need oxygen to thrive, while others need a complete lack of oxygen in order to survive.

We can take advantage of this to manipulate conditions and pasteurize a substrate without heat, lime, or any other chemicals. The basic process involves soaking a substrate (such as straw or wood chips) in water, draining, and then placing in a **sealed** container. 5 gallon buckets work really well.

If properly sealed, the **aerobic** contaminates will eventually die off, and the **anaerobic** contaminates will proliferate.

Once the container is opened, and the substrate is exposed to the air, the anaerobic contaminates will die off, and there won't be any aerobic contaminates to worry about, at least for a little while. This gives the mushroom mycelium enough of a head start to take over the substrate.

This topic really deserves it's own post, hopefully I'll get to that soon!

Laundry Detergent and Soap

Some people have had success using **laundry detergent**, or even just regular dish soap.

I guess it makes sense, because soap is antibacterial and I'm sure laundry detergent is the same. Although I haven't tried this myself, the process involves soaking a substrate in cold water with laundry detergent for a day or so, in a very similar fashion to cold water lime pasteurization.

I imagine this might work OK for home and hobby growers, but is not something that would make much sense to do commercially.

Also, I would be a little concerned about the quality of the mushrooms if the substrate is pasteurized in this way.

Ash Pasteurization

Wood ash has also been used to successfully pasteurize substrates. It works in a similar way to hydrated lime, by raising the PH enough to kill off contaminates in the straw.

Some have reported that this method actually results in the **best yields of any method**, and considering it is a low cost material in many parts of the world, Wood Ash Pasteurization might be the best way to go for many growers.

Give Lime A Chance

I haven't run any strict trials, but many growers report that hydrated lime pasteurization actually has a much **higher Biological Efficiency** (BE) than steam pasteurization.

Some growers will actually calculate the exact amount of water needed, so there is no excess high pH water to get rid of. For example, if you had 25 lbs of dry straw, you would use about 10-12 gallons of water, most of which will be absorbed by the straw. This is much different than hot-water pasteurization, where you need to dispose of all the hot water.

All this and you don't need to wrestle hot straw, continuously monitor temperatures, and burn off expensive propane.

Don't you think it's worth giving lime a shot? I sure do!

Straw Log Tek

by

Skyypilot

original source: http://mycotopia.net/archives/discus/messages/5/26684.html

The inspiration for this Tek came from reading Paul Stamets book, Growing Gourmet and Medicinal Mushrooms. He describes a similar process for growing Oyster mushrooms on straw in vertical columns, where the fruits only form at holes you have previously punched. This works great if you're working with a strain of edible which will cooperate that way, but many mushroom strains simply want to fruit wherever they choose. It is for those strains of edibles that this Tek is intended. Although all edible and dung loving mushrooms love fruiting on pasteurized straw, the author wishes to make clear that this Tek is intended for the cultivation of legal, edible mushrooms only.

The Tek assumes the grower is familiar with grain spawn production, because building a 36" log, which we will be doing in this Tek, requires from 4 to 6 quarts of colonized rye or corn. If you're using smaller than quart (.9 liter) jars of colonized spawn, you'll have to do the math to figure how many to use. More spawn is better, as fast colonization of straw is essential. The pasteurization process doesn't kill all the contaminants; it only renders them harmless for approximately two weeks. If the mycelium hasn't colonized the substrate by then, contamination naturally will occur. The pasteurization process also spares the 'good bacteria' which help the mycelium to naturally fruit better, as well as to help fight off contaminants. If one were to put straw into a pressure cooker and sterilize it, harvests would be much lower as a result of killing these beneficial bacteria, and it would be considerably more susceptible to contamination. I've worked hard to put together what I think is the most concise and easy to follow directions for pasteurizing small amounts of straw on the net today.

Pictures accompany every step. Don't cut corners, and you'll be guaranteed success. I've tried to shrink the pictures as much as possible without sacrificing detail, to make downloads faster. I would recommend the reader print a copy of the Tek for future use.

1) Ok, the first step is to get a bale of straw from the local co-op or feed store. If you can find organic straw, it is preferable, because any contaminant or pesticide that is in the straw is likely to end up in the fruit bodies. The feed stores in my area carry organic barley straw and it works great. I know that wheat straw would also work.

2) Using whatever tools are at your disposal, chop the straw into 1-3 inch lengths. This is VERY important. The mycelium simply doesn't like to colonize straw if it can't get inside the hollow interior of the stems. Consider any length of straw longer than your pinky finger as too long. It's a pain in the neck, but don't cut corners here. Your project will fail.

3) Once the straw is cut, put it in a Sterlite or Rubbermaid container (or anything else similar, like a clean trash can) and cover it completely with hot tap water. I use the sink sprayer, to wet the straw evenly as the container fills. When you have enough water in the tub, place a screen and weight over the straw to push it down under the water. It needs to 'pre-soak' like this for at least an hour, but not longer than 2 hours. This is to hydrate the straw.

4) During the time the straw is hydrating, you need to get the pasteurization bath ready. You will need a container large enough to hold 14-16 gallons of water, plus the straw. Place one Sterlite or Rubbermaid container inside another for the insulation properties the dead air space between them provides. A very large insulated ice chest would also work well for this. The idea is that you want to hold the temperature of the pasteurization bath for an hour and a half. Without insulation of some sort, the bath will cool off before the time is up and not be effective.

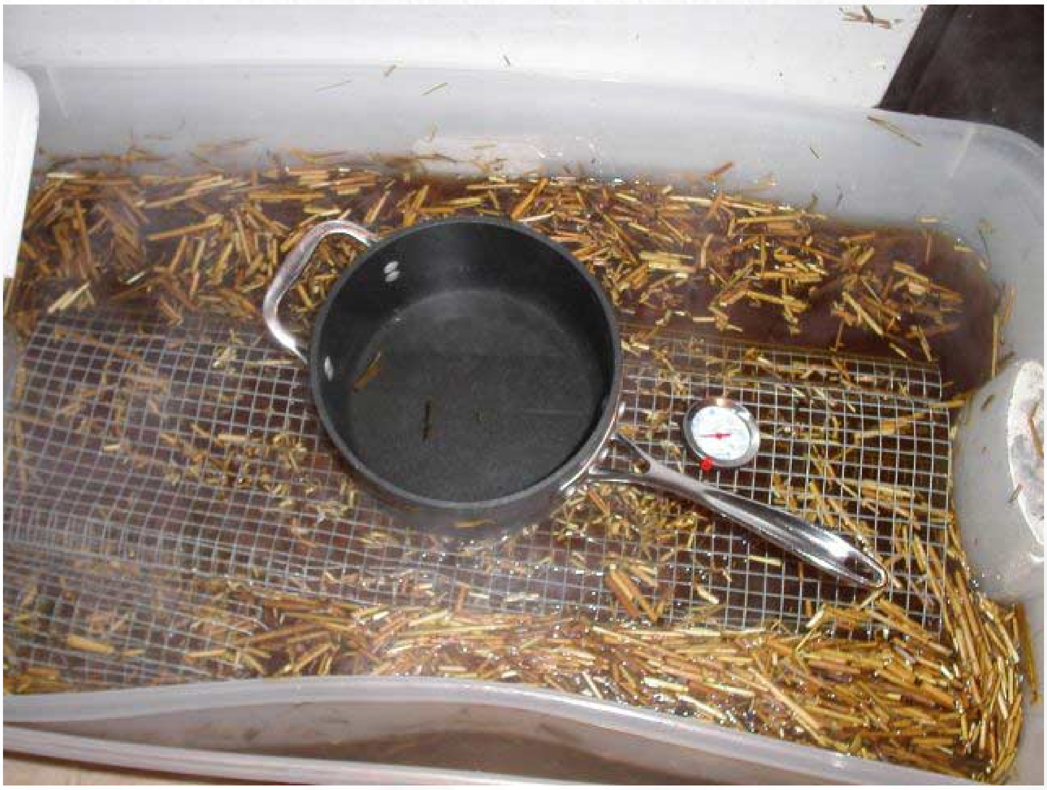
Don't start this process until the straw is soaking, or else the pasteurization bath will be ready before the straw is hydrated, and either you put the straw in too soon, while it's still dry, or the water cools off too much waiting on the straw. What you want is to have a temperature of 140F-160F, after you put the wet straw into the hot water bath. I've found the best way to do this is to heat up six gallons of water on the stove until it boils. The two pots you see in the picture add up to six gallons between them.

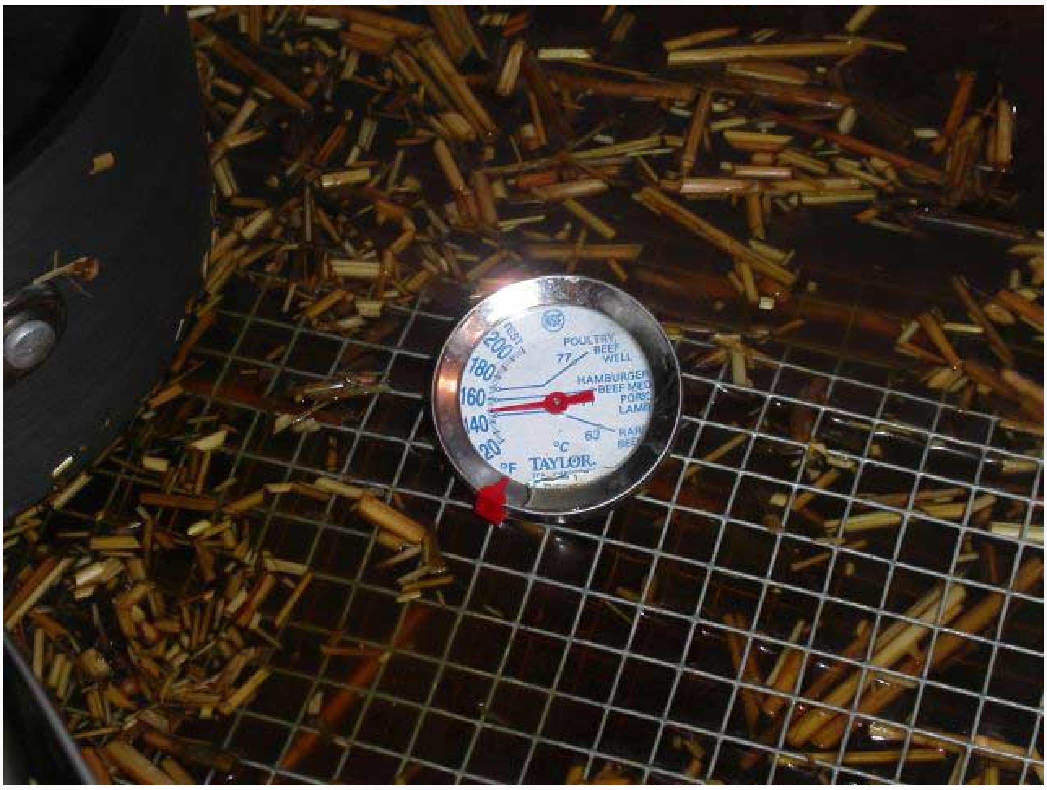
When you have six gallons of water on the stove boiling, place two gallons of plain hot tap water into the clean tub, before pouring the six gallons of boiling water into it. Immediately place the two lids on the container to hold the heat in. Refill the pots with another six gallons of water and set them on the stove to boil. When this water boils, it will make 14 gallons total so far. Just before pouring in the second batch of boiling water, it's a good time to add the lime. Use ½ cup of hydrated lime for this recipe which uses 14-16 gallons of water. Be sure to stir the lime into the water very well. If you're making a larger or smaller batch, adjust the lime accordingly. This will give the water a ph of 12-13 before the straw is added. This radical swing in ph, along with the heat will render the contaminants inactive for a couple of weeks.

Hoffman
Hydrated Horticultural
Lime
A hydrated lime that helps reduce soil acidity.
Satisfaction Guaranteed
Net Wt. 5 lbs.

5) Once you've added the second batch of water, it's time to put the wet straw into the pasteurization bath. At this time, the temperature of the bath will be around 180F, but as soon as you add the wet straw, it will cool it down to the proper range of 140F-160F. Simply use your hands to lift the straw out of the bath, let it drain briefly, then place it in the pasteurization tub.

Once all the straw is in the bath, stir it around gently to lift any lime that has settled on the bottom of the tub. Place a screen (hardware cloth works great) over the straw, and put whatever object you have handy on top to keep the straw submerged. Don't worry about a few floaters that escape the screen. They will pasteurize just fine floating on the surface. You don't want to mash it all the way to the bottom or pack the straw tight while in the bath, because you want the hot water to be able to circulate throughout the straw during pasteurization.





Now, put the double lid on the tub to hold the heat in, and leave it alone while you go clean up all the mess you just made. Make a note of the time. Check on it after 45 minutes, and if the temp is approaching 140F, go ahead and add a couple more gallons of boiling water to bring the temp back up. Don't worry about adding more lime. After an hour and a half, it's done. Don't go more than an hour and a half either, or you'll kill too much of the 'good bacteria'.

6) Ok, it's been an hour and a half and it's time to take the straw out of the pasteurization bath. Place the screen that was holding the straw submerged into the bottom of a clean tub, and transfer the straw to this new tub to drain/cool.

Cooling will take an hour or more. Don't waste all your hard work, by spawning hot straw. It will kill the mycelium. Leave the lid off the tub so air can get to it, and if it's cool outside, take it there. Don't worry about contaminants landing on your straw; Millions of them will, but with the high ph of the straw, they won't be able to grow for at least two weeks, and your log will be pinning by then anyway. By that time the mycelium will be strong enough to fight off all invaders.

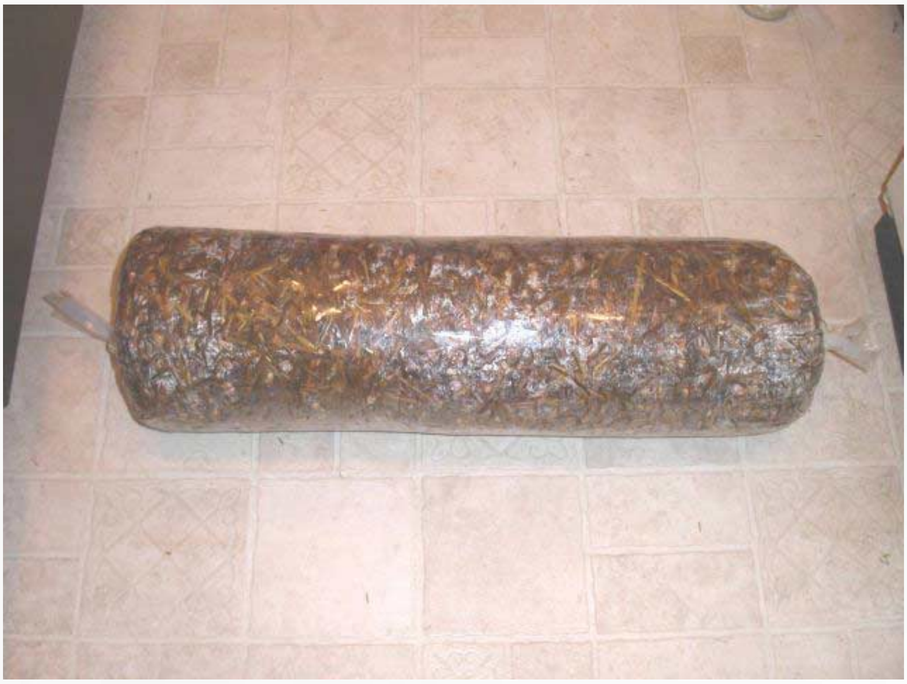
7) Now that your straw has cooled to room temperature, it's time to move it from the screen it's been draining on, to a clean tub for spawning. (You DID wash the pasteurization tubs while the straw cooled didn't you?) Don't squeeze it out or anything. The water that drains naturally while the straw cools will leave it at the right moisture content for spawning. At this time, cut your tubing to the appropriate length. We're making a 36" log, so cut it 18" longer than that.

Tie a knot in one end of the tube, and using a sharp kitchen knife, poke a few small holes in the plastic near the knot. These holes are to let the air escape as you pack the log. Take the 4-5 quarts of colonized grain or corn you have so carefully incubated, and beat them against a car tire to loosen up the kernels so they can be poured out into the tub of straw. I like to start with 2 quarts right on top of the straw.

Mix it into the top two to four inches only, before loading this top layer of spawned straw into your tube. Add another quart of spawn and mix it in, and continue the process until you reach the bottom of the tub, and your log is built. It seems to work better to thoroughly mix the spawn into the straw, as opposed to making a layer of straw, followed by a layer of spawn. This next part is VERY IMPORTANT. As you fill your log with straw, hold the straw in your hand, and gently sprinkle it down into the tubing, making sure it spreads evenly. You don't want big clumps of straw, with air cavities between them. After each handful or two of straw, stop and pack it down really tight with your hand.

Hold the tubing in one hand and pull up, while you stick the other hand down the tube and push down on the straw with all your might. I weigh close to 200 lbs., and I push down on the straw as hard as I can. It's very important that the straw is packed tightly into the tube. The mycelium can't colonize across large air gaps, so spread the straw out evenly, and push it down really good. Don't stand on it or use mechanical means to get it tighter. Just push as hard as you can with your hands, and that will be perfect.

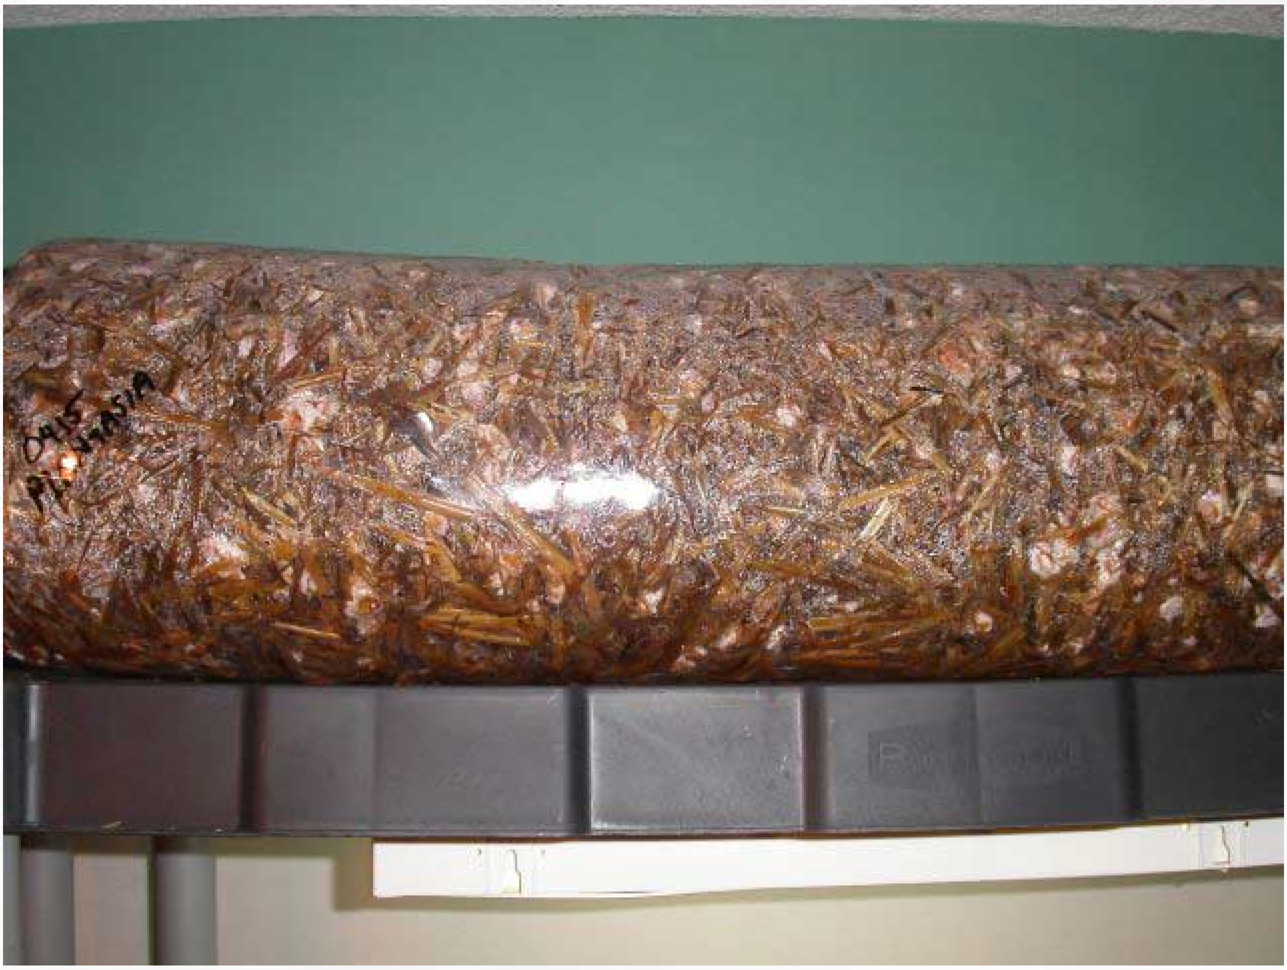
8) Now that you've filled up your tubing to within 9 inches of the top, it's time to tie the second knot, sealing the log. Push the straw down really tight, and squeeze the neck of the tubing against the straw. Holding the tubing with one hand, spin the log around with the other to wrap up the plastic tubing so you can tie a knot in it. Just make sure you tie the knot right against the straw, so the tubing keeps the straw tight. Now lay the finished (almost) log on the floor, and with both hands, roll it gently back and forth, to even up the surface. Roll it like a piece of dough, to get it very smooth on the outside surface.



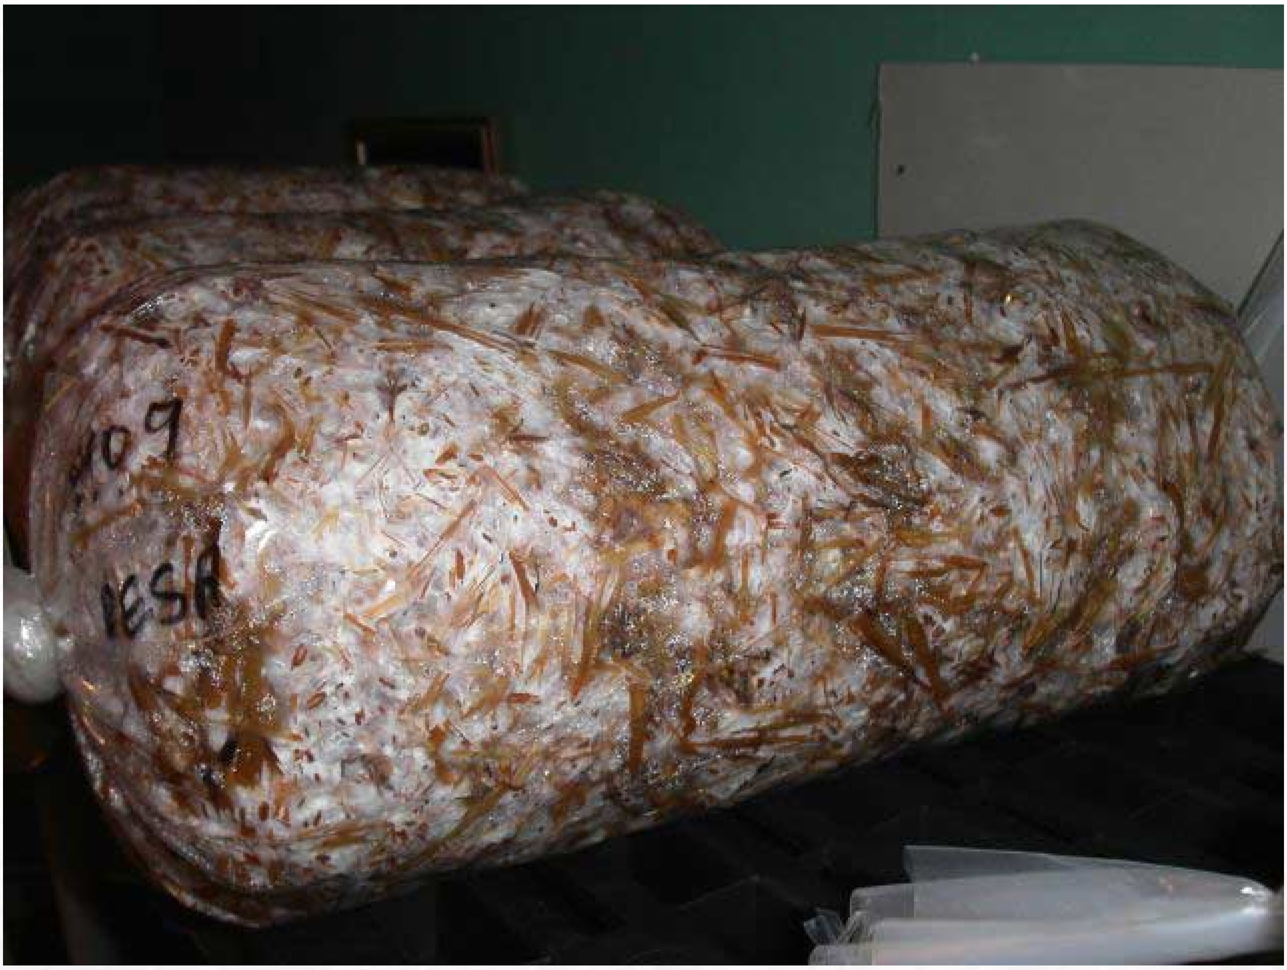
This is an important step to help achieve full colonization. Now, carefully take your log, and place it on the shelf you are going to incubate it on. Leave it alone for 3-5 hours, but not longer than 8 hours before doing this next step.

9) Almost done. Your log has been sitting for 3-5 hours now, so the moisture content has had a chance to equalize. All that packing during filling had pushed your moisture to the bottom of the bag. Some excess water may have run out the small slits you cut in the bottom of the tubing while you packed. That is good. Now, for the mycelium to colonize the straw, it needs a small amount of air exchange. It doesn't need a lot of air, just some. Also, you want to keep as much of the CO2 inside the log as you can during colonization. I use a hunting arrowhead to punch holes into the tubing. You can just as easily use a sharp knife, or box cutter. Cut slits in a + shape about every 2 to 3 inches all along and around the log. The slits only need to be half an inch or so long. Just make sure no place on the log is more than 3" from a vent. The idea is to have a small amount of air exchange, while maintaining moisture content. Now, put your log into its final fruiting location, and don't touch it again until you see pins forming invitro. This will be in two to three weeks. The growing mycelium HATES to be handled, so resist the temptation to pick up your log, or otherwise disturb it. Let it be exposed to normal room lighting during colonization, and don't let the temps get too high. Room temperature is fine. With a marking pen, record the date and strain on the end of the log.

The logs will produce more than casings, and much faster than casings, hands down. Yeild is hard to pinpoint, because so many other factors come into play, such as the age of your spawn (senescence), vitality of strain, temps and humidity, your ability to LEAVE THE LOGS ALONE to colonize, etc. Here's the catch 22; larger logs yeild much better, but they are more likely to get bruised by handling if you move them in any way. I found by experience that smaller logs don't bruise as easily, but they tend to dry out sooner, and the fruits are smaller. Here's an example of how fast this works. This picture is the 36" log built 24 hours ago to demonstrate this tek. As you can see, the corn is already growing out.



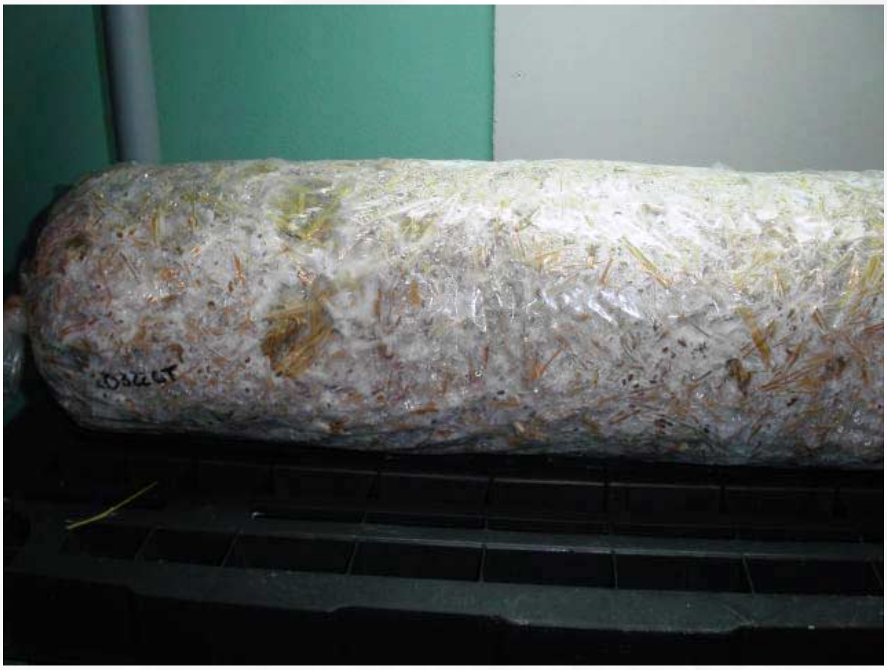
The picture below is a log spawned 7 days ago. Almost full colonization!



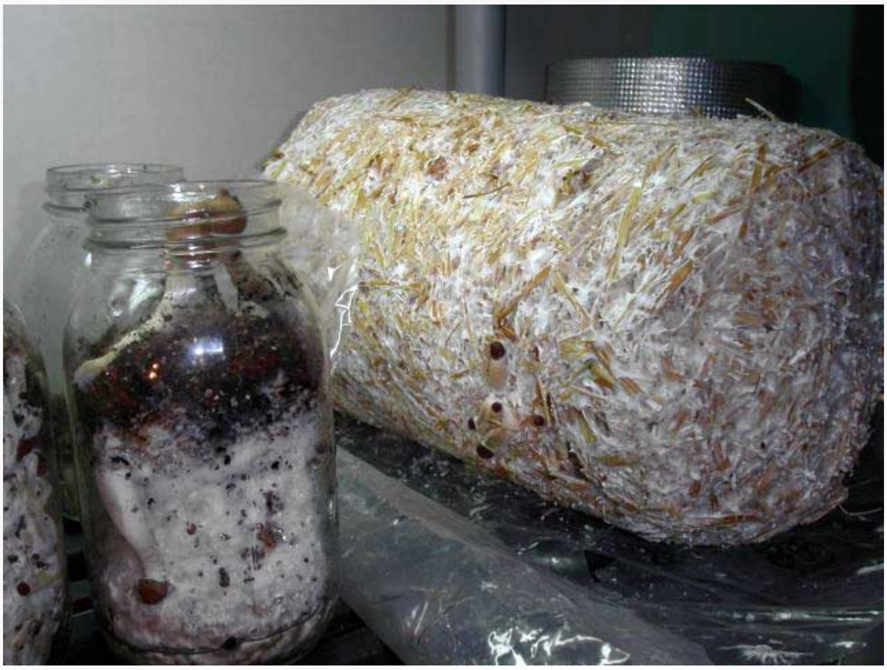
10) It's day fifteen, and you have pins! You've noticed for a few days already, that you had full colonization. It's time to birth your log. Try to do this without moving or disturbing the log in any way. Use sharp clean scissors to carefully cut the knots off both ends of the log. You'll have to cut a circle around the knot to get it off. You can't cut the whole knot off in one snip, because it's up against your log, and you'd bruise the mycelium. Once the knots are cut off, carefully cut the tubing lengthwise along the top edge of the log, trying not to touch the mycelium with the scissors. Peel the plastic down and away from the log, exposing the entire surface to air, then gently and loosely fold it back into place. There should be lots of air gaps around the log now. Once each day, fold the plastic back, then immediately replace it. This will stimulate a massive pinning. You can cut another length of tubing to go over the top of the log where the seam is, to keep it from drying out. Be sure to cut lots and lots of holes in this plastic. All you want to do is slow down the rate of evaporation, so you don't have to mist. You do want lots of constant air exchange. If you see a great deal of condensation forming on the plastic sheeting, make the holes a bit bigger. As your log fruits, the mushrooms will push the plastic away from the log as they grow. Don't worry about the fruits being in contact with the plastic. It won't hurt or bruise them. They'll love the humidity, and you'll love not having to constantly mist.

original source: http://mycotopia.net/archives/discus/messages/5/26705.html

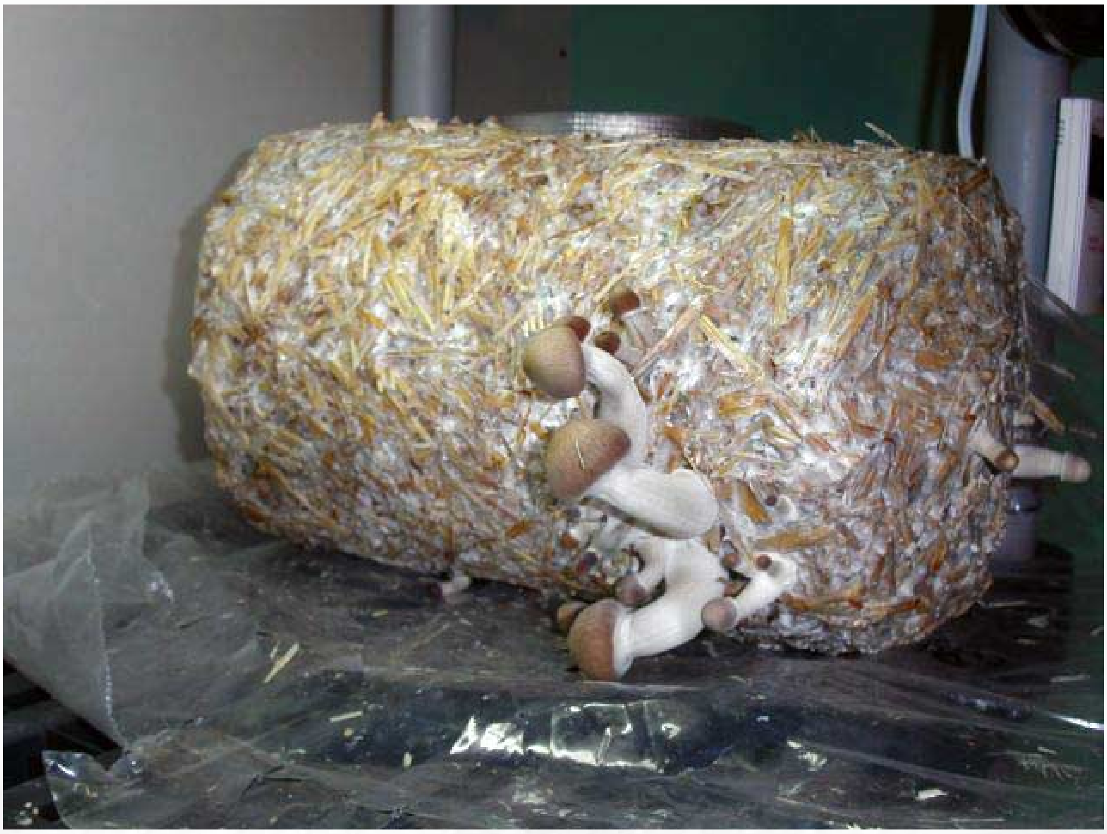
I've been working on this new TEK for a few months now, trying to perfect the process. I hope a bunch of you will try it and let me/us know how it goes. I think it's the next logical progression from the Laundry Basket TEK, because it completely eliminates the need to mist. The straw gets colonized inside a vented plastic tube, so the moisture and CO2 stays inside where it belongs. After the first few pins form (invitro), you cut the plastic off, and use it as a 'humidity tent' to allow air exchange while keeping the evaporation level under control, so the most awesome flushes can develop. I'll write the full TEK and post it here if anyone is interested. These straw logs produce the FASTEST and largest crops I've ever seen. The logs you see in the pix below were pinning on the 14th day after spawning with grain. The longest I've waited for pins to form was 18 days. Some were spawned with rye, and some with corn. I've made straw logs anywhere from 12" in length up to 72". The smaller ones are easier to handle, and I've stopped making them any longer than 24" for that reason. The six foot log weighed in at over 100LBS, and was very hard to move after full colonization without bruising the mycellium. The fruits form in a full 360 degrees around the log, so the yield is incredible. You don't case, don't fan, and don't mist! The 48" log you see below produced 17 lbs of fresh mushies, including the 74 gram fatty, on the first flush, from less than a dollars worth of straw. It was spawned with 6 quarts of either rye or corn, I forgot which. (I've even mixed rye and corn together in the same log) The 72" log 'only' produced 18 lbs, because I damaged it quite a bit getting the plastic off. After full colonization, they don't like to be moved, because if the log flexes, it bruises the mycellium. Try to let them incubate where they will fruit at. I incubate mine on a shelf in a 72F room. Enough heat is produced by the mycellium running through the straw, that if it was in much warmer of a room, it would overheat and kill the myc. The 12 inch log shown below has over 100 pins on it, so I think smaller logs are the way to go.



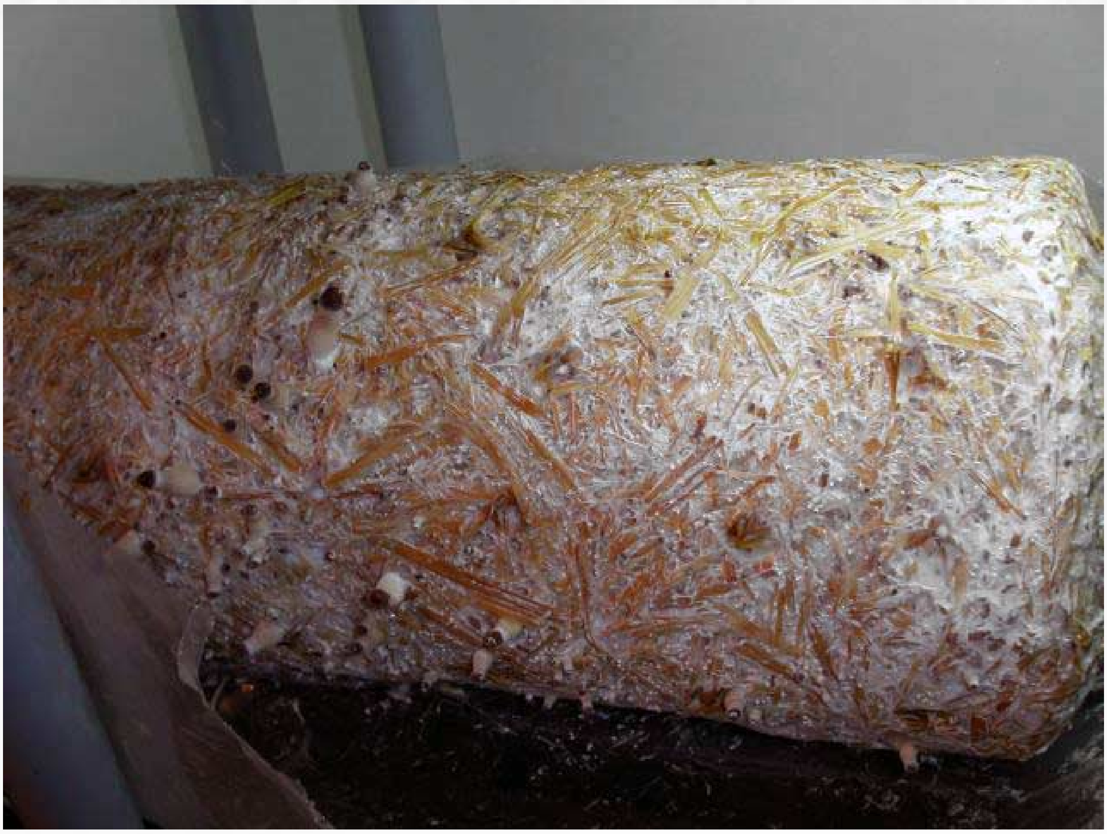
Full Colonization. Invitro pins forming. The two spots you see at the left that aren't fully colonized is where I didn't pack the straw tight enough in the tube. You want to really pack it with all your weight, so it's pressed tight against the plastic tubing.



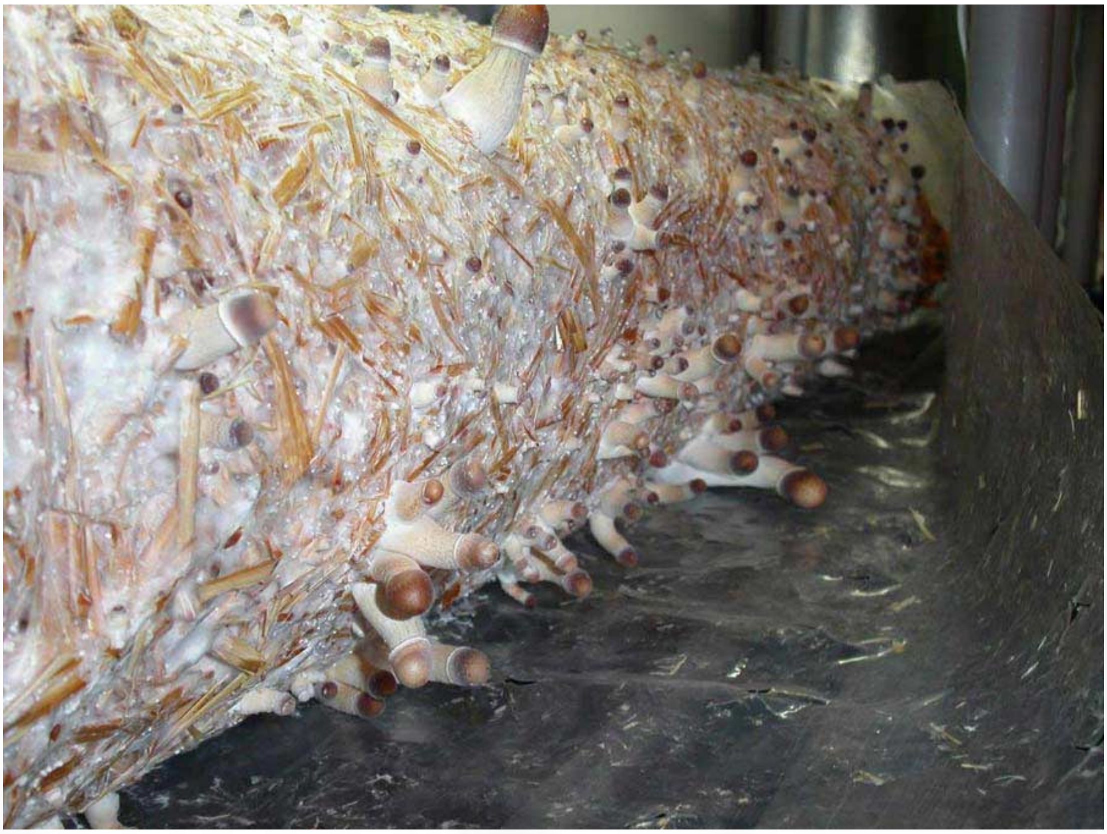
A 12 inch log that has just been 'birthed'. Use scissors to cut the tubing along the TOP edge of the log, and let it serve as a 'tray' for the log to sit on. (you can cut another piece of plastic to lay loosely over the top to keep the humidity up, just be sure to poke lots of holes in it for air exchange) Also if you HAVE to move the log, use the plastic so you don't touch the log.



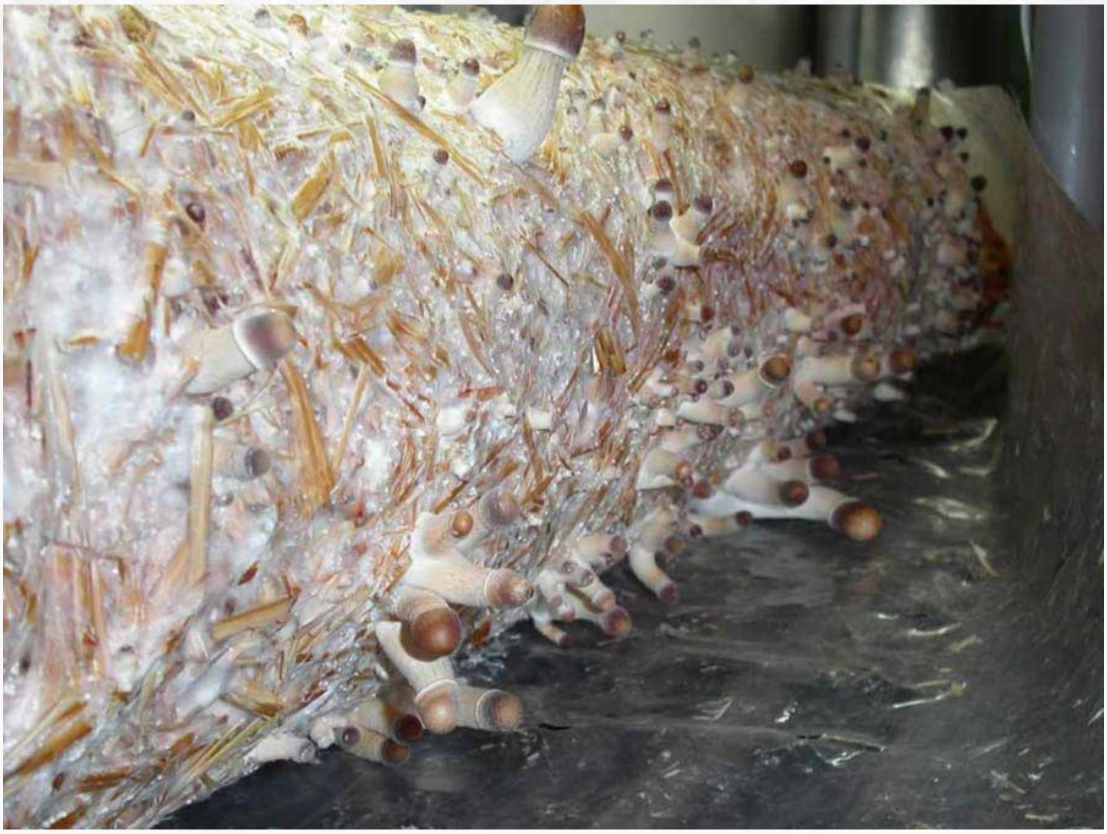
The same 12" log, 24 hours later.



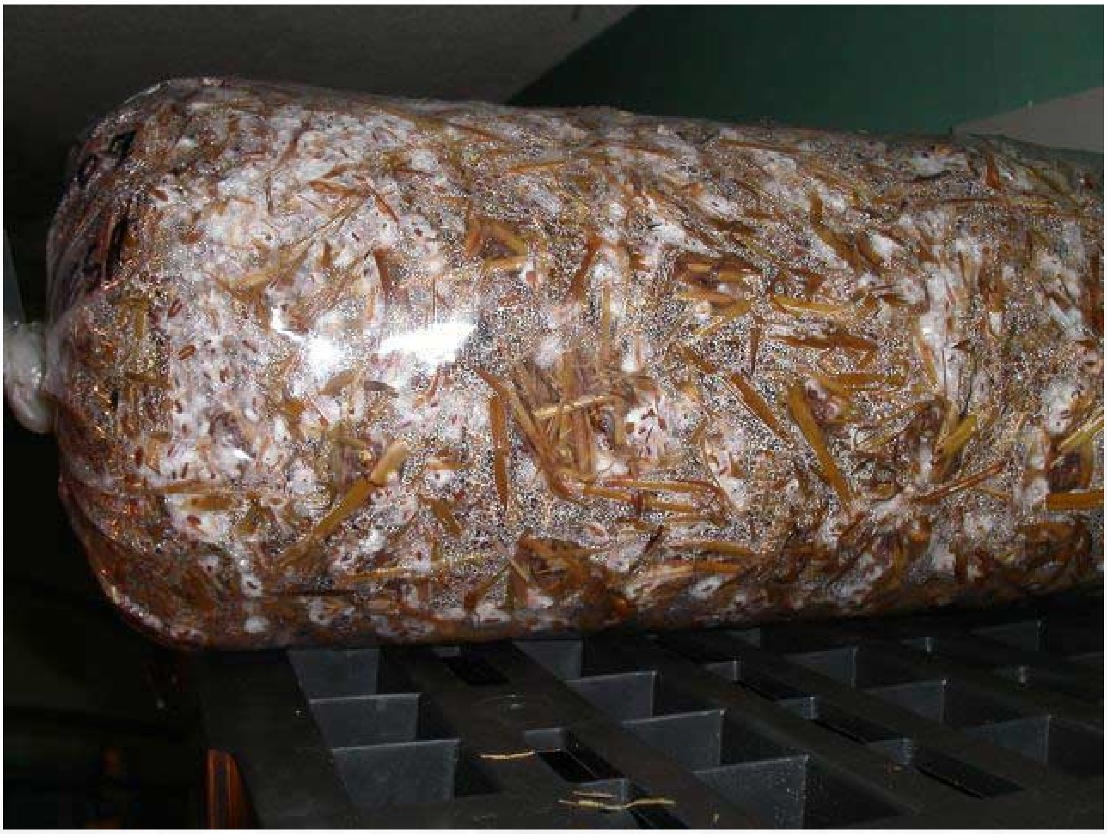
This is a 48" log, 24 hours after birthing.



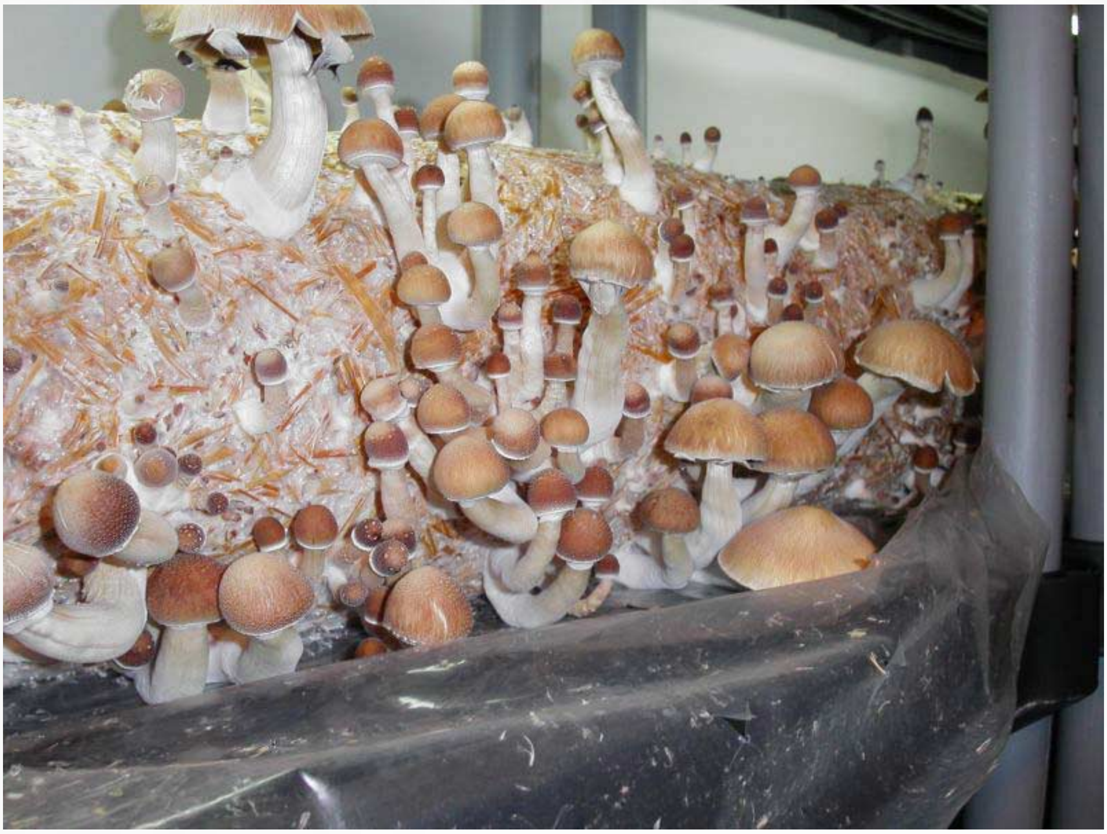
The same log, 48 hours later. Notice how the pins just exploded! I counted over 800 pins before I lost count. All on less than a dollar's worth of straw!



Here's a 24" log, on the second day after spawning. You can clearly see the mycellium growing out of the rye, and into the straw.



I've only pulled 5 aborts out so far! For some reason, they don't abort on the logs. I don't know why. I've had ZERO contams, probably because the straw colonizes so fast, and this is in a house with wall to wall carpet. Hell, I even build the logs on the kitchen floor. Can't think of a worse place, but it's all I have.



Hungry?

Mushroom Mans Sock Log Tek

by

Mushroom Man

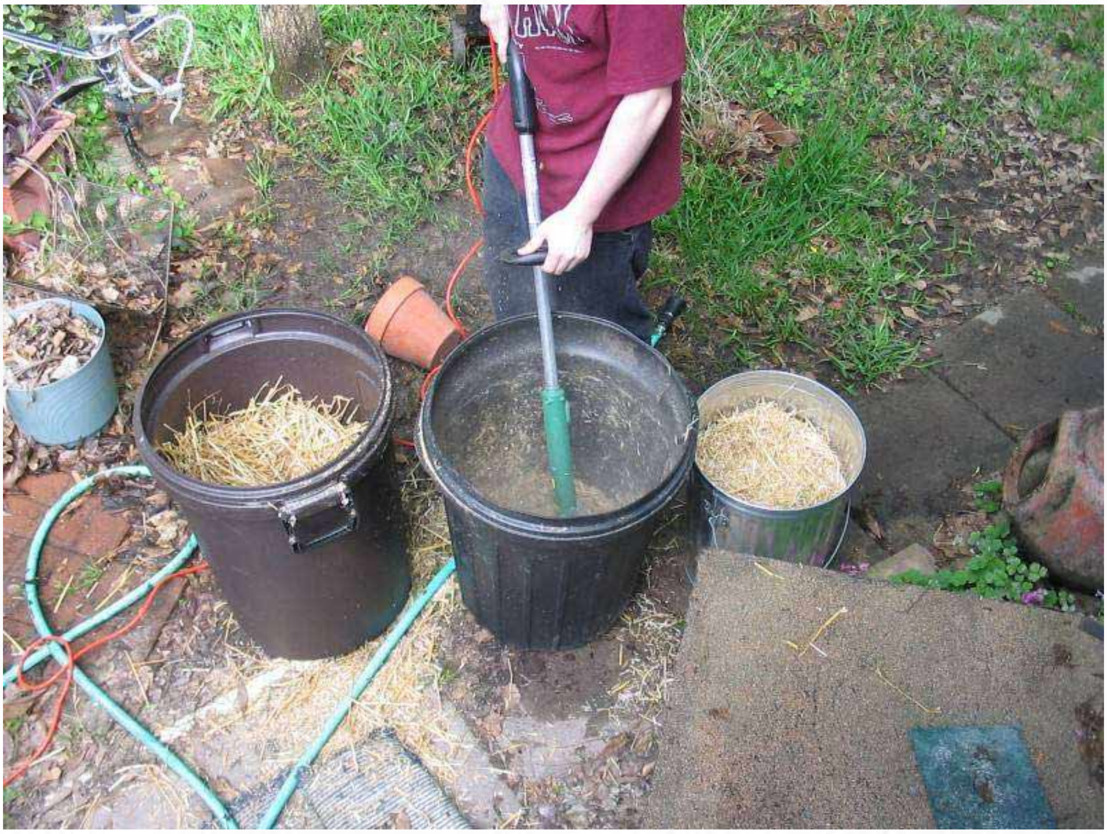
original source: http://mycotopia.net/archives/discus/messages/5/135826.html

I'll try to make this easy for ya, so i'm including this list of supplies you will need to get before doing this tek.

Supplies.

- Straw (Can be found at most feed stores for $4 a bale.)
- Something to chop the straw. (Scissors, weed eater, lawn mower, chipper/shredder)
- Colonized grain (You can use WBS, rye, or any other suitable grain)
- Drainsleeve Filter Fabric Sock for Perforated Drain Pipes (Home Depot $20 for 100ft)
- Insulated Cooler (For holding your pasteurizing straw)
- Form to pack straw in (4in PVC pipe, or wood frame.)
- Zipties (You can skip this one if you are good at tying knots)
- Vermiculite (Found at hydroponic stores and nurseries)
- Pillowcase (To hold straw while pasteurizing)
- Thermometer (So you don't overheat the straw)
- Craft Hoop(Used for stretching fabric in to stitch through. Can be found at craft stores)

The first step is to chop up your straw. You need to get the pieces of straw somewhere between 1 and 3 inches long. What I do is i use a weed eater to chop it in the bottom of a trashcan. It really shreds it, almost to the point of being straw flakes. Another way to chop it is by hand. Chopping by hand can become a real pain after a few logs. Another good way to chop it is with a lawnmower, or leaf shredder. Its not too important to get the straw the perfect size, just around the right size, you can have some long pieces here and there, doesn't matter. In the picture you see the unchopped straw on the left, the straw being chopped in the middle, and the chopped on the right.



The second step is to get the straw in a pillowcase and get it soaking in lukewarm water. You need to do a one hour soak before pasteurizing the straw. One pillowcase full of straw will be enough for 3 foot long logs. After the hour long soak, you take the straw out of the water and let it drain while you do the next few steps. First get a large insulated cooler with a lid, and pour a few large pots of boiling water in (enough to cover the straw thats draining). Then, use your thermometer to check the temperature of the water, when the temperature drops to 180, put the pillowcase of straw into the cooler, and close the lid. You might need something to hold down the straw while it pasteurizes. Once you put the straw in the cooler, you start a timer for 1 hour. After one hour, you open up the cooler and check the temperature with a thermometer. If the temperature is down to 155 or lower, add a pot of 180 degree water to bring the temp back up. If the temp is high enough, then just close the cooler and leave it for another hour to finish its full 2 hours of pasteurizing. Once the straw is done pasteurizing for 2 hours, take it out and let it drain until it cools. You can let it drain overnight if you want. Here is a picture of the straw during pasteurizing.

The next step is to toss the straw into a tub to do your mixing in, i recommend doing half a pillowcase at a time. After the straw is in the tub, you can throw in some vermiculite to add moisture, you can use anywhere up to 50% vermiculite for your logs without negatively effecting yield (it can actually yield more with verm). To get the vermiculite ready, bake it in an oven at 400F for about 30 mins, then rehydrate with water.

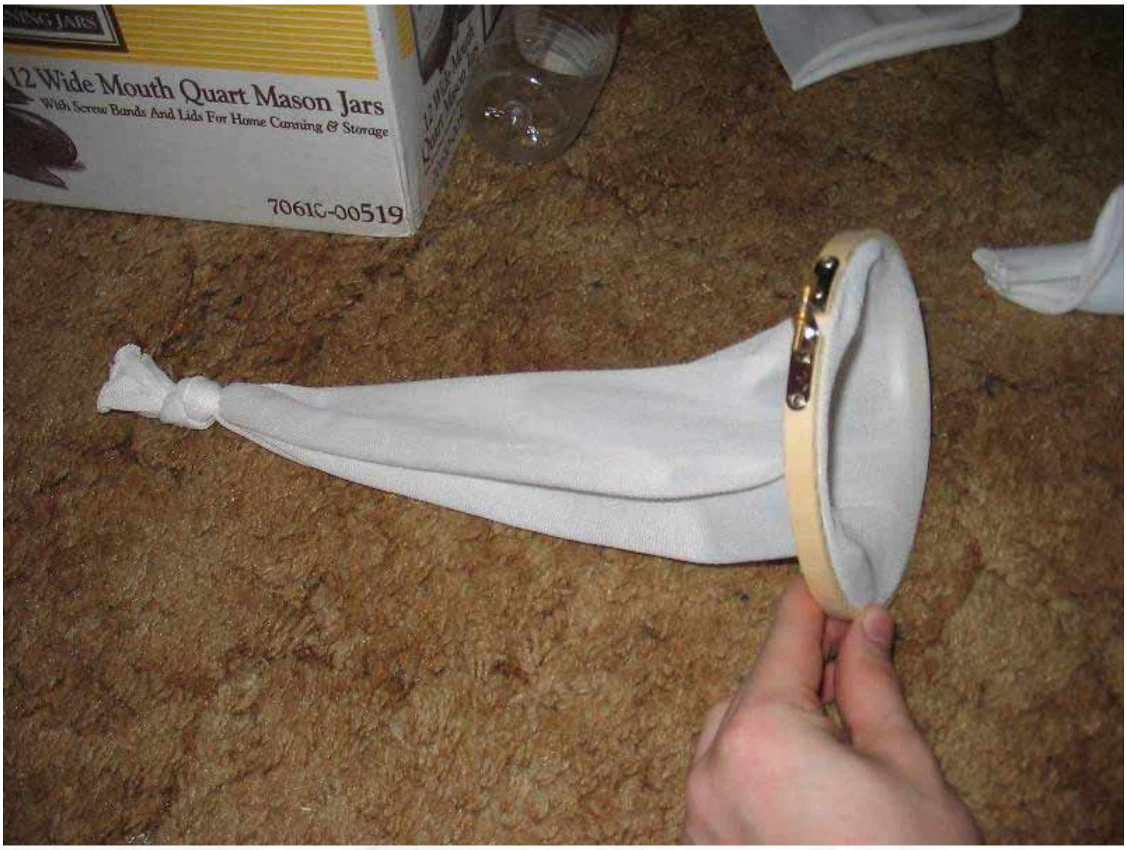
Then, toss in some colonized grain. For every full pillowcase, you need 2 quarts of grain, and half a pillowcase is 1 quart. Make sure the grain is good and crumbled up so it mixes in good.

Then, mix it all up. The grain usually falls to the bottom of the tub while mixing so make sure to grab the straw seed mix and roll it over and mix that around to get it evenly everywhere (you'll understand when you do it).

Okay, now that its mixed real good, you can start on getting the fabric tube ready. First, cut off a section about 1 1/2 feet long.

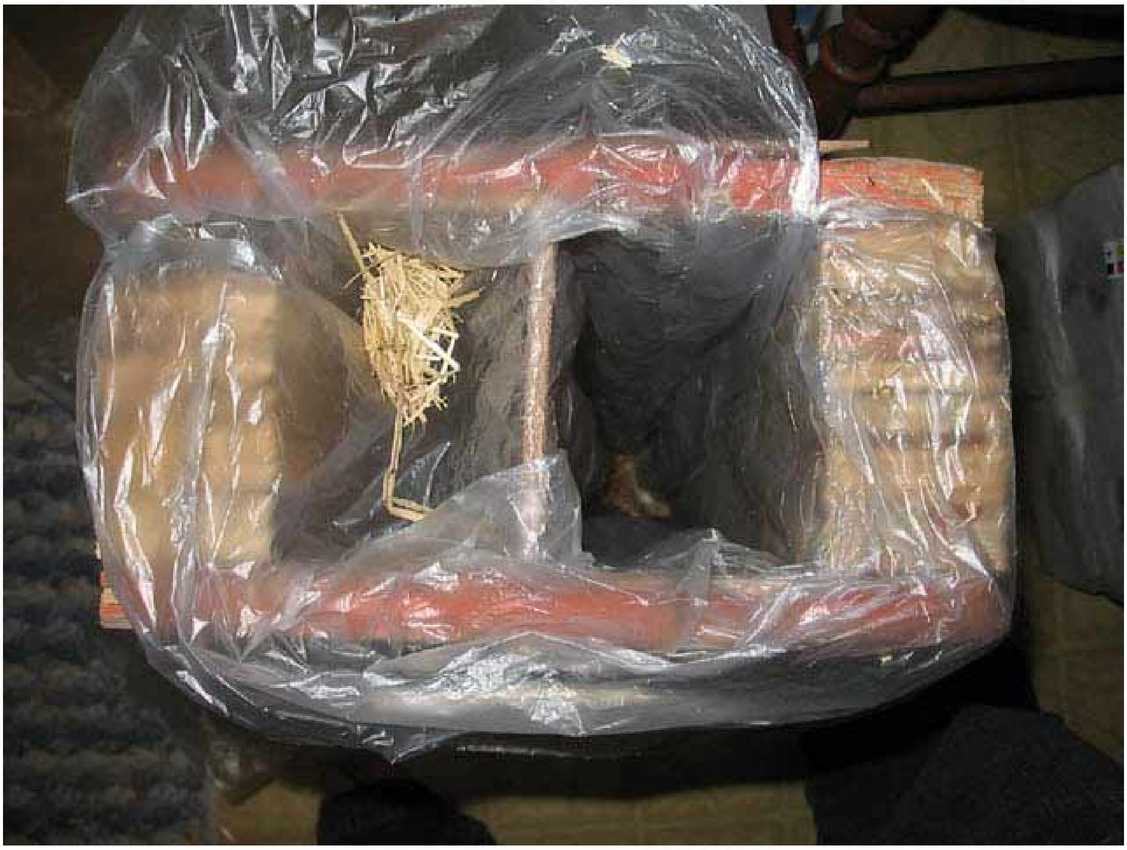
12 Wide Mouth Quart Mason Jars
Kerr
HOME CANNING JARS
12 Wide Mouth
Quart Ma
70610-0
70610-00519

Then tie one end, and put the hoop on the other.



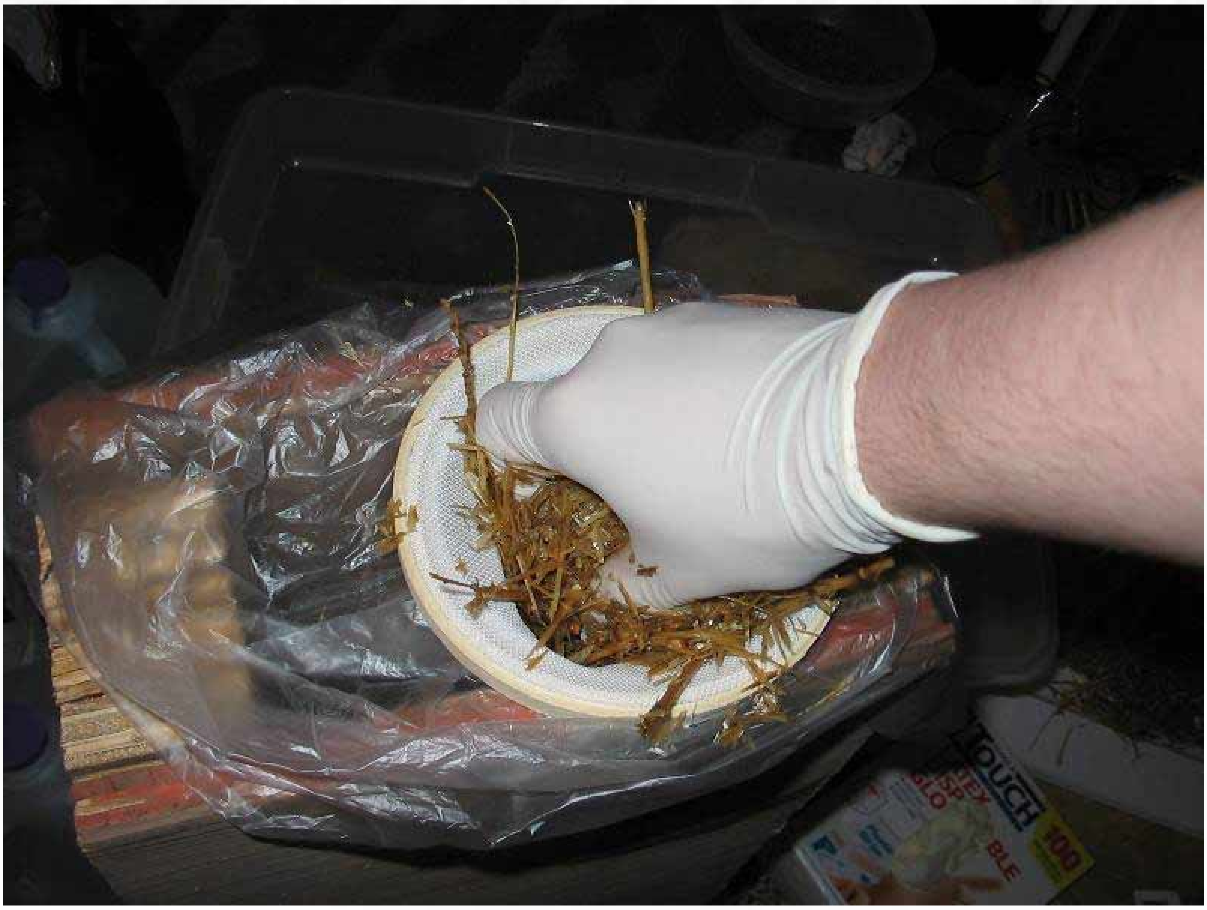
12 Wide Mouth Quart Mason Jars
With Screw Bands And Lids For Home Canning & Storage
70610-00519

The next step is to drop the fabric tube into some sort of form to hold it while packing. You can use 4in PVC pipe, or a wood form like i made. If you use a round form made of pvc pipe you can get a hoseclamp and clamp the fabric right onto the pipe instead of use the fabric hoop, it will work alot better. I used a layer of plastic with my form because i didn't want the fabric tube to touch the wood or catch on any splinters. Make sure to get the tube all the way down in the form.

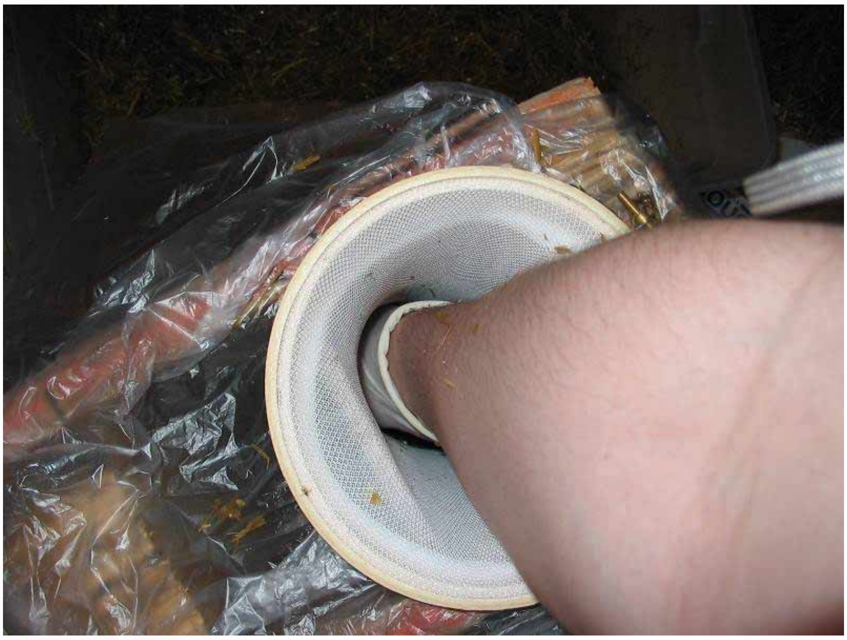


Next, grab a handfull of straw and ball it up as tight as you can.

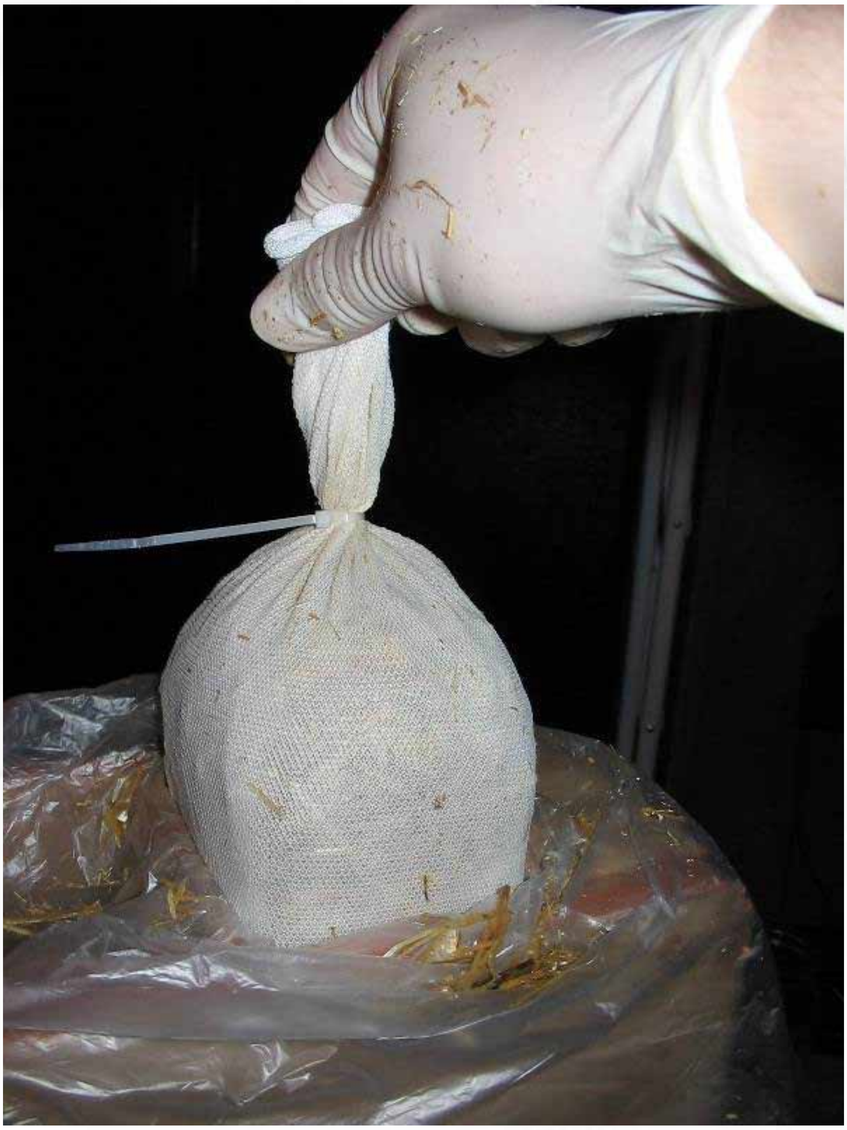
Then place the ball of straw in the opening of the tube.



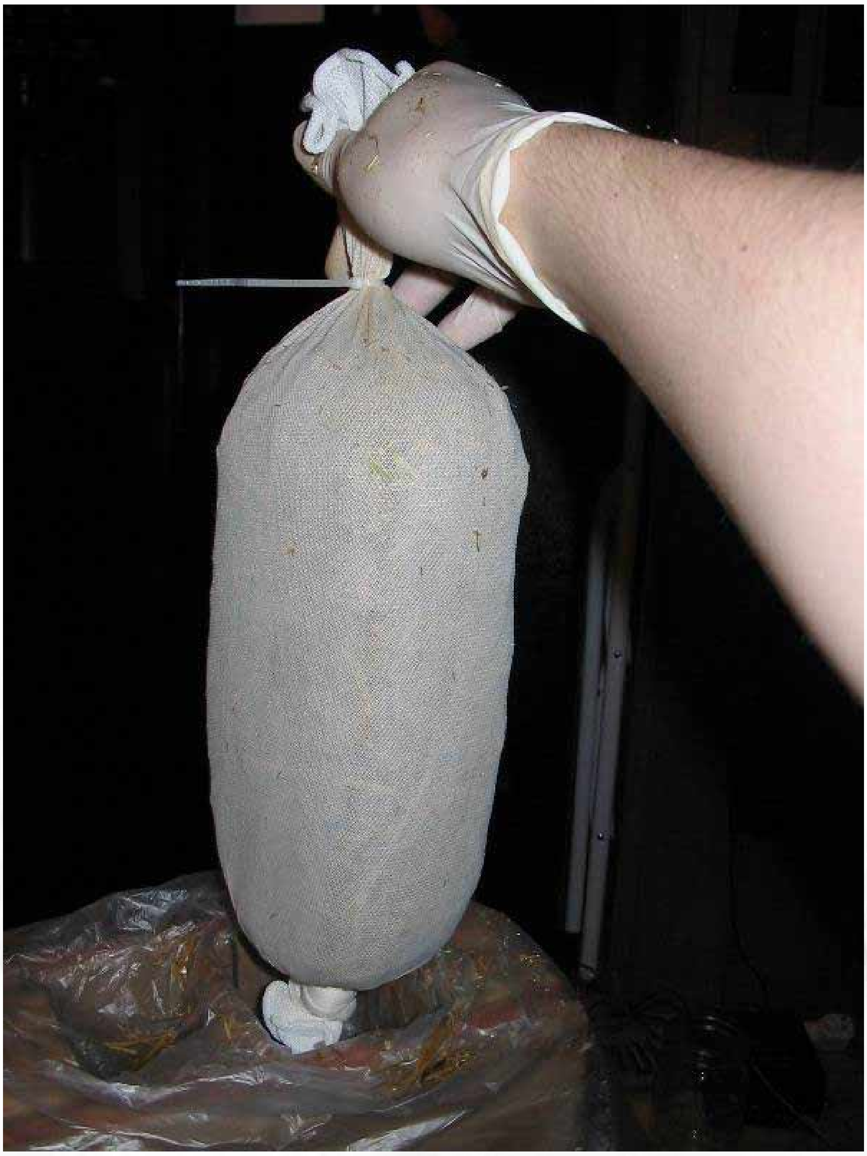
And shove it down as far as you can with your knuckles Make sure to push hard and get it packed really tight, then pack the straw to the sides with your fingertips to make sure its tight everywhere.



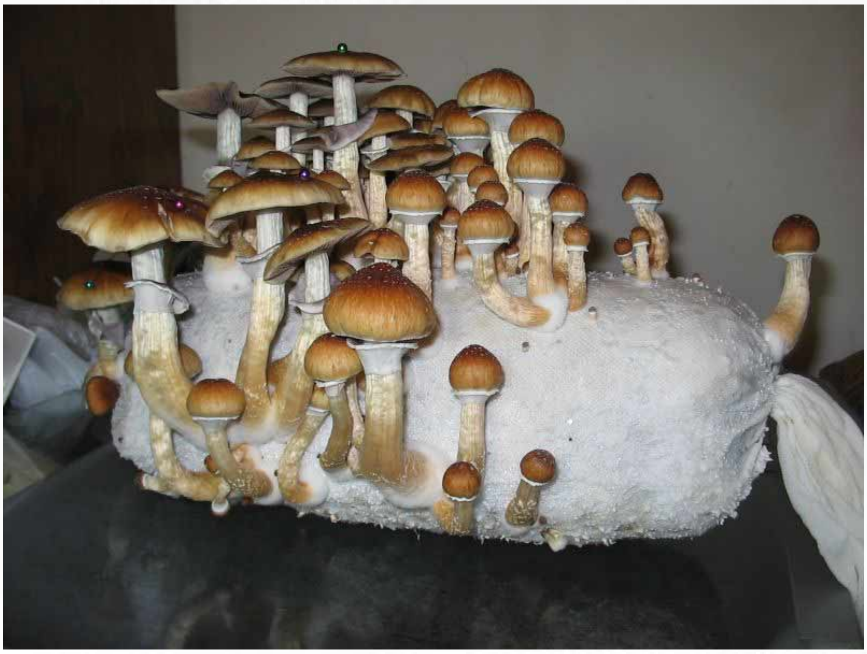
Keep packing straw until your are a few inches from the top, then take off the hoop, and pull the log out a little bit, twist up the end of the fabric and put a ziptie on the log.



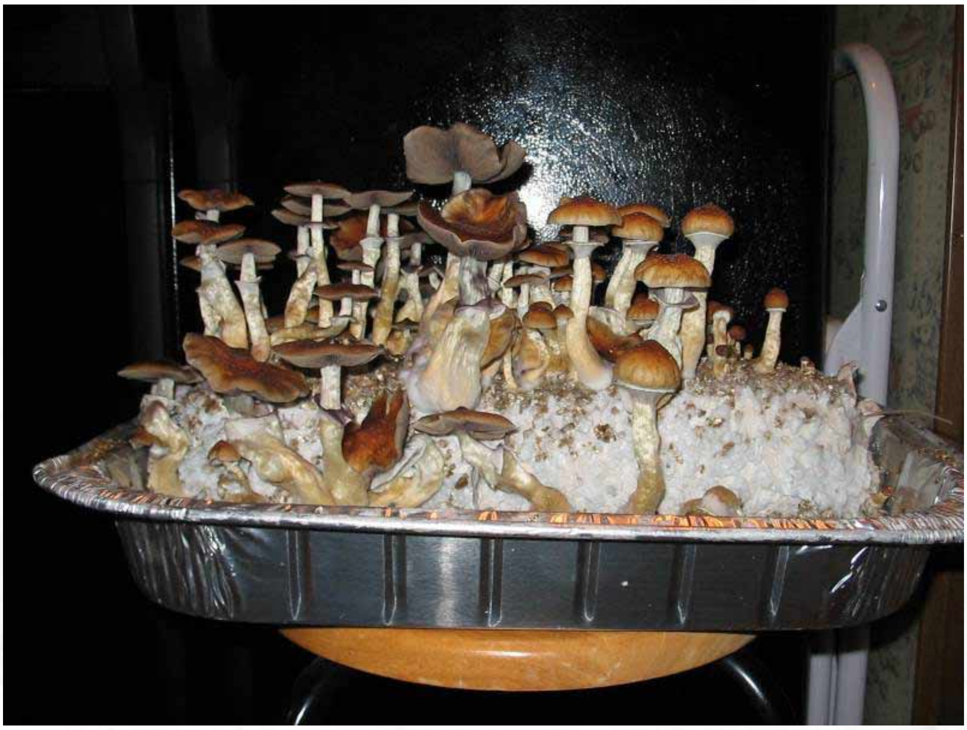
Pull it out, and you have just made your very first sock log. Congratulations!!! Now you can put the log into any terrarium for colonization.



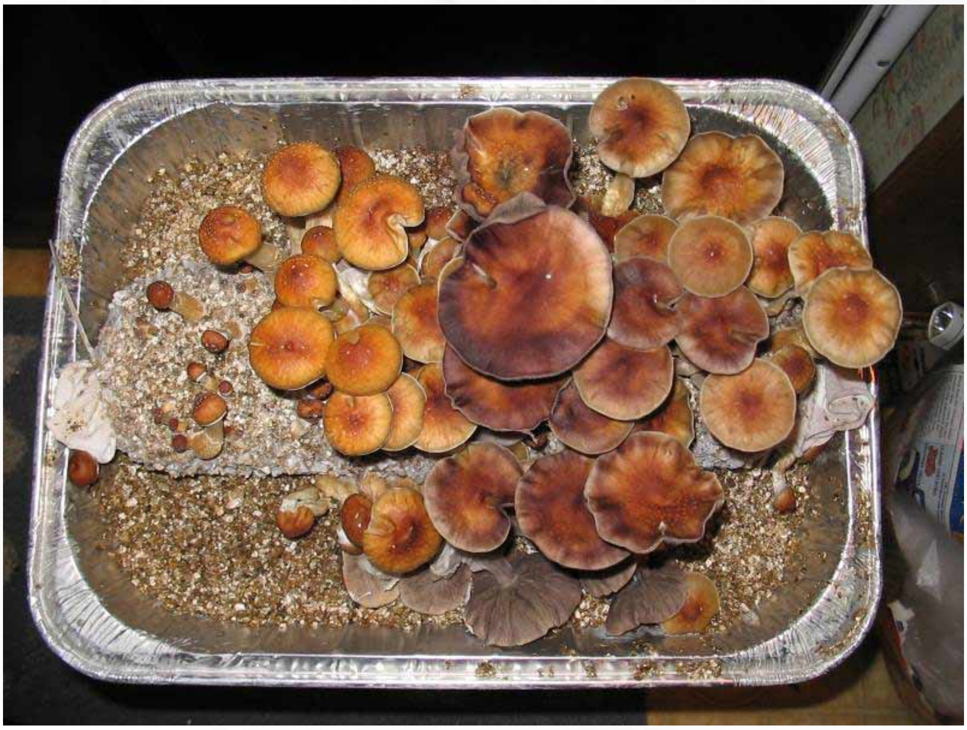
When its done, it should look something like this.



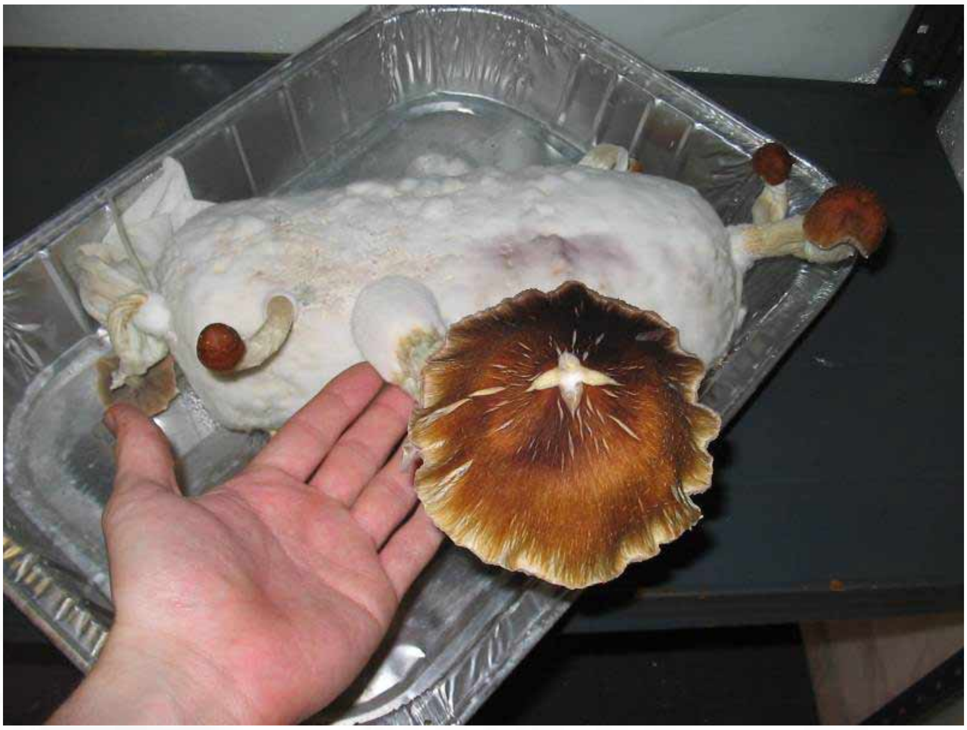
I'm back with a few updates. First, it seems that the sock logs need either vermiculite in them, or on them like a casing. I've done a side by side test of two logs, the cased one (not made with vermiculite in it) has finished flushing with a massive yield, and the uncased (no verm inside) has about 5 puny mushrooms on it. A good amount of vermiculite to use in the logs is somewhere between 10% and 45%. If you choose to case the logs instead, then a half inch works fine. The vermiculite content of the logs also seems to have an impact on how the log colonizes and fuzzes up. Without vermiculite in the straw mix, the mycelium grows through in long spikes, and does not like to pin, and with vermiculite, the fuzzing is even throughout. I think it is because the vermiculite fills in the gaps in the log, makes it more dense, and adds moisture content to the logs. Here is a picture of the square cased log I did, its yield is 671 g wet. Notice that it didn't pin on the sides where there wasn't any vermiculite. A little vermiculite added to the mixture will make it pin all over.



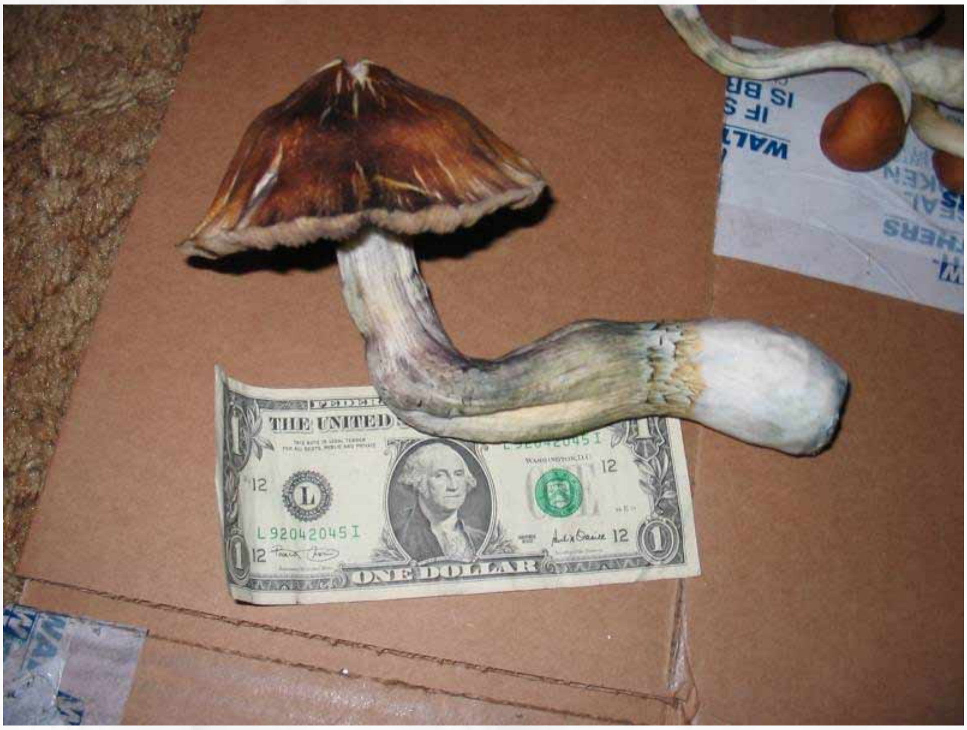
Top view. The log was birthed into an aluminum tin with vermiculite in it, and covered with about 1/4 to 1/2 an inch of vermiculite. [671g wet yield.]



As for the first sock log I made, it just finished its second flush. I never even dunked it. Its vermiculite content was about 45%. Here it is right before harvest.



Largest shroom from second flush. Isn't it beautiful. 120g wet. I had to break it in half to weigh it.



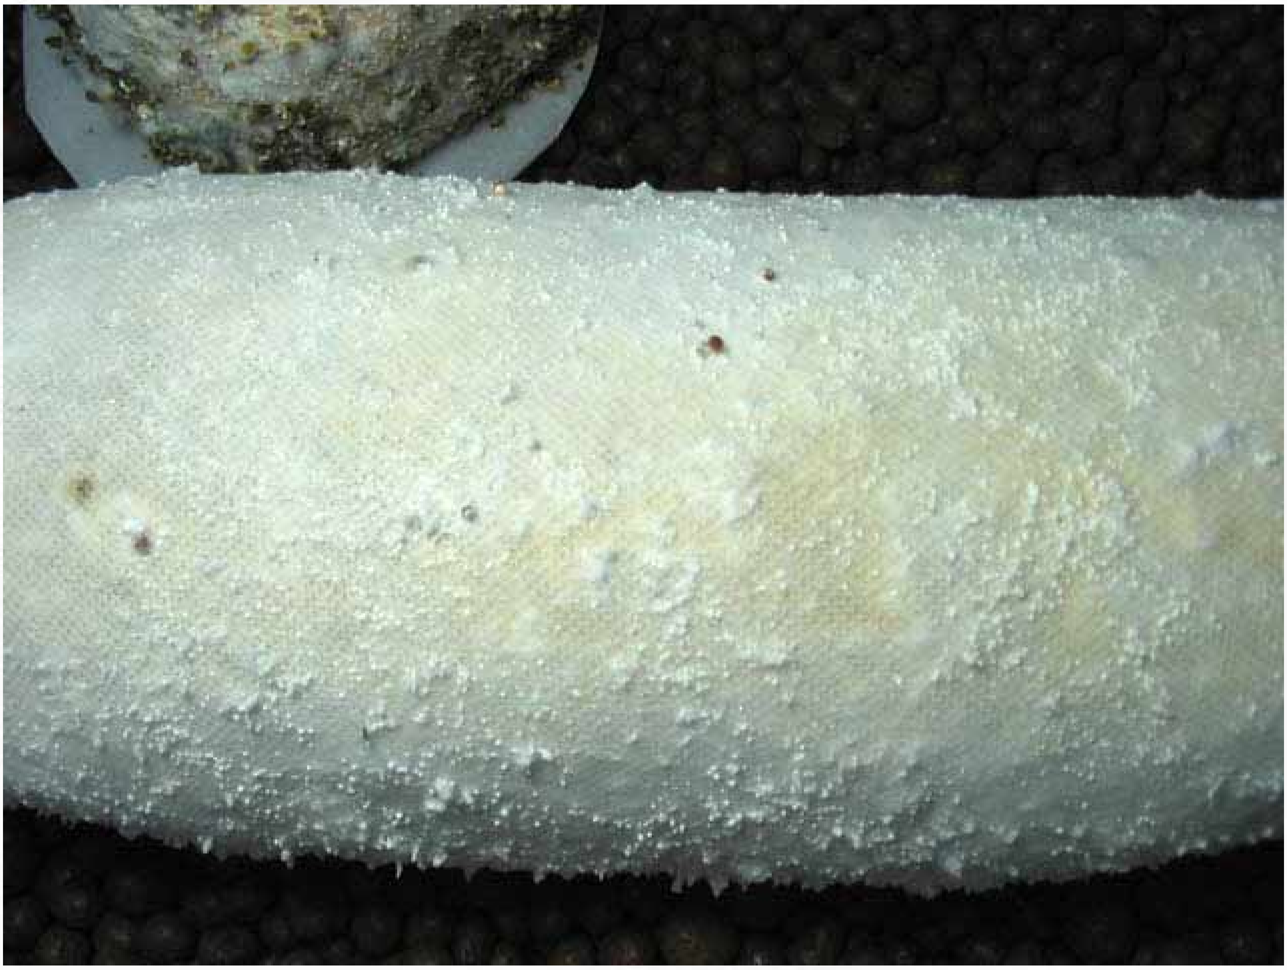
I should add that i'm currently trying a log with vermiculite in it, and on it. I'm also working on a form to make triangular logs (those should be neat). My hanging log is knotting up, so there should be results of that soon also.
I never really incubate the logs, they sit at room temperature which is about 78 most of the time. When its time to fruit the logs I crank up the AC and drop the room temp to about 70. I've always given my logs regular room lighting conditions, and regular temperatures. I've never really had that much of a problem with pinning. As for second flushes, there are always alot less shrooms. Soon i'll be adding dung to one of my logs to see how that works out. I've got a bag of worm castings, and i'm making some more logs tomorrow, so we may find out how that works out really soon. I'm going to try dunking the sock log and go for a third flush. I've got a nice

idea for dunking the logs by attaching hooks to the bottom of a tub and hooking the fabric to the bottom of the tub when its full of water. The logs float alot, and you could dunk quite a few logs that way.

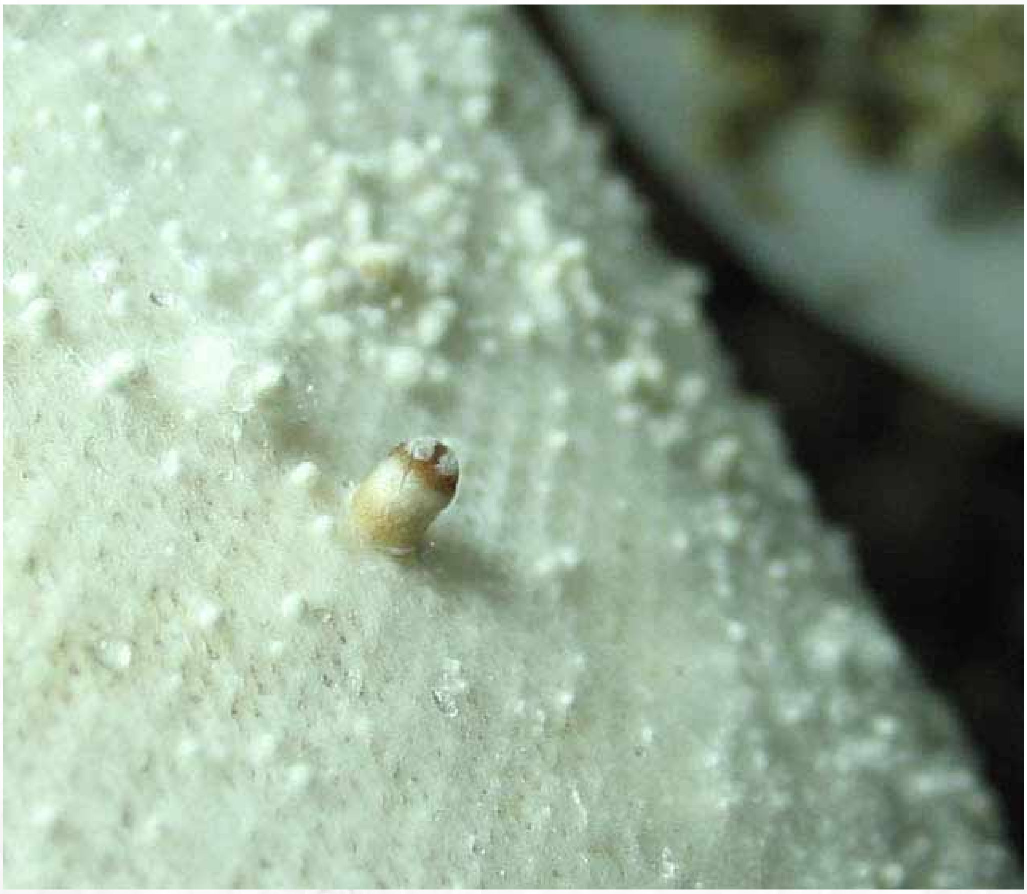
Skyypilot, the fabric is much too thin to be used as a casing itself, its actually see through. I have been thinking about the second fabric and vermiculite layer, but i'm going to put that off till later. I chop my straw really fine, almost like straw flakes, so thats why i like to use vermiculite, and it increases the weight of the flush alot, so far, it seems like mixing in vermiculite is the best way to go for ease and performance. The vermiculite on the outside is just there because those logs did not contain any vermiculite inside them, and i saw how poorly they performed, so it was pretty much an attempt to save them. The yield from my one foot long 4in wide logs is about 1.5 pounds wet, and about 6 logs produces one pound dry. I can guarantee that the straw is dense enough, i've packed them so hard, i've ripped the fabric and stretched the plastic tubing. One of my 4in wide foot long logs (without vermiculite) typically weighs in at 1000g right after i make it. Also, the purpose of the sock material isn't to hold moisture, but to hold things together. It makes things alot simpler, you don't have to worry about straw being stuck to the mushrooms, its really easy to pick,and they colonize a bit faster than polytube logs. I've tried larger logs without the sock material and I never seemed to get that much of a better yield per cubic inch of straw. Sorry if this doesn't make much sense, I haven't slept much lately.

original source: http://mycotopia.net/archives/discus/messages/5/136901.html

I've been working with the log tek for some time now, and i've been doing a few experiments. A few weeks ago i was at Home Depot and found some tubing made of fabric. The holes in it were small enough to hold straw, but also let mycelium grow through. So a few days after that, i made a log out of it. Here is what I have now.



You can see that the mycelium grew through the fabric and knotted up on the outside. The pins are on the outside just like i had hoped. Closeup of pin on outside of fabric.

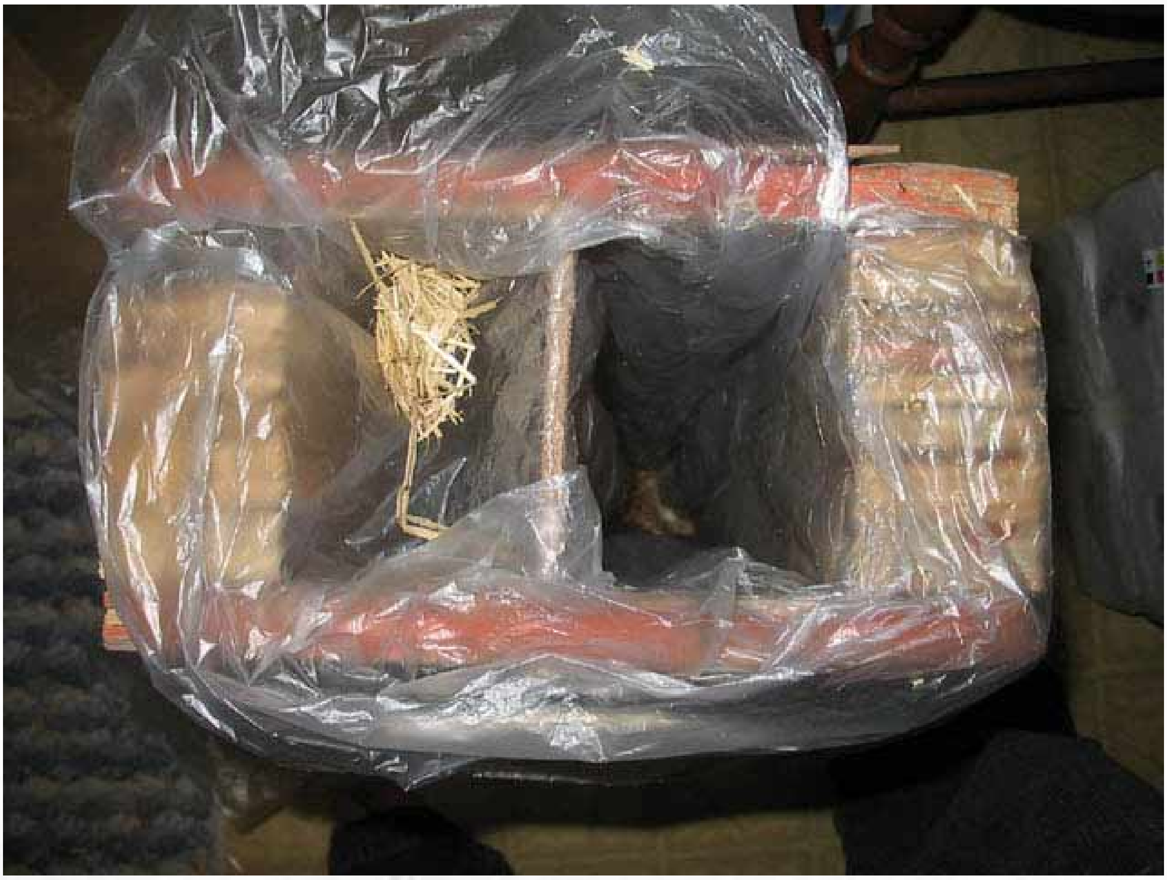


More pins.

I've been working on a few other ideas also. One is a rectangular prism shaped log. I got the idea from the straw biscuit. When its colonized enough i'm going to place it on a bed of verm, and cover the top with verm like a double end casing for a cake. A log with flat sides.

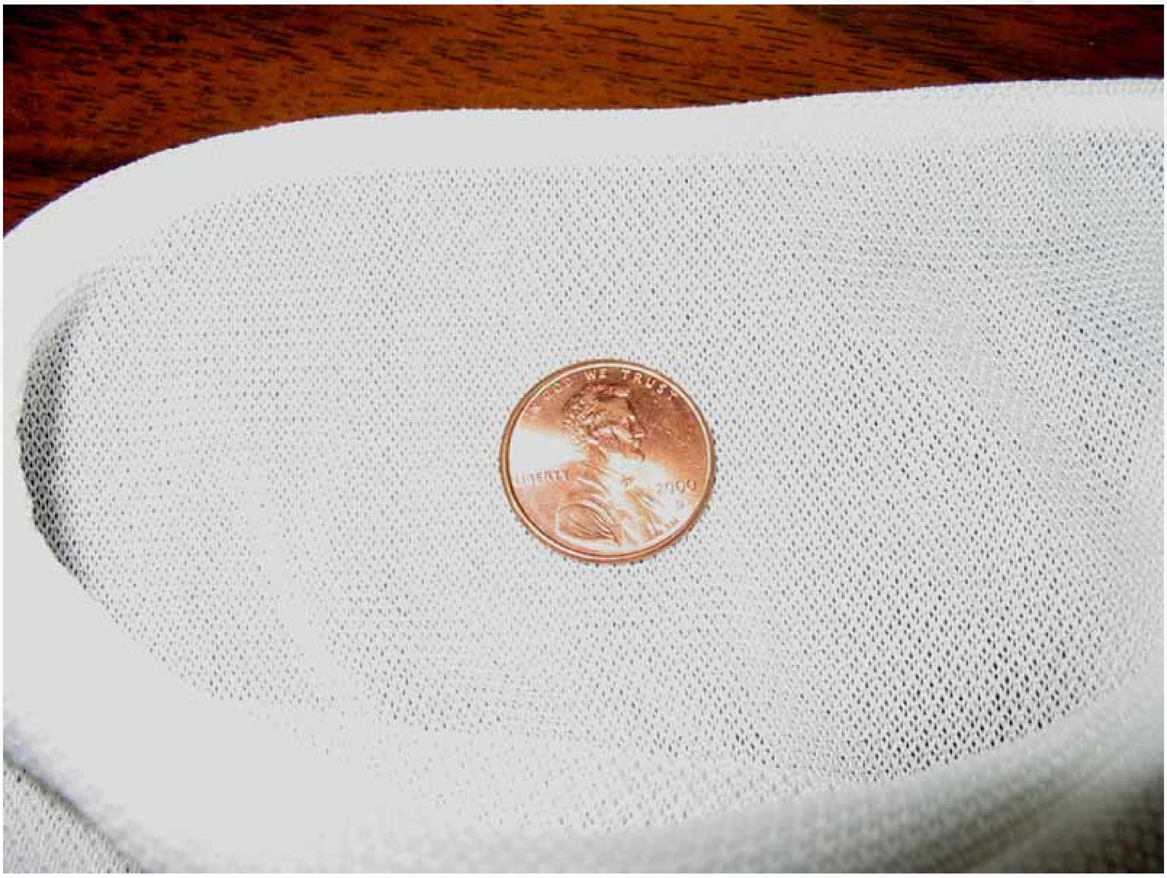
Another pic.

I made the logs square by packing the log inside of a form i made out of plywood.



How much for the tubing?

It was 20 bucks for a 100ft roll. **Its filter fabric sock tubing for septic tank drain lines,** here is a closeup of it.



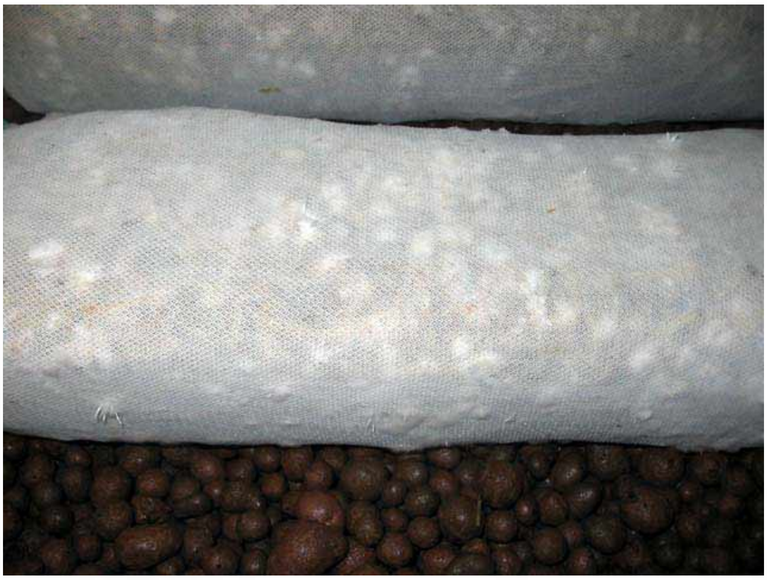
> rodger rabbit (Skyypilot) comment:
> The myc is definitely NOT colonizing that covering. It's synthetic.

I colonized the straw in a humidified environment. It colonized inside of the terrarium. The mycelium has totally grown through the fabric, and fuzzed up over the fabric, so there's no need to slit or do anything to it, its already covered in hyphal knots and the pins form on top of the fabric layer, so they shouldn't suffocate. I've been thinking about hanging the logs too, but it would be harder to case, but i have a way to make that easier too.

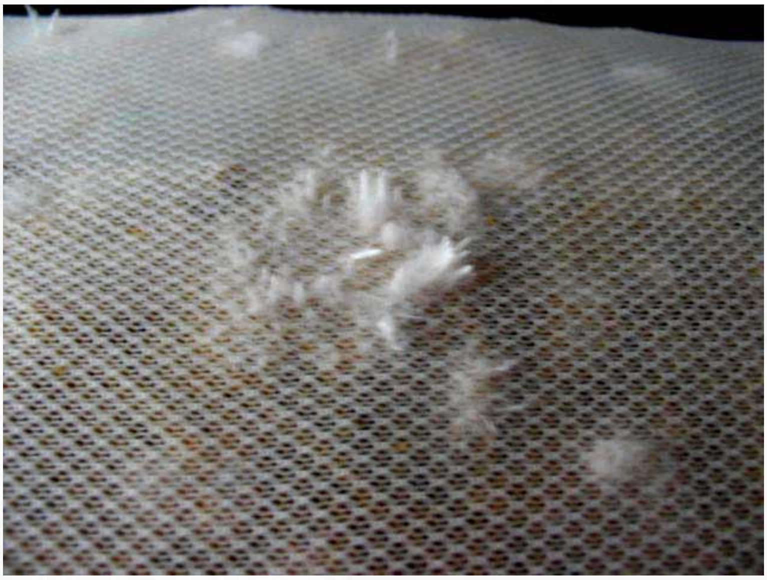
> rodger rabbit (Skyypilot) comment:
> Every vertical log I did was a disappointment. Gravity pulls water to the bottom where it drips out and is lost. The top of the log will dry out, because the mycelium isn't strong enough to pull water from the bottom by capillary action. If you hang them, build hanging shelves, and try to keep the logs horizontal.

I should also mention that this log is part of another experiment, the log is about 30% verm. I'm not sure how it will effect the yield. The flat sided logs are 100% straw.
The log drying out doesn't seem to be a problem as long as you have plenty of humidity. I weighed the log b4 and after colonization and its the same, so that eliminates moisture loss as a possibility. As for the fabric stretching, it does stretch, but in a weird way. If you make it wider, the tube gets shorter, its sorta like it pulls on itself. Thats why I used a form to stuff it, if I didn't, it would have come out all lumpy. You can also use 4" pvc for a form. Just tie the end, drop the fabric in the tube and stuff away.
This is a new log at 24 hours of colonization. See the fuzzy bits of mycelium sticking out. Very nice.

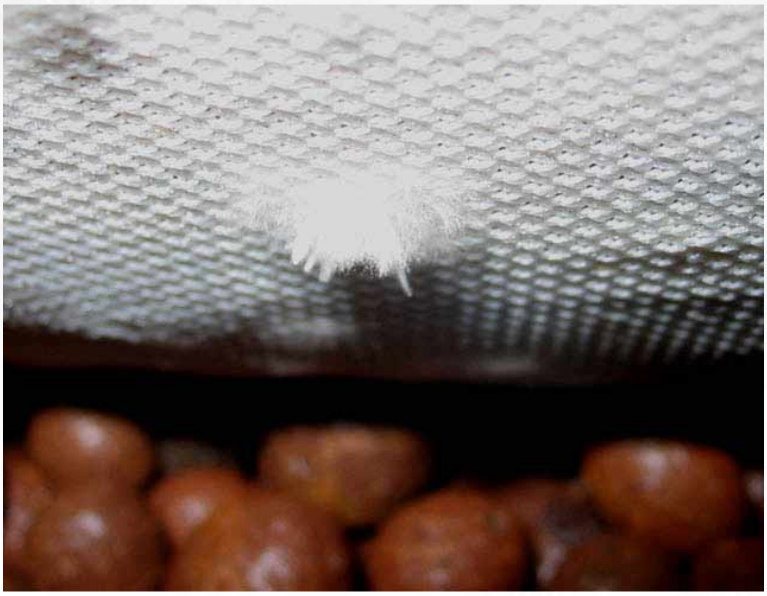
Here is another pic of the log.



Here is a closeup of the fuzz. You can tell it has great air exchange like this.

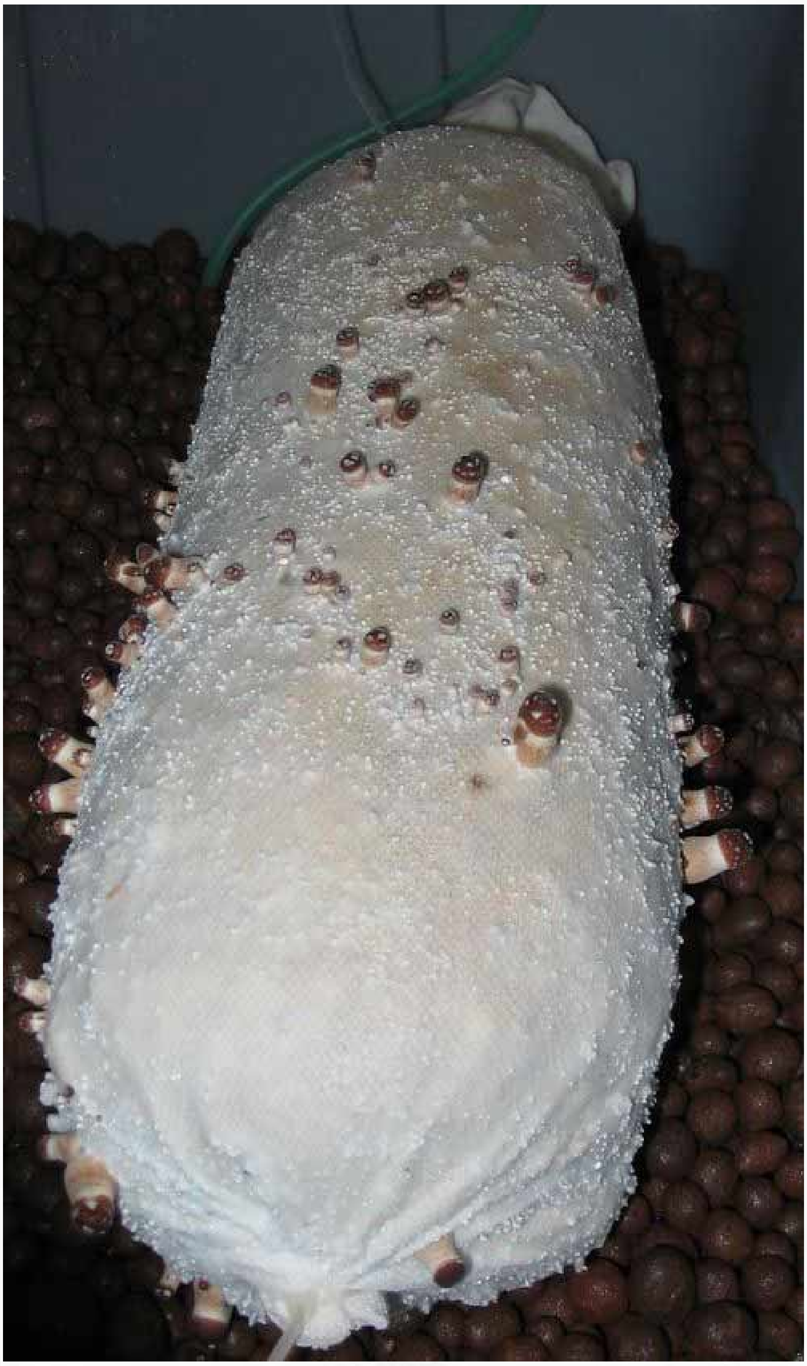


Another fuzz closeup.



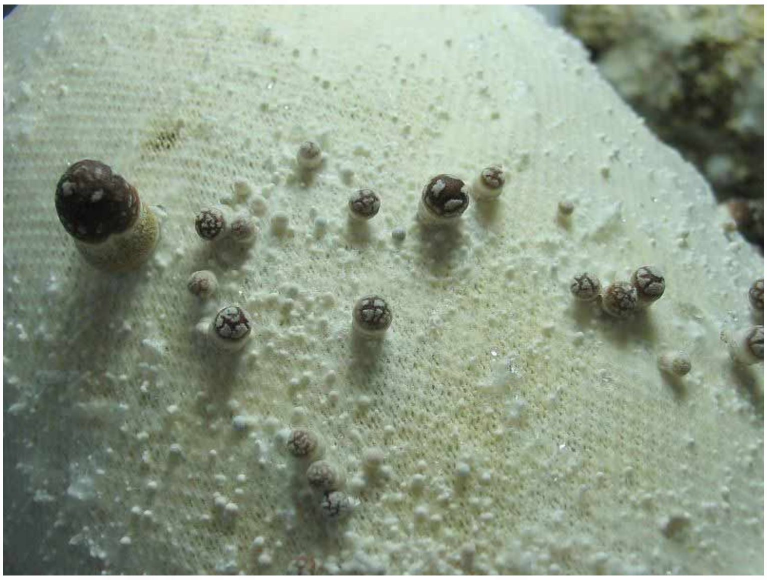
I birth the log directly on the geolite and leave them alone, Its like one of those "set it and forget it" ovens, you just birth and watch. Its incredibly low

UPDATE!!! The log is looking good. Still slow pinners as usual. Here are some pics i snapped a few mins ago.

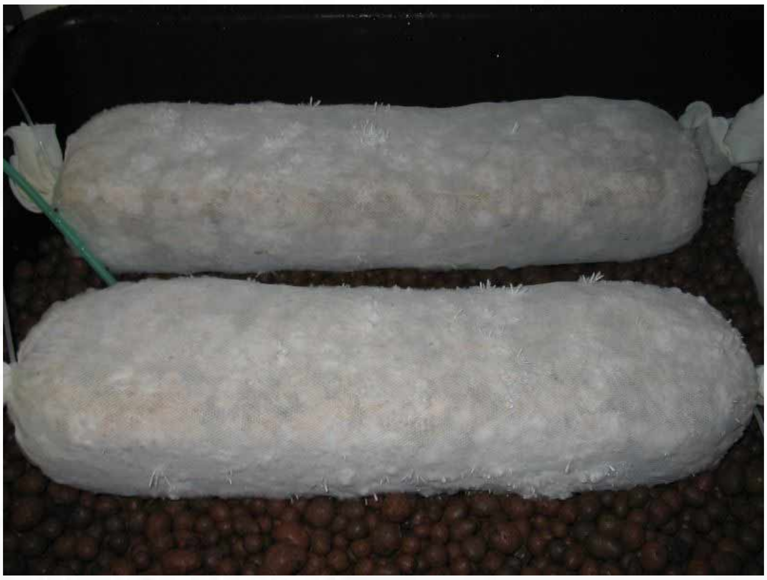


Another.

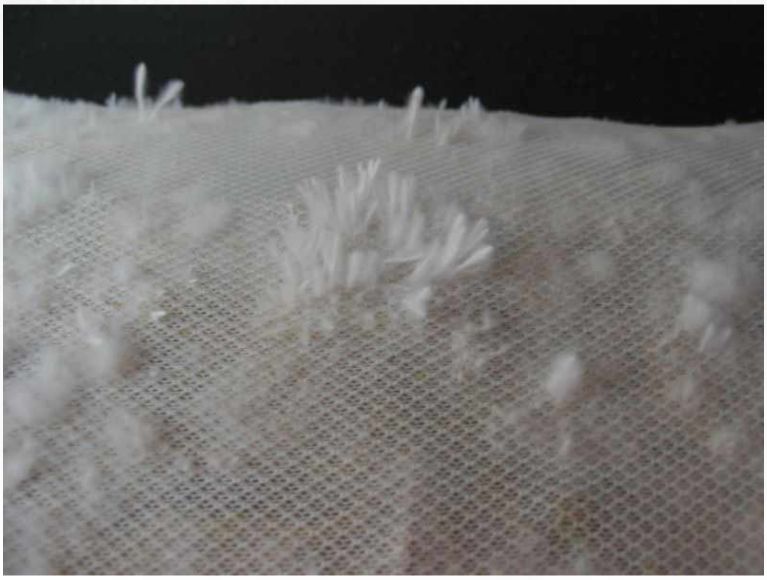
Here is a closeup pic of the knotting and pinning action.



Here is a pic of the logs that are colonizing. Amazing eh?

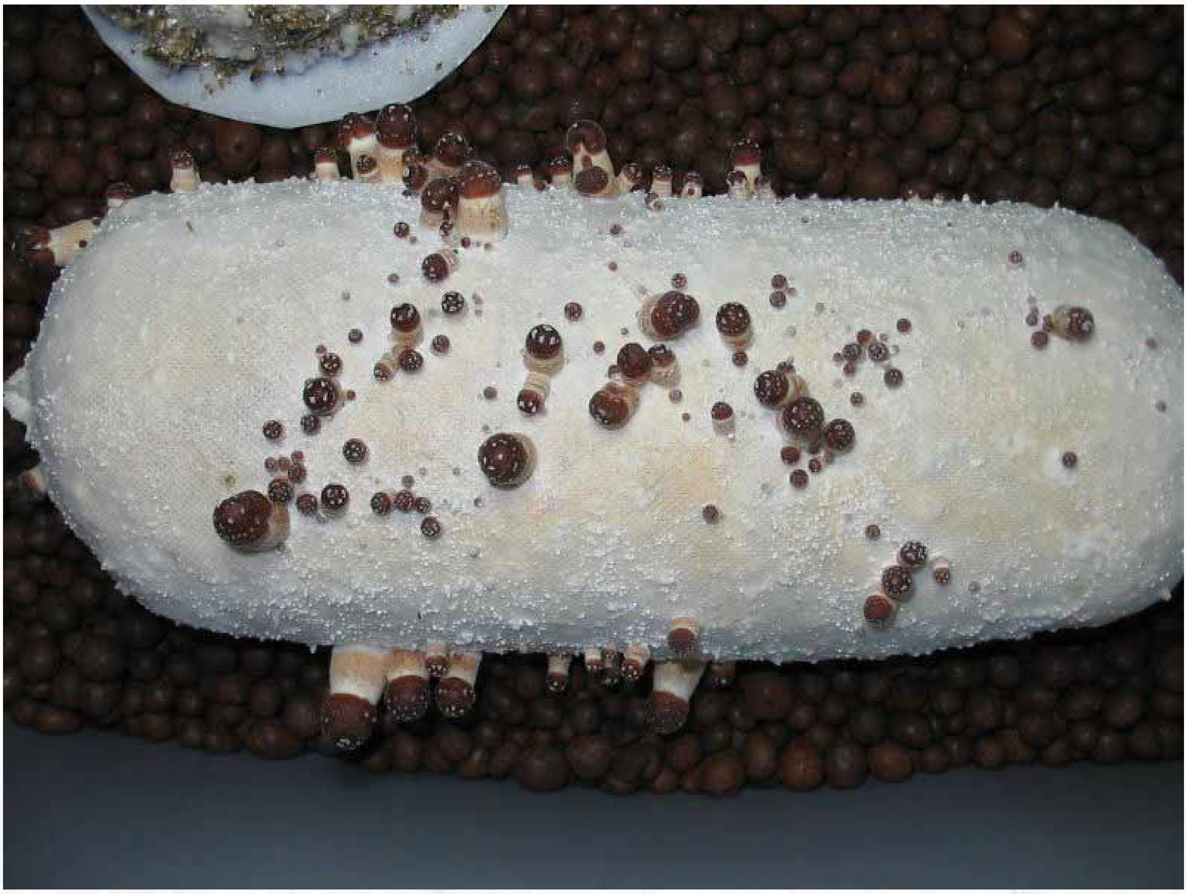


Closeup of the spikes of rhizomorphic mycelium coming through the fabric.



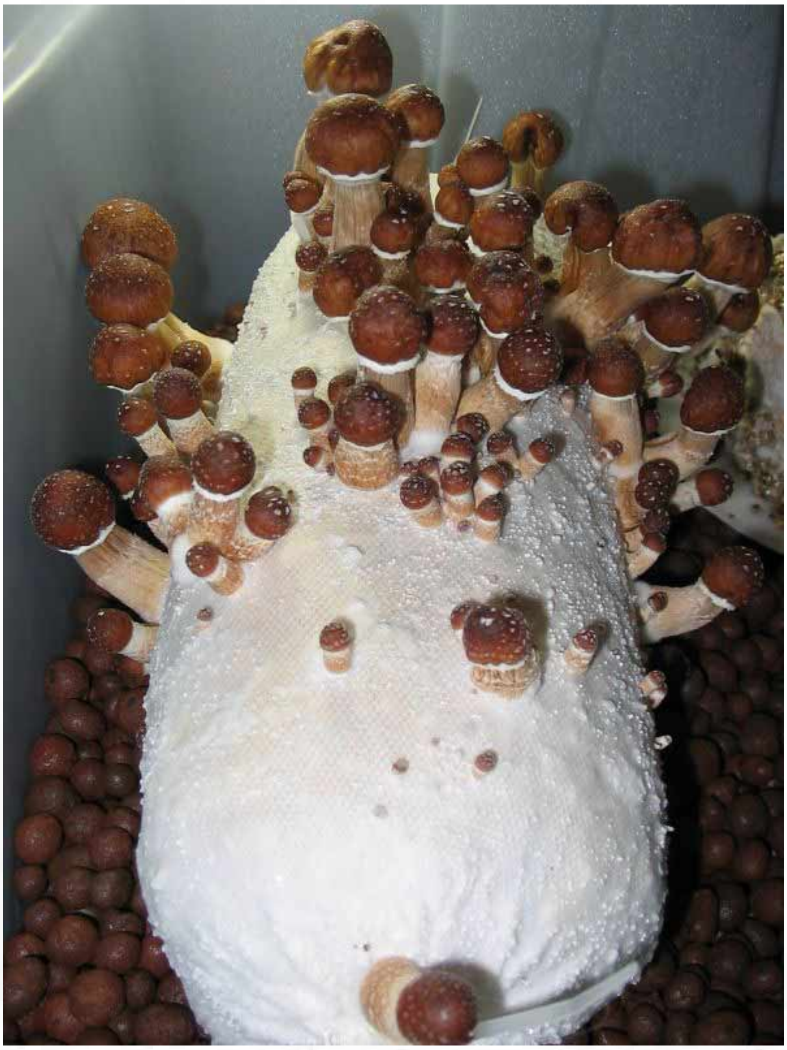
I use bottled water.

PINS!!!

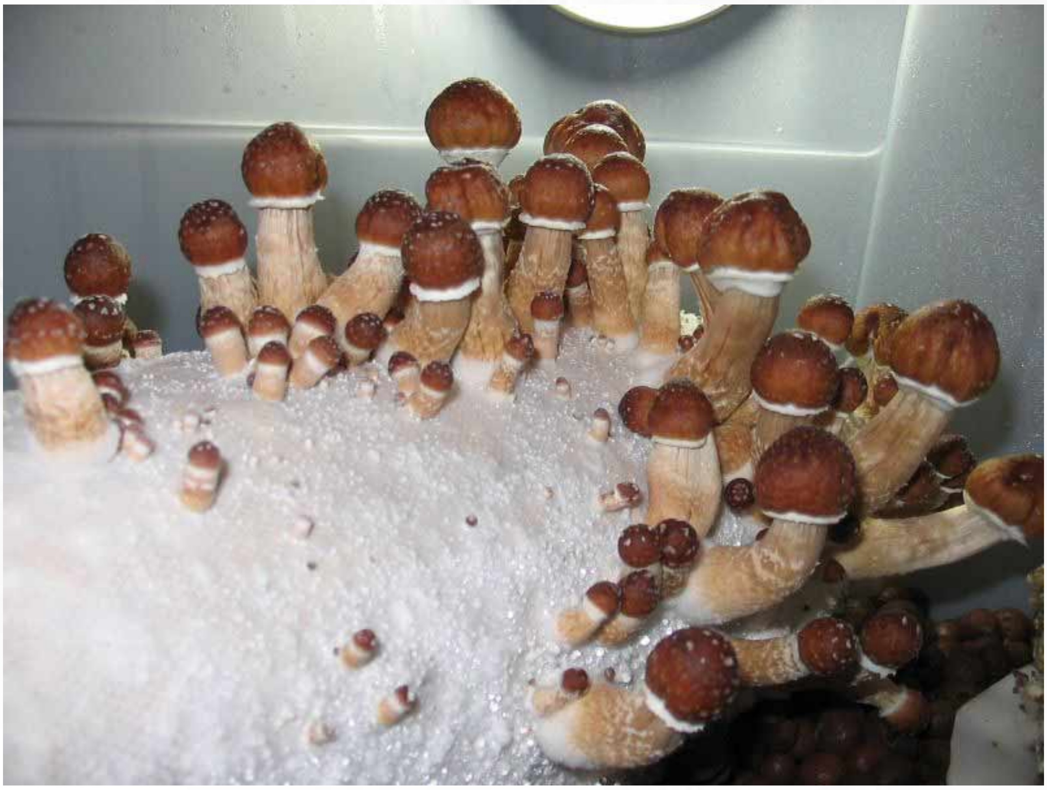


The colonizing logs are looking really nice.

Getting closer



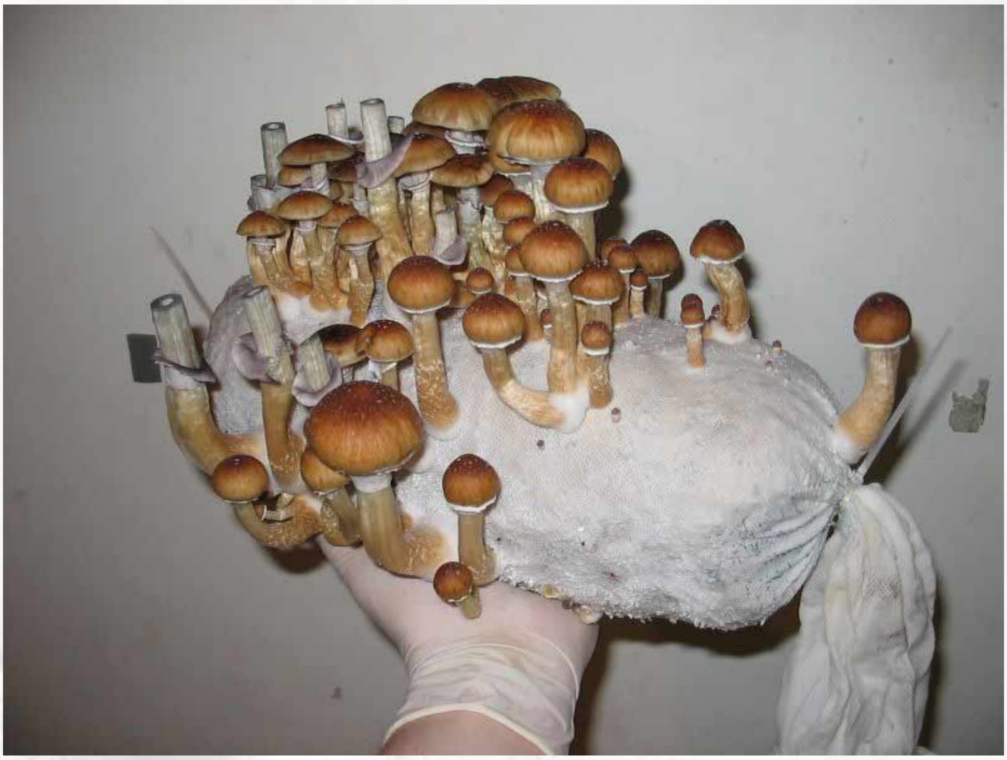
I like the looks of these pins, they're fat, should grow up big and strong.



I just got done harvesting the log and I figure i might as well tease you a little b4 posting the yield. Here is a little eyecandy from b4 i harvested.

Isn't it beautiful.

I love teasing you.



And the grand total yield is 414g wet, that should give a nice 41g dry. 3 logs will give you a quarter pound of dry shrooms, 12 will give you one whole pound of dry mushies.

Well, i'll get some pantyhose from my gf and give it a try. The tubing i use doesn't really stretch at all. I would suppose that if you used a form you could use panty hose, but i would think the straw would snag it and give it runs. We'll see. The logs don't really shrink like cakes, so there's no gap. It was really easy to harvest since i didn't have to clean one bit. Oh, BTW, those dots on the caps that look like bb's are pushpins. I use them to hook and move caps for printing.
I just weighed the caps i printed from the harvest, and they weighed 90 grams, add that to the yield, and you get a whopping 514g wet!!!

The Great Timothy Hay Cob Cubensis Method

by

Nanook

original source: http://mycotopia.net/archives/discus/messages/5/3001.html

First, you must obtain a clean culture of Psilocybe cubensis. I don't see any reason why multi-spore inoculation wouldn't work (presuming they'll germinate on hay) or why one couldn't use a multi-strain grain culture, but I used a pure culture I'd previously isolated. (Note: Don't be afraid! Agar work is much easier than you might think!)

Grow out some Grain Spawn. I use 'organic' whole rye grain steeped in near-boiling distilled water for an hour or so (as suggested by Stamets, produces uniform water content grain and minimized contaminants). Just before the grain is ready add some Gypsum to the pot and stir well (I use about a gram for every quart jar's worth of Rye Grain, but I don't know how important precision is...doesn't seem to matter much...). The gypsum helps keep the rye from sticking together post sterilization. Sticking frequently results in bacterial contamination. So use the gypsum (Try health food/herb co-ops).

Drain the grain, scoop into mason jars and sterilize at 15 lbs for 1 hour.
I use Autoclavable Filter Disks (from Fungi Perfecti and others) in lids with holes cut through, but I'm sure loosened jar lids would work fine. I Inoculate the sterilized, cooled-down grain with Mycelial Solution. Shake once after three days or so and perhaps once more several days later if needed, but the grain should be fully colonized within 10 days at most if liquid inoculum is used.

Get an "LM" brand "Timothy Hay Kob" from a pet store. Should cost $3-$4 for a package like a big bread loaf. (Note: I ended up cutting up the hay AFTER pasteurization, but you'll probably want to do this beforehand. Try and keep the pieces no longer than 4 inches or so. But don't worry about some bits being longer)

Place as much of 'cob' as possible in a large pot. Fill with distilled water (actually, I think I used a 50-50 mix of distilled and tap and it worked fine). You must be able to submerge the hay completely with a weight or a weighted lid.

Bring the water to a near boil and reduce heat to keep temp more or less stable. Pasteurize for one hour. Drain hay in a colander. Shake well.
Place hay in an "oven bag". These are special plastic bags used for cooking turkeys and so forth. They are heat resistant. Hold bag with hay upside down with bag open. Shake and squeeze to get rid of remaining excess water. Let hay cool in bag until it fully reaches room temperature.
Take fully colonized jar of grain spawn. Wash hands and rinse with rubbing alcohol. Air dry. These were the ONLY sterile precautions I used, but you may want to observe some more. Break up grain spawn and mix thoroughly with hay in bag. I used most of a quart spawn jar (figure one pint of spawn). Liquid mycelial inoculation would definitely work at least as well, spore inoculation is a possibility.

Let hay sit in bag for three-four days. The bag should be twisted loosely closed but not sealed or tied. You want to allow some respiration while retaining most of the moisture.

After 3-4 days the mycelium should be growing out vigorously onto the hay. Handling the hay through the outside of the bag, knead and pull at it between shakings. You want to break up the bigger mycelial mats and redistribute them throughout the hay. You can also open the bag and work it like a bellows to help exchange the air. You may find that the hay punctures numerous small holes in the bag. This is okay, and may help respiration.

I gave the hay a couple of squirts of distilled mist at some point fearing that it might dry out. But I doubt this was necessary, despite the very dry climate.

Every few days, repeat the breaking, mixing, and aerating procedure.
DON'T worry about contamination. If you pasteurized the hay properly, you should have a couple of weeks before anything else really has a chance to compete with the mycelium.

When the hay looks like there's mycelium within an inch of any given spot of hay, leave it alone to complete colonization. The whole process should take a bit less than 14 days.

When there is at least wispy mycelium across all the hay (and if you've been mixing well, throughout it), it is ready to be laid out. You can use whatever terrarium setup you used for PF cakes, or use this low tech setup:

1. Get a big Rubbermaid storage container, a plastic drop cloth, and some chicken wire. Melt a hole in one of the bottom corners of the container. Wash it out well.
2. Cut a piece of chicken wire and fold over the ends and sides to make a platform that will stand at least an inch above the bottom of the container. Fit this down into the container. Spray the insides of the setup with lysol or the like and let completely dry.
3. Break up the colonized hay and lay it out on the chicken wire. It should be more or less evenly spread but don't go crazy breaking up the hay. Make it at least two inches deep. Don't know what the maximum depth would be...
4. No more than 3-1/2 to 4 inches. Unfold plastic drop cloth and drape over container. It will not make anything like a sealed environment BUT IT DOESN'T SEEM TO MATTER. Your mileage may vary so if you feel the need be more precise with environmental controls.
5. Let hay recuperate for a couple of days.
6. Twice per day, take off plastic tarp. Use lid of container to vigorously fan hay to exchange air. Replace tarp and lifting up one end stick spray bottle beneath and spray distilled water with the finest possible spray into the air. Experiment. I used only a few spritzes at first and more and more as the mushrooms grew. The lack of a drip shield doesn't seem to matter, though when I'd redrape the tarp I'd arrange it so that a piece without major condensation or water drops was above the hay. Redrape plastic. If necessary, tilt setup to allow excess water to drain out hole. Leave setup in a temperate place (mid to upper seventies to allow pinhead formation) with some light exposure. Any light is probably fine, a little natural light probably best. Don't overdue light. Very little is required.
7. In one to two weeks, the texture of the hay should begin to change dramatically, you may not realize that this is pinning, as it should appear that the entire service of the hay is turning to pins.
8. Keep up the fanning, spraying routine as the pins turn to primordia, and the primordia to carpophores. Enjoy the sight of dozens of large mushrooms springing forward.
9. Pick them just after or as the veil is breaking. While you won't have to clean off any vermiculite, you will want to pull off as much hay as possible. Some hay will be inside the stems. Don't worry about it.
10. Dry or eat fresh. Enjoy!!

Mushroom growing Invitro

by

Hyppie3

original source: http://www.mycotopia.net/archives/discus/messages/5/18237.html

Notes: This tek is primarily designed for anyone who, for whatever reason, cannot fruit in humidified terrariums. While the yield from each cake per flush is a bit less compared to some other methods, over time and multiple flushes the yield per cake can easily reach 7+ grams dry weight in mushrooms, particularly when the Dunk Tek is used between flushes. Some few strains are rather poor performers with this method so use them at your own risk. Pf's Classic aka Amazonian aka Matias is probably one of the best for this tek. The cakes can be left unattended for long periods of time, there is no need to do anything to them in between picking sessions. You can open the jars any time after full colonization to remove the cake for picking, drying out the jar, etc. The only real concern is to be alert to any sign of decay or rot on the fruit. If it turns black or appears slimy/wet then it's best to pick ASAP.

"Authority defied
Birthright defined
Life, liberty
The pursuit of happiness
The freedom of the mind
Emancipation of the soul
The courage for adventure
The safety of the secret
The unspeakable beauty
The birth, being, life and death
A surreal notion
The spark of revolution
The enforcer cannot get me from afar
I do it all
In one jar"
by Karna

invitro cambos at 5 weeks

invitro south americans, 2nd flush

1. get spores, preferably syringes. One good place to try is Fanaticus.com, whose PF TEK was the inspiration for my invitro method.

cambo print in gladware

home-made syringes, z strain

The PF Classic/MR is one of the strains best suited for this tek. But all strains can work, some better than others.

2. buy at least one dozen half-pint canning jars with lids. the half pint wide-mouth jars are the best for this method.

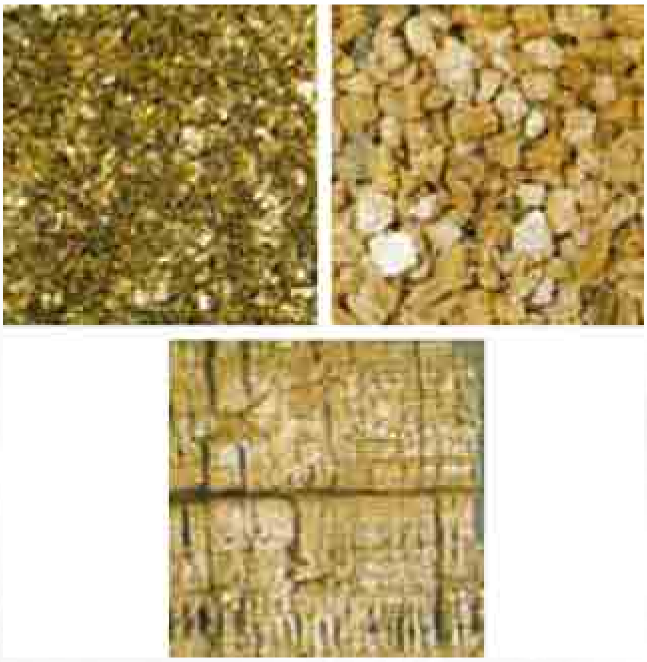
half pint wide-mouth jar

3. drill/punch-out 4 holes equidistant around the rim of each lid.

4. buy some brown rice and grind it into flour using a coffee grinder, blender, etc.

5. buy a bag of vermiculite at garden store. [note:there are very few good substitutes]

COUNTRY COTTAGE
HORTICULTURAL
Vermiculite



Verm. sizes/grades

6. buy a bottle of spring water at grocery store. [note:any water, even tap, can be used, in a pinch.]

7. pour 1/2 cup of the verm. in medium mixing bowl and level it out.

8. cover the vermiculite with 1/4 cup of the ground rice flour evenly.

9. sprinkle on 1/4 cup of spring water.

10. mix well.

11. load mixture into a jar, until level with the bottom of the lid's threads, discarding/recycling excess.

12. carefully clean the rim of jar of any material.

13. fill jar rest of way to rim with plain, dry vermiculite.

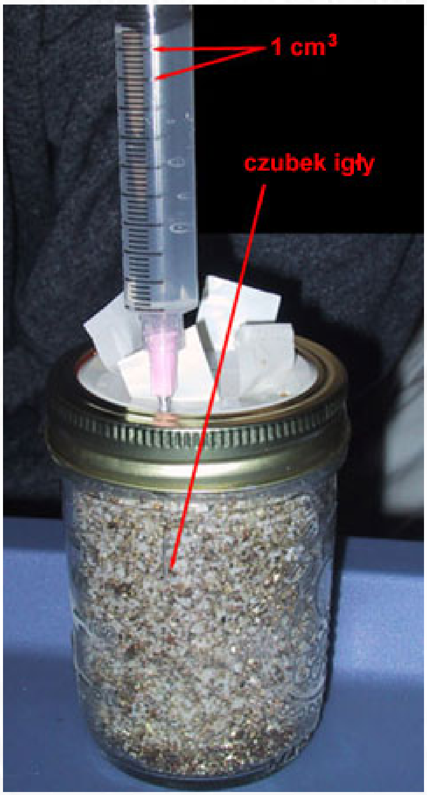
14. screw on lid, and cover holes/lid with aluminum foil.

15. repeat until you have all jars filled.

16. place jars into a large pot, add enough water to reach 1/3 up the jars' sides, cover with lid, and boil/steam 45 minutes.

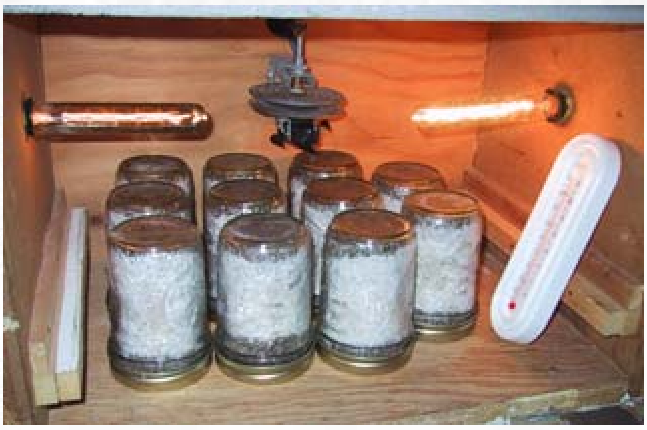
17. remove from heat and cool to room temperature.[note:overnight is safest]

18. inject 1 cc. from the spore syringe into each jar, splitting it evenly between the 4 holes.



inoculating jars

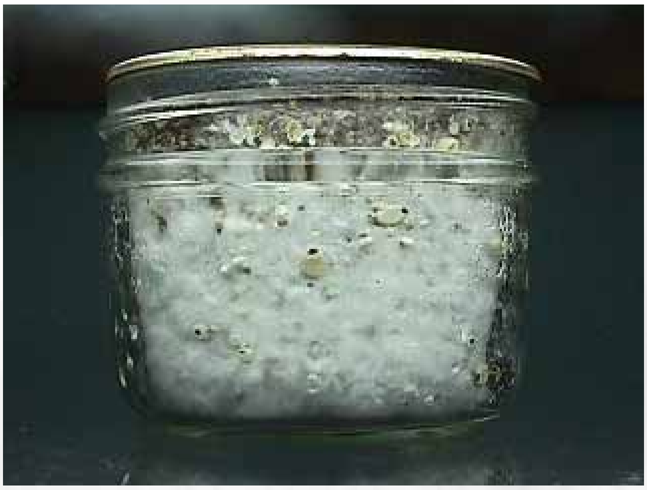
19. keep in warm, clean area for 2 weeks, or until the jar is completely covered with white growth. Meanwhile, from the very beginning if possible, expose to light several minutes a day, eventually you'll see little shroom-like growths called pins.



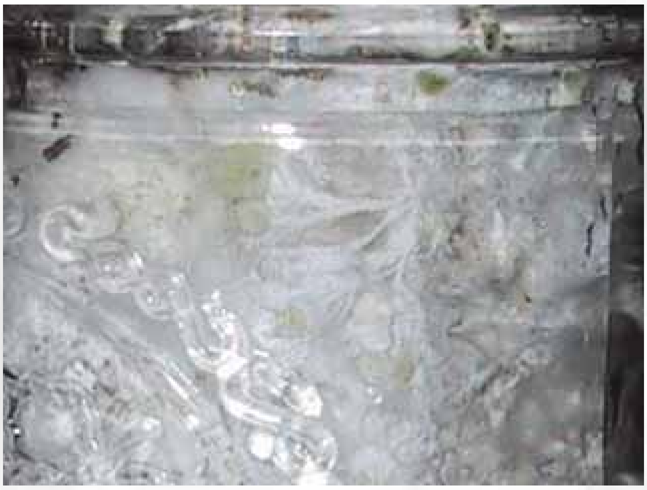
incubator

lamp

fully colonized jars



pins

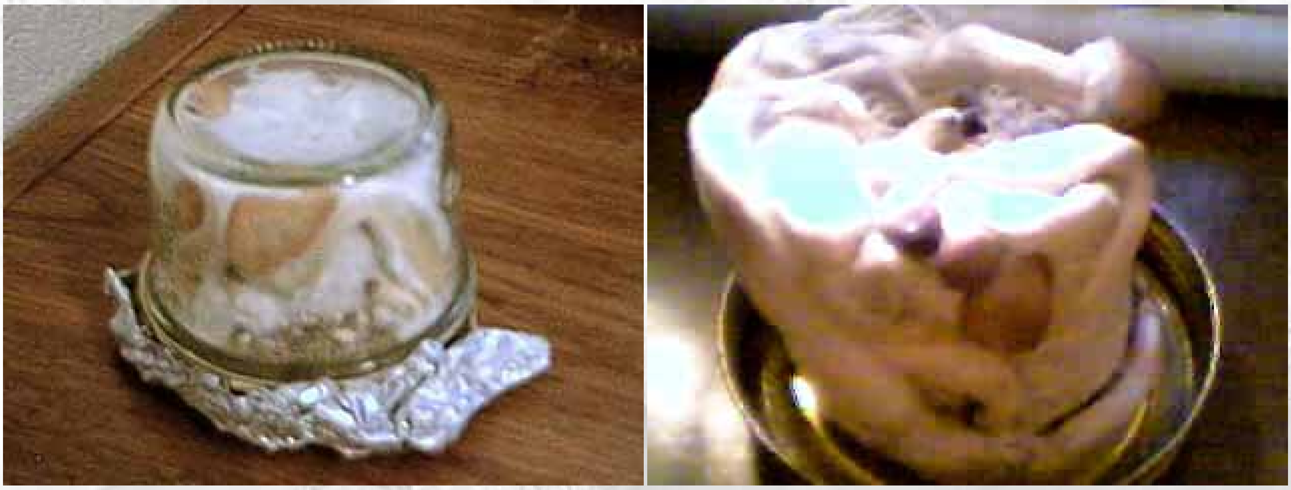


invitro pinning

20. flip the jars over so the cakes rest on the lids.

21. pick shrooms when caps open and the veil under the cap tears. or when they quit growing, or turn dark in color.

22. dry them if you want, or eat them fresh. store un-picked but ripe invitro jars in the refrigerator for freshies all-the-time, year-round.



Detailed Grow Log-Tek - Penis Envy in a Monotub

by

monstermitch

original source: http://www.shroomery.org/forums/showflat.php/Number/6194327/fpart/1/vc/1

Table of Contents:

STAGE ONE: Liquid Culture Creation
STAGE TWO: Prepare and Inoculate Grain Spawn
STAGE THREE: Construct a Monotub and Prepare a Bulk Substrate
STAGE FOUR: Spawn and Substrate added to Monotub and Preparation of Casing Material
STAGE FIVE: Pasteurization and Application of Casing Material and Fruiting Parameters
STAGE SIX: Harvest, Dunking a Bulk Substrate and Later Flushes

This grow log isn't so much about one grow. It's about the process used for this kind of grow.
You'll notice many missing or incorrect pictures, yeah I'm not so much a camera guy, but in the future I'll clean it all up.
The point is to follow and understand the process and materials used to get from a spore syringe to healthy fruits using a simple method. Comments are very welcome. Any improvement suggestions are also welcome.

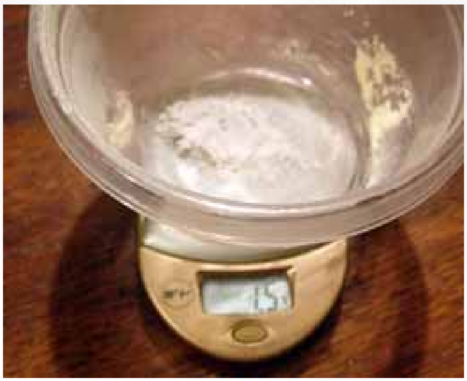
STAGE ONE: Liquid Culture Creation

First step was to order spores from a sponsor here at the shroomery.
While awaiting their arrival, I made a batch of liquid culture.

I started by making sure I had a new or very clean coffee pot. One of the ones that brews 12 coffee cups at a time. That equals roughly 1.8 liters.

I added to the basket: light dry malt, dextrose, gypsum, and activated charcoal.
I used one coffee filter fit for this type of machine.

15 grams each of dextrose and light dry malt

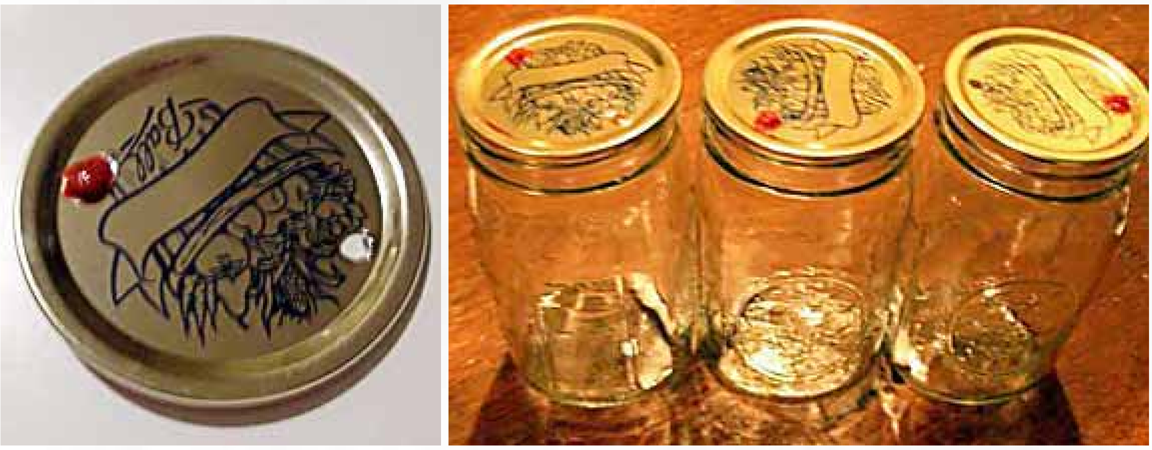


1.5 grams of gypsum flour, and a tiny amount of powdered activated charcoal.
No measurement, just look at the above picture for amount.

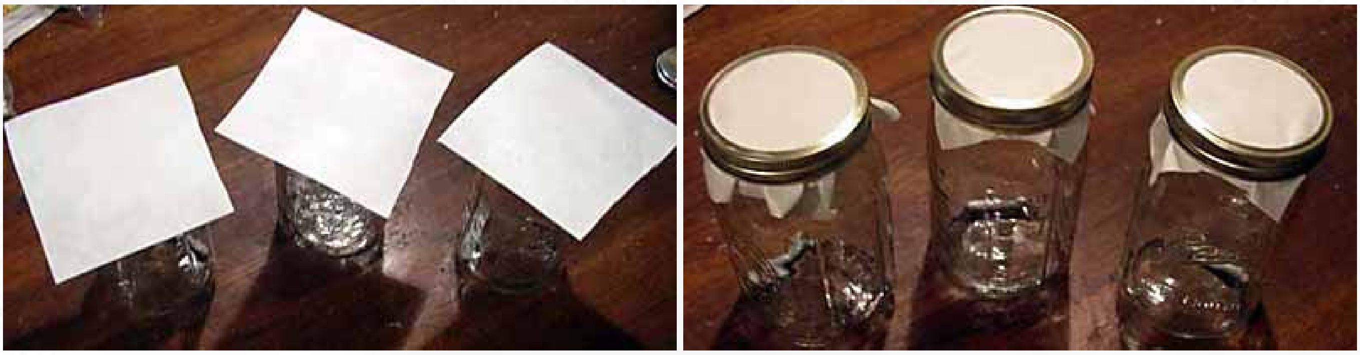
12
10
8
6
4
452

I filled the reservoir full with distilled water and brewed it as I would brew a normal pot of coffee.

I added a magnetic stir bar to each of three quart jars and I poured this solution into them up to the 600ml mark each.

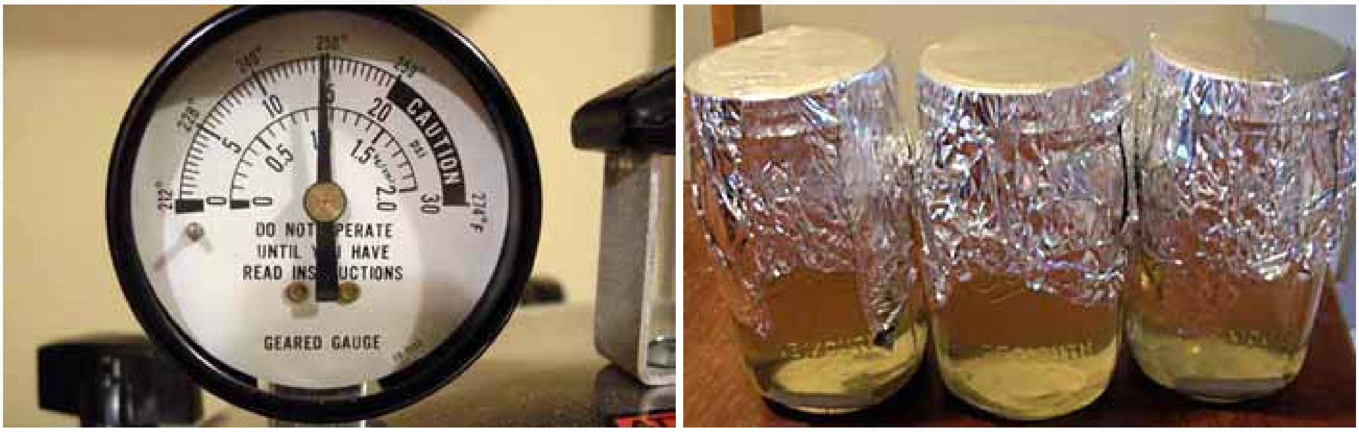


I added these lids to the jars, RTV port on one side, 1/4" hole on the other.



I covered the jars/lids with a piece of tyvek and tightened the band over the tyvek.

WARNING
ADVERTENCIA



CAUTION
DO NOT OPERATE UNTIL YOU HAVE READ INSTRUCTIONS
GEARED GAUGE

I covered the jars with aluminum foil and pressure cooked them at 15psi for twenty minutes.

I removed the jars and let them cool.
I removed the foil and cleaned the tyvek off.

For safety, I wrapped the lid/jar area with micropore tape.

And I added some coffee filters on top as dust covers. I can never be too safe with LC.

Truth be told, I pressure cooked the jars empty first to ensure they were clean when I began the process.

The spores arrived in the mail, and it was then time to move on to inoculation...

I inoculated a quart of liquid culture with some Penis Envy spores from a sponsor here.
This was the process:

I showered first and put on clean clothes.
I used listerine before and after brushing my teeth.

Apothecary Products
F405-603
NIOSH N95
Apothecary Products
F405-603
NIOSH N95

I wore an N95 mask and a shower cap.

I wore latex gloves and cleaned them well with 70% isopropyl. I wiped down the needle and jars with an isopropyl paper towel.

I sprayed the hell out of the air with oust brand air sanitizer. I gave the oust a minute to work and then I folded up a paper towel.

I soaked that paper towel with 70% isopropyl and folded it over the needle cover.

I removed the cover, keeping needle covered with the paper towel.

I shook the ever living hell out of the syringe, holding the needle tight.

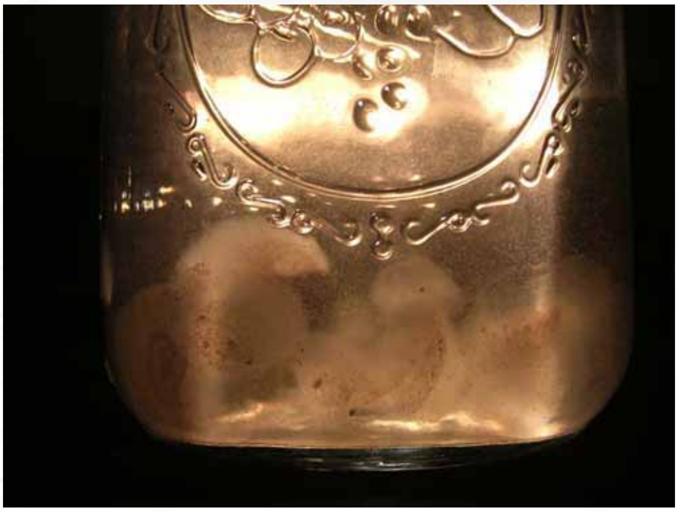
I inoculated each liquid culture jar with one half cc of spore solution.

I removed the needle, still keeping it in the paper towel and I applied a piece of micropore tape to the tyvek's hole.

This piece of tape was soaked in isopropyl prior to it's application.

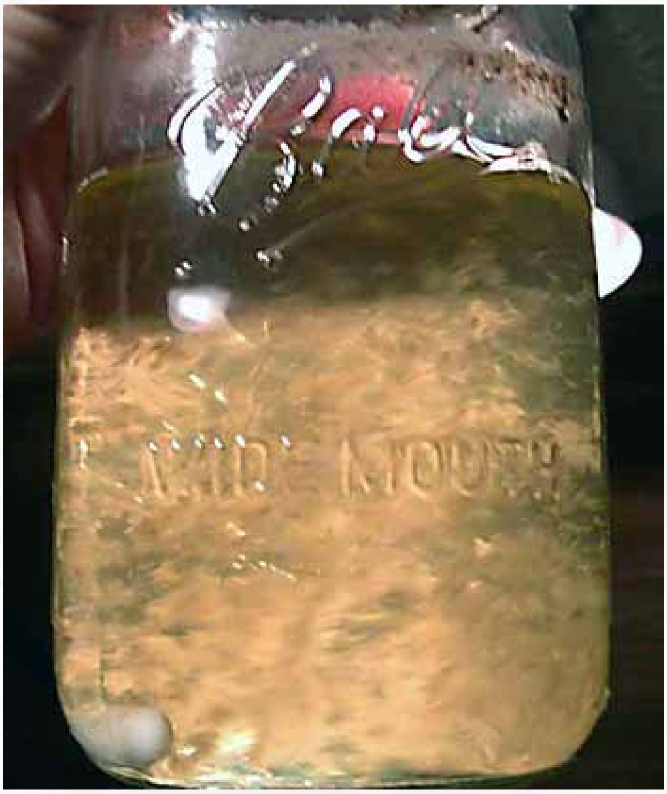
I re-covered the jars with the coffee filters and labeled them PE Spore LC.

These jars were left in a room that sits at 75 degrees steady for a couple of days.



Soon puff balls began to form and grow.

I used my magnetic stirrer to help colonization along.



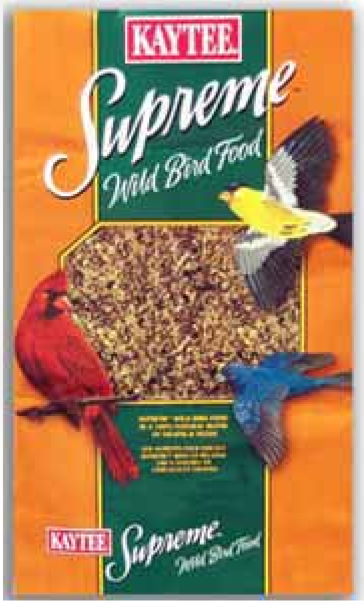
Soon I had a liquid culture that was ready to use.

So I filled a big syringe with the finished LC, and got some grain together.

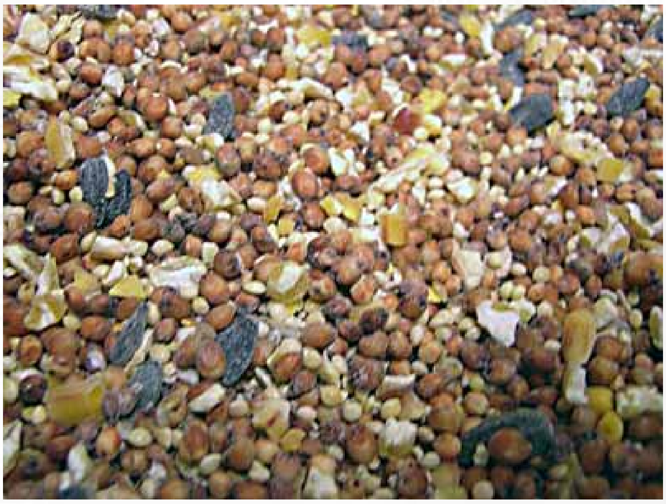
Table of Contents

STAGE TWO: Prepare and Inoculate Grain Spawn

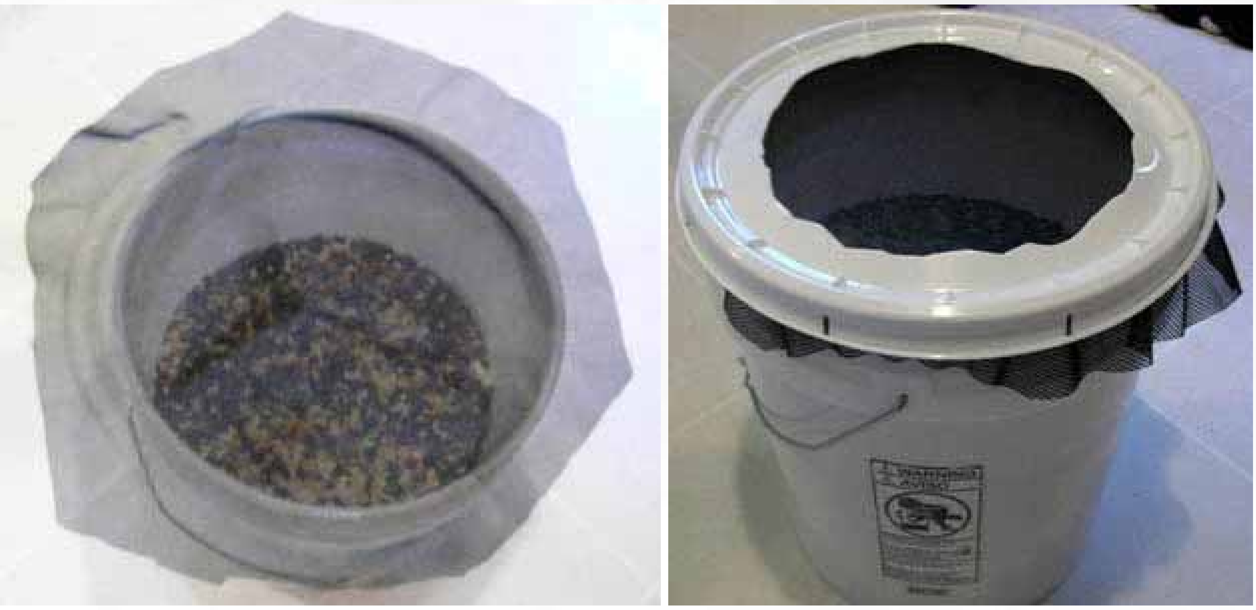
I chose this birdseed to use as my grain, I like it.



KAYTEE
Supreme
Wild Bird Food
KAYTEE
Supreme
Wild Bird Food

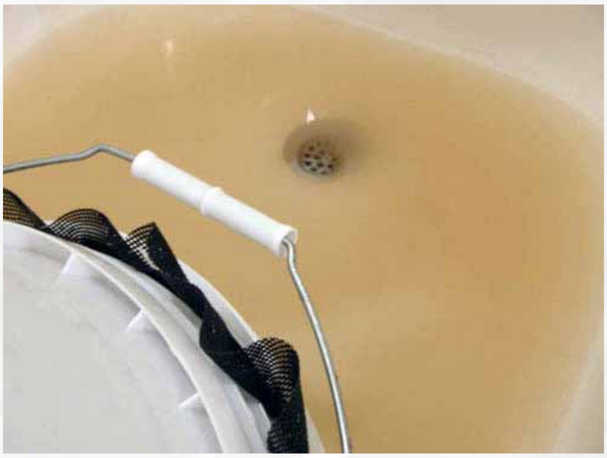


I filled a five gallon bucket with twenty pounds of birdseed.
That brought it to about 2/3 full.



I added a piece of house screen and a lid with a big hole to the bucket.

I filled the bucket with hot water, dumped it out, filled it, dumped it out... Until the water ran perfectly clear. This was like ten reps.



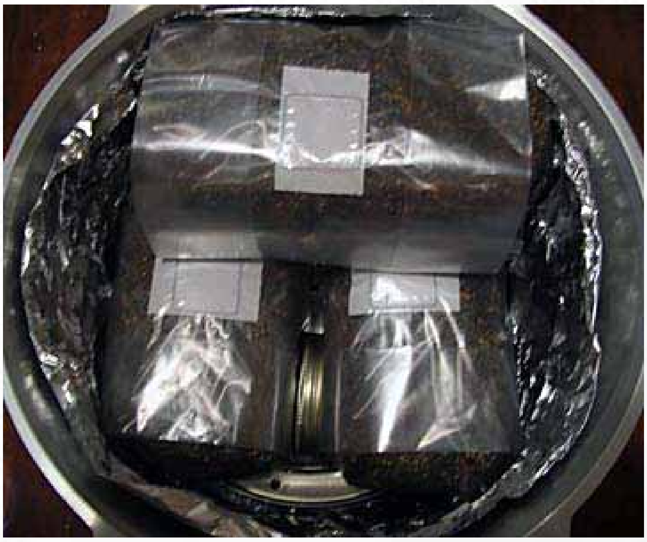
I opened the lid and took off the screen.
I added six cups of hot coffee and three tablespoons of gypsum to the birdseed.
I replaced the screen and lid, and filled the bucket up to within two inches of the top.
I set the bucket out of the way and left it alone for 24 hours.
After the 24 hour wait, I again dumped, filled, dumped, filled, dumped...
Until the water ran completely clear.
I used very hot water for the last couple of fill and dumps.

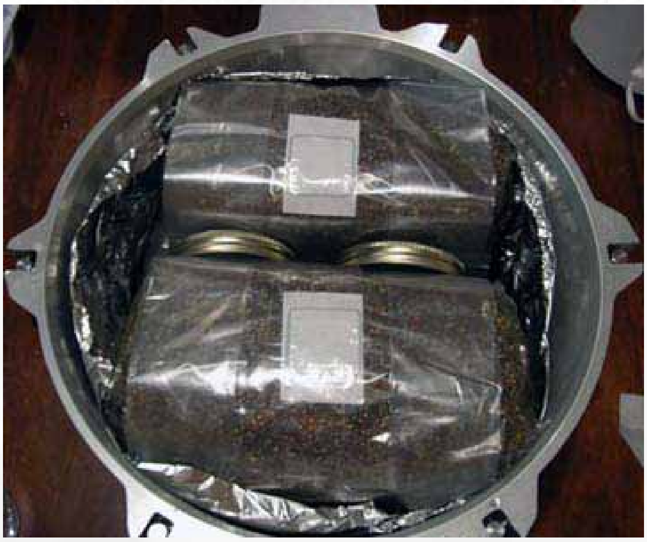
I inverted the bucket and let it drain through the screen for six hours.

After the drain, the birdseed was ready to be sterilized in filter patch bags.

Some of the following pictures show not just birdseed in the bags. They show a different substrate, this is because I suck at taking pictures.
So just visualize these bags always having birdseed in them.
There are other discrepancies too, like some bags not having RTV ports on them, again, just bare with me, at least there are pictures...

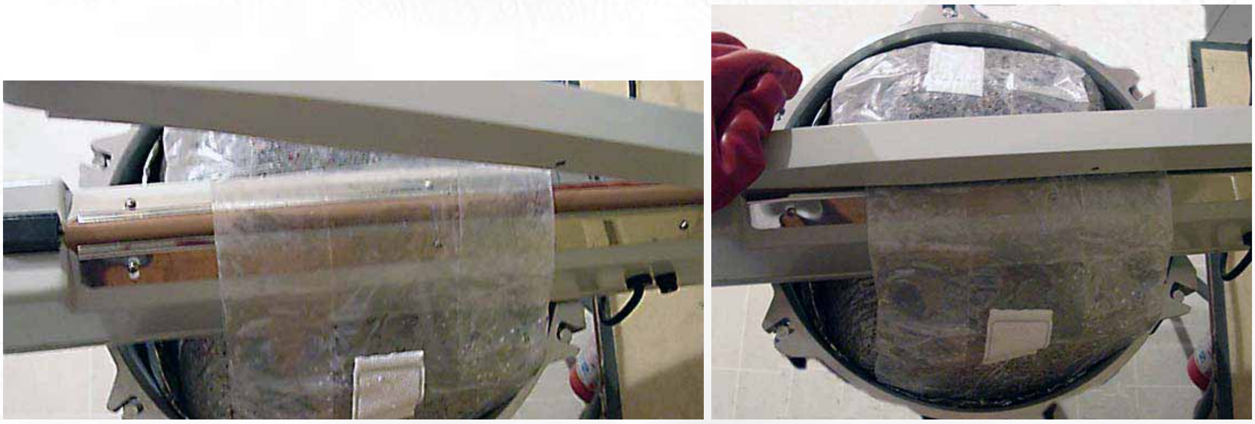
I put three full quarts of birdseed into each bag and folded the



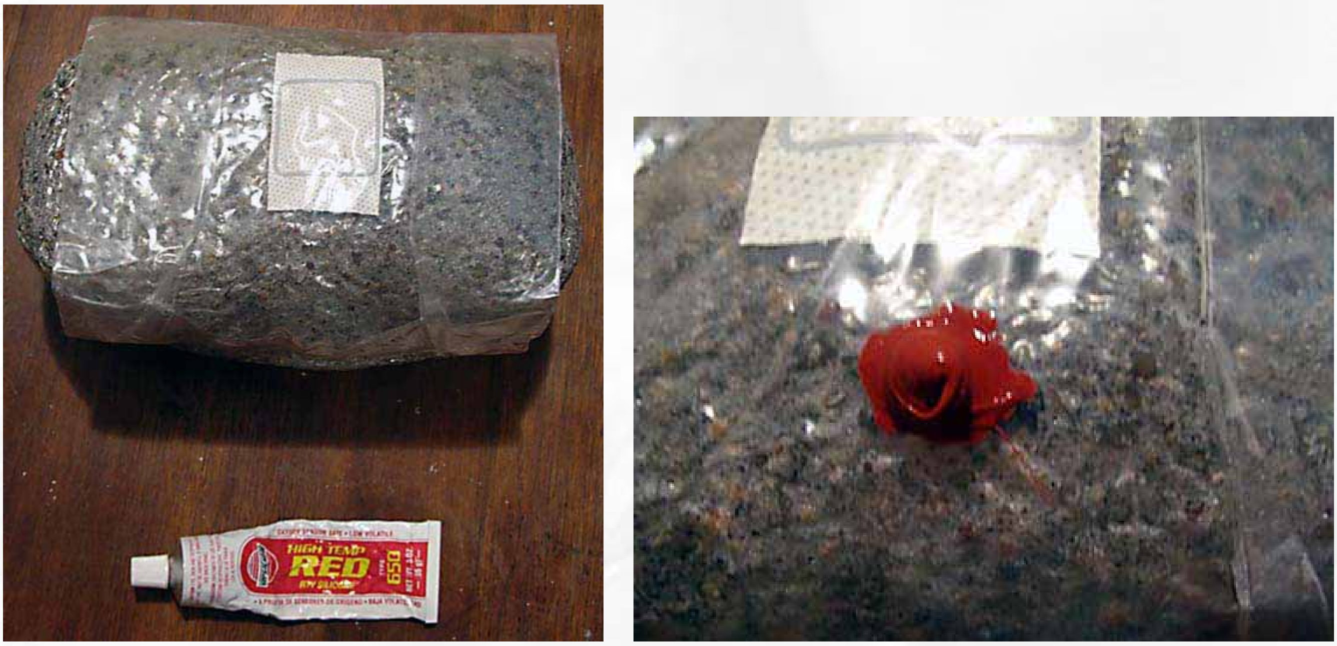


WARNING
ADVERTENCIA
CAUTION
DO NOT OPERATE
UNTIL YOU HAVE
READ INSTRUCTIONS
GEARED GAUGE

I loaded the bags into my AA-921 and pressure cooked them at 15psi for three hours. Four bags per batch.



After the pressure cooker cooled and de-pressurized, I opened it and impulse sealed the bags.

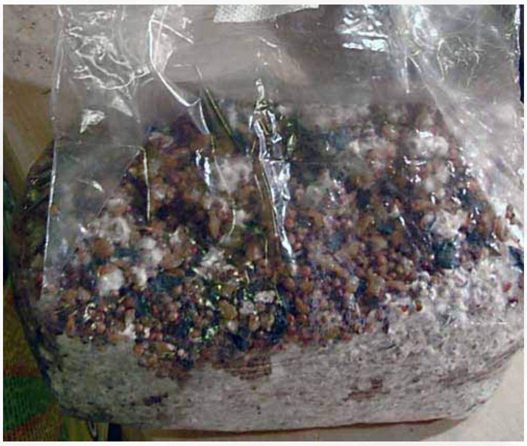


I then removed the bags and made some RTV ports on them. The ports went on the opposite side as the filter patch, below it.

I then hung the bags like so to cool and self-inflate.

I inoculated the grain bags with the PE LC and put them on wire shelves.

These were the bags, hanging out, colonizing.



Colonized to 25% or so, so time for massaging.

After massaging.

Growth began again quickly and took off.

Here they were, finished and ready to go.

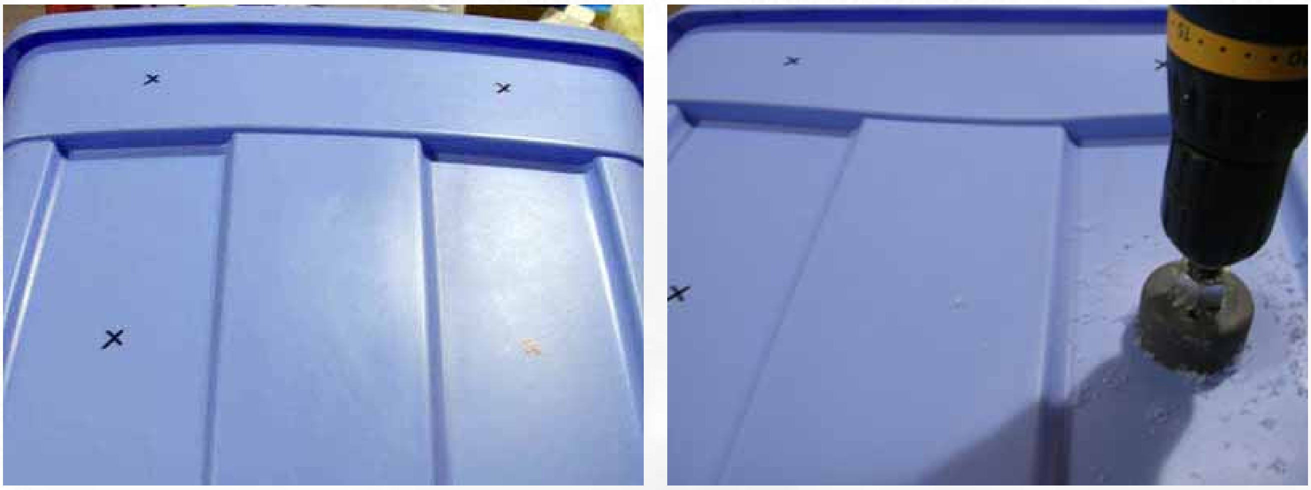
This grow log will follow the life of two of these bags and their try at it.

So I needed something to mix with this spawn...
What do I choose this time, so many options...

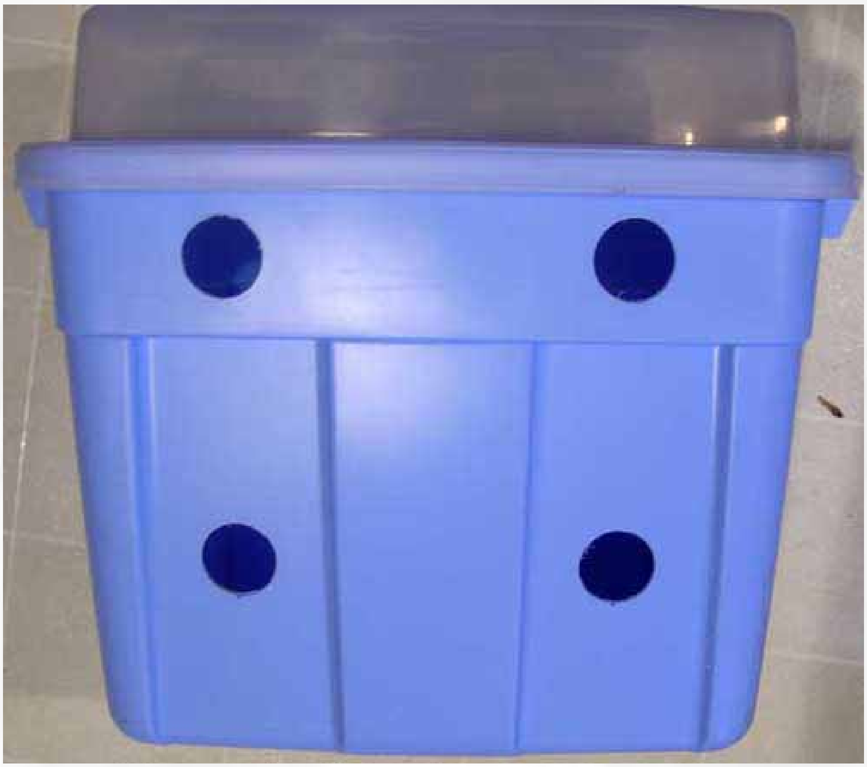
Table of Contents

STAGE THREE: Construct a Monotub and Prepare a Bulk Substrate

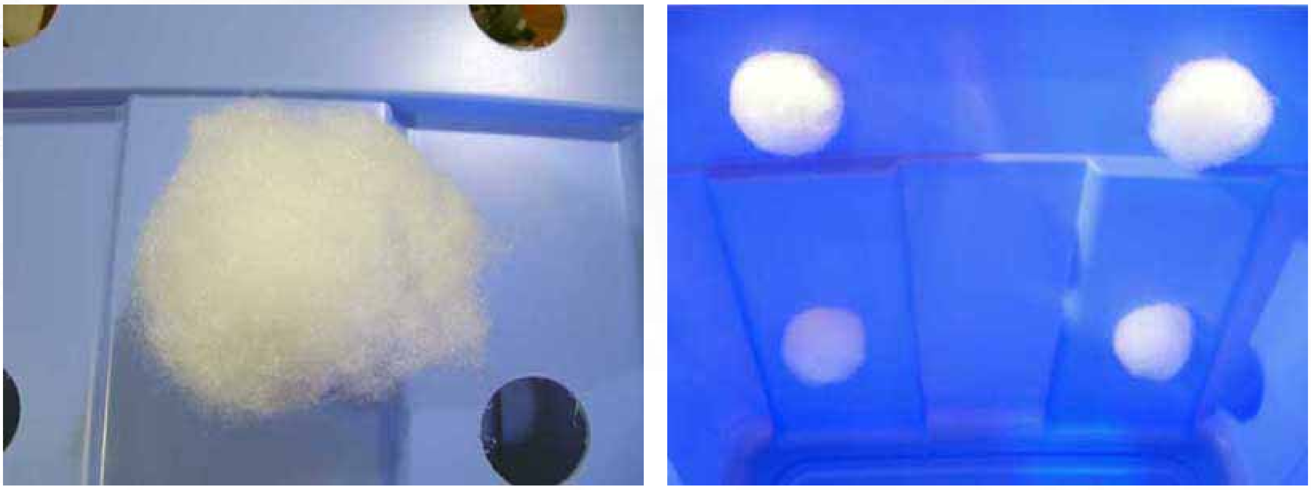
Following my monotub tek, I took two of these tubs and made them into monotubs.
These things are great, no plexi glass needed, the lid is clear(ish)!



I marked and drilled four 2" holes in each side.



The bottom holes are 5.5 inches from the bottom of the tub.
The top holes are 8 inches above the bottom ones.



I cleaned the tub well with vinegar and isopropyl and stuffed the holes with poly-fil.

I lined the bottom with a black trash bag, like with this tub.

Once complete, I just set these tubs aside to wait for use.

So I needed a bulk substrate to mix with the colonizing grain.
I was all out of horse manure, the other bags ate all of that.
Next best thing to horse manure in my house is...

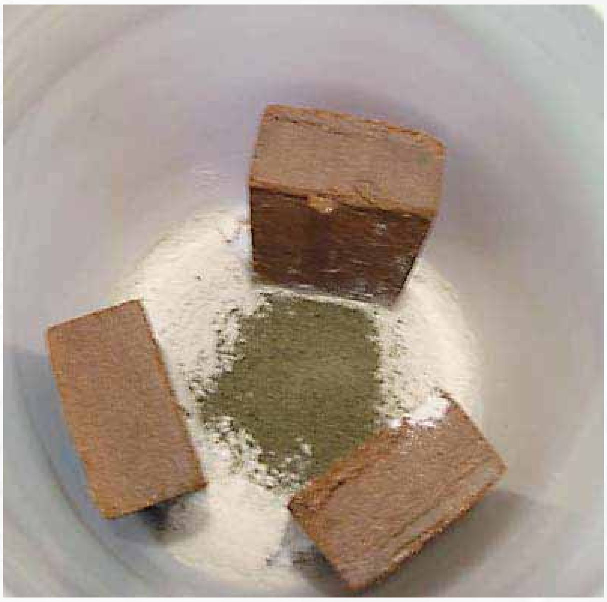
So three bricks went into a five gallon bucket.

distilled water
wardley
BULLSEYE
7.5
Basic pH REGULATOR

Three gallons of distilled water and three teaspoons of 7.5 pH regulator...

were heated on the stove to 150 degrees.



I added some hydrated lime, gypsum, kelp meal and blood meal to the bucket.

I added the three hot gallons of water and stirred well.
The stirring incorporated all of those powder additives into the water.
The coir then, in turn, absorbed that water and those additives.

A cover was placed on the bucket with a hole in it, and the coir bricks were allowed to expand for a half-hour.

After the half-hour, I opened the bucket to find three very expanded bricks.

I broke up the bricks very well using a knife at first. No big chunks at all left, all broken up.
These pictures suck, sorry, I suck with a camera. You can imagine though...

I dumped the coir into a mixing tub and added in the last little bit of tenn stud I had to the mix. But I wanted more...

Worm castings, diatomaceous earth, and maybe a touch of stevia leaf were added.

This was mixed very well until incorporated.
Some vegetable oil was added and mixed in.
And 7.5 pH regulated distilled water was added until the mix was field capacity.

PAINT
STRAINER
TRIMACO
5 GALLON
Elastic Top

A five gallon bucket was lined with a paint straining nylon bag.

The bag was filled 1/2 to 2/3 full with this finished substrate mix.

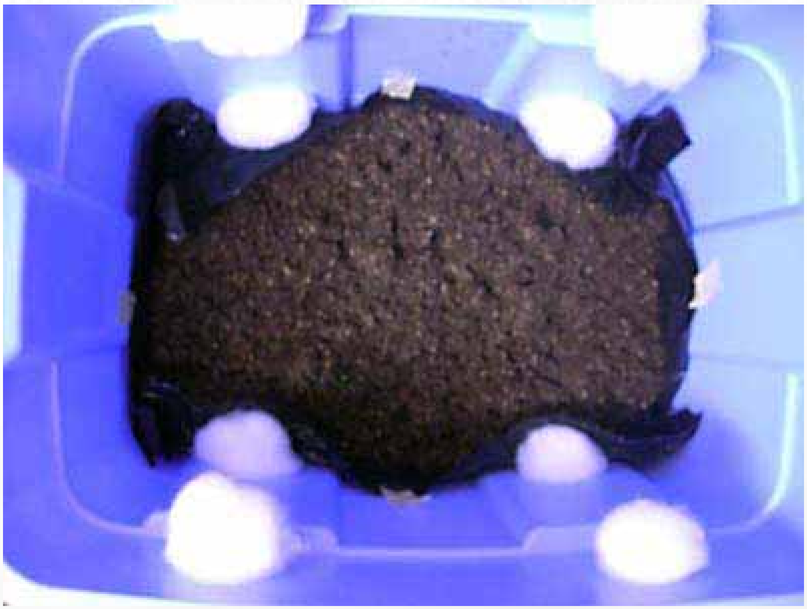
The bag was closed and cinched together with a rubber band.
This mix was enough to make two nylon bags full.

So the first one done was loaded into a five gallon bucket.
(I always place them on their side, they fit much better.)

And the second one was placed on top of the first, filling the bucket.

Sticking to my bulk substrate tek, I heated about 3 gallons of water to 175 degrees.

I filled the bucket with 175 degree water, covered it with a lid, and let it sit and pasteurize for two hours.



Once the two hours were over, I put the two bags into a clean tub to drain and cool.
I squeezed them fairly hard at first and then just let them sit.

Okay, now I had some colonized spawn and some pasteurized bulk substrate material.
It was time to put the two together into my newly constructed monotubs.

[Table of Contents](#)

STAGE FOUR: Spawn and Substrate added to Monotub and Preparation of Casing Material

I showered and put on clean clothes.
I used listerine before and after brushing my teeth.

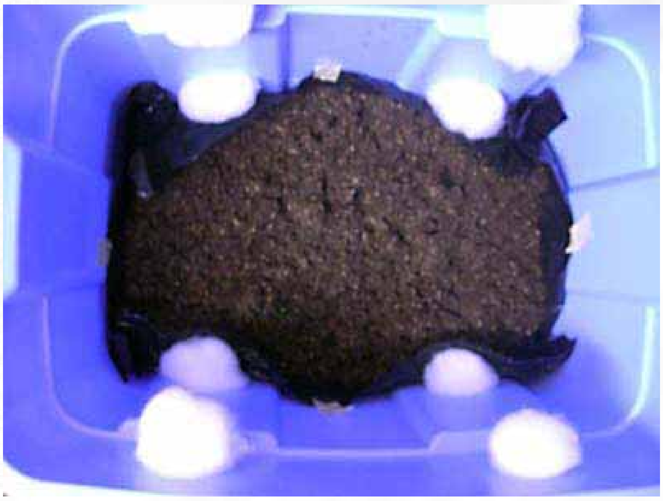
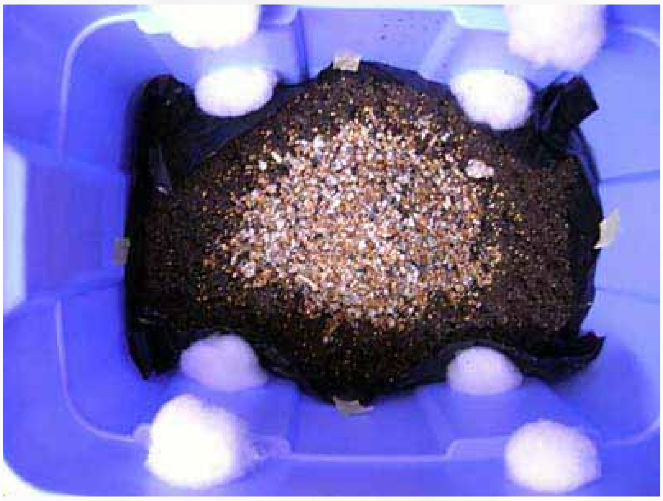
oust air
oust air
oust air
oust air

I sprayed the hell out of the air with oust brand air sanitizer.

I gave the oust a minute to work, then opened the first tub.

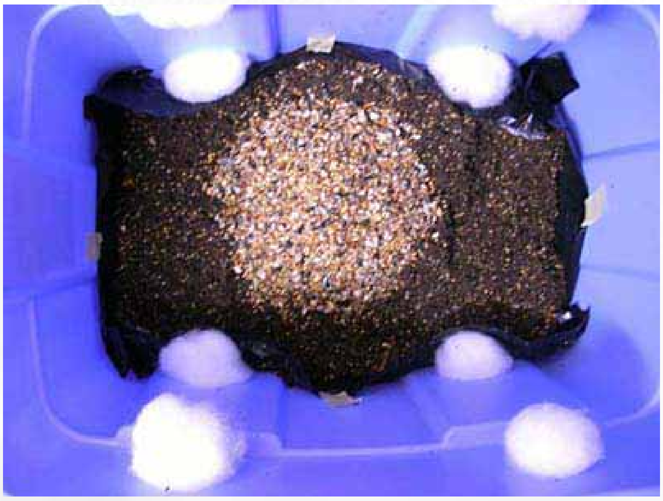


I emptied the bulk mix into the monotubs, leveling them out at around four and a half inches deep.
Sorry these pictures really suck in quality, I was trying to be clean.



I dumped the spawn on top of the substrate.
Each tub required one bag which was 3 quarts of birdseed spawn.

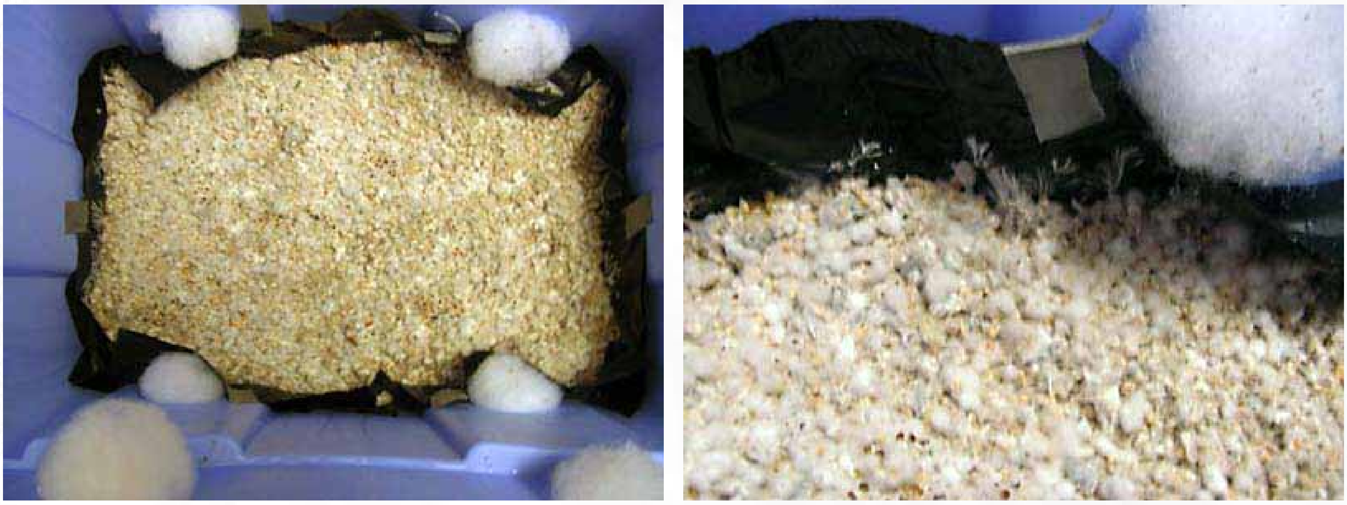
I mixed it in really well, especially the bottom.

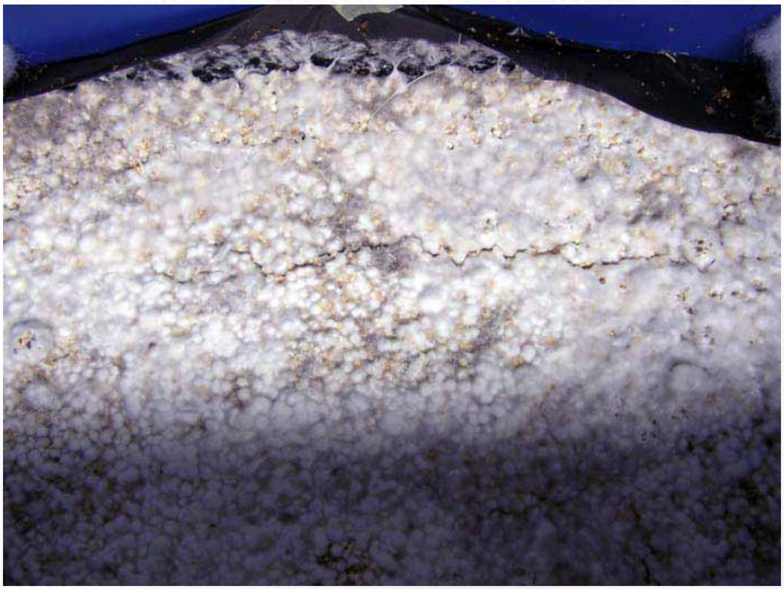


I added more spawn to serve as a spawn frosting layer.

I evened out the spawn frosting and closed up the tubs.

I placed the tubs under a blanket for about a week and a half.
74 degree room, blanket not too tight at all, allowing gas exchange still.





They colonized quite well and started to shoot up some rhizomorphs.

Now casing mix had to be made.
In recent past, I would make a traditional 50/50+ casing mix.
But this was more recent past, and I used a store-bought bagged product...

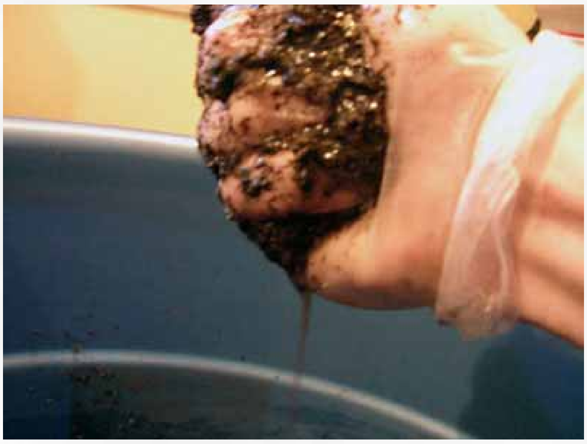
Grows Plants Twice As Big!
Miracle-Gro
Moisture Control
POTTING MIX
Feeds Plants up to 3 MONTHS!
8
Miracle-Gro Moisture Control Potting Mix.

I said this would be easy, and it is.
So I made up only six quarts of this stuff, because that's all I need for two of those monotubs.
I forgot to take pictures of this part, maybe I'll make more soon and remember to take some pictures...

Recipe I used for my casing mix:
38 cups of Miracle-Gro Moisture Control right out of the bag
(I removed sticks and large pieces)
1/4 cup of hydrated garden lime
1 cup of oyster shell flour
1 cup of food grade diatomaceous earth

I mixed this all very well before adding any water.

I added 7.5 regulator distilled water until field capacity.



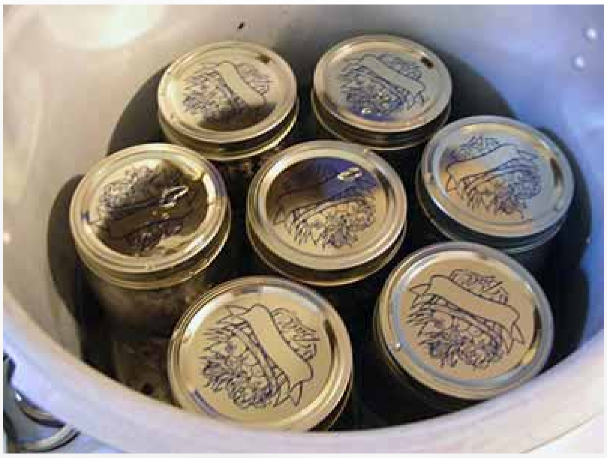
I tested the pH with my pH/Moisture probe and it was 7.5.
Perfect, now time to pasteurize the casing material on the stove.

Table of Contents

STAGE FIVE: Pasteurization and Application of Casing Material and Fruiting Parameters

I filled six quart jars full of casing material, NOT packed down tight.

I used new lids, not altered in any way and placed them on the jars.



I screwed the band down tight and loaded the jars into the Pressure Cooker.
(the middle jar is full of just water, to help keep the jars in place)
I filled the pressure cooker with cold water so the water was 2/3 up the side of the jars.

WARNING
ADVERTENCIA

I put the lid on the pressure cooker, but not the weight, and started the stove on high.

I let the heat build and the water boil.
I let steam escape the valve for five minutes and shut off the heat.

I let the pressure cooker just sit there and begin to cool for a half of an hour.

I turned the heat back on high and repeated the boil and five minutes of allow steam venting before shutting the heat off again.

This time the pressure cooker was allowed to cool for two hours.

I removed the jars and brought them to a room to cool to room temperature.
Casing mix was then complete and awaiting it's use.

I moved the tubs out of darkness and into the clean room with still air.
I showered and put on clean clothes.
I used listerine before and after brushing my teeth.

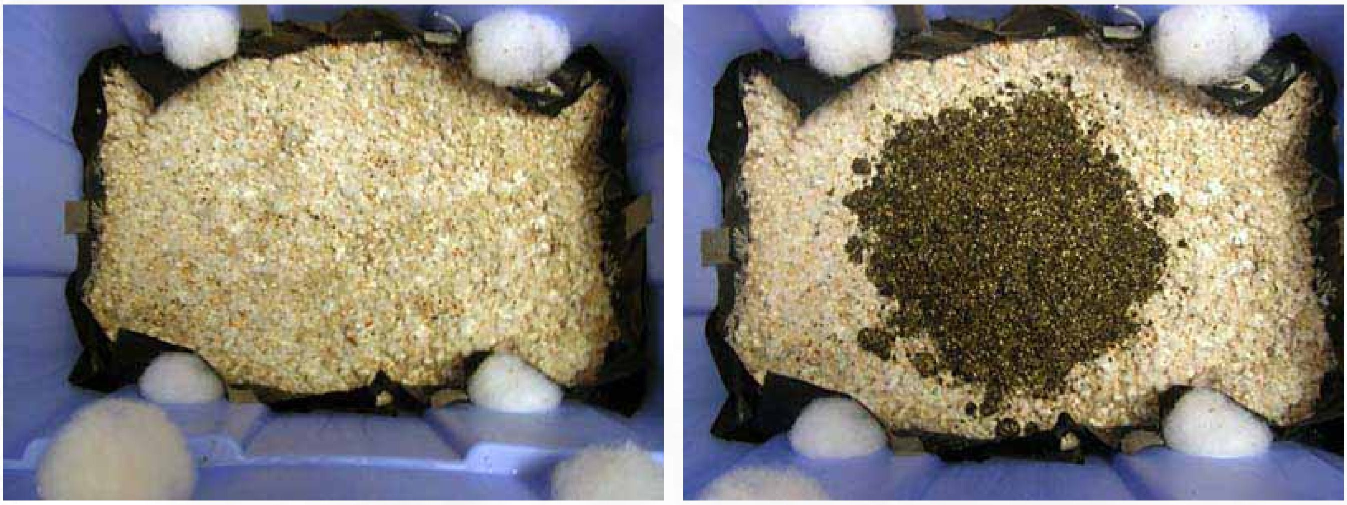
oust
oust
oust
oust

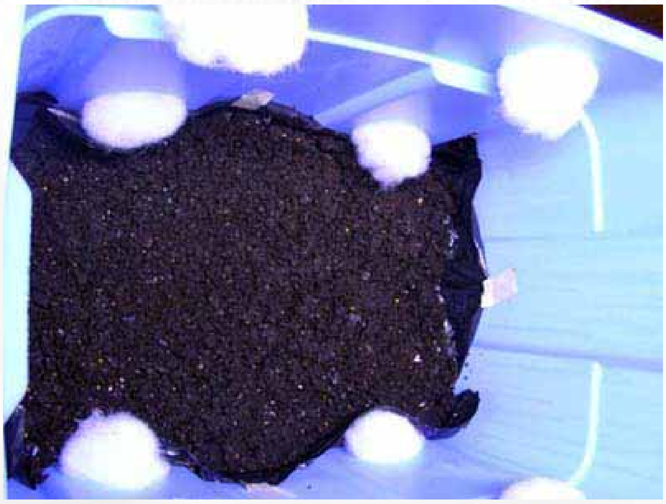
I sprayed the hell out of the air with oust brand air sanitizer.

I gave the oust a minute to work.

I shook each jar well then popped the vacuum seal and set it aside.



3 quarts of casing per tub were added and leveled out very evenly.



The tubs were closed immediately and put back into darkness.
After three days, the mycelium began to poke through and the tubs were taken from darkness and placed into their fruiting room.
Fruiting is super simple with monotubs.

Parameters the tubs were placed in:
74-76 degree room, whole room heated with a radiator-type space heater.
Box fan on a shelf high in one corner, running on medium.
Another small fan in the opposite corner, oscillating on medium.
Empty, inverted tubs or milk crates used to sit the tubs on.
A fluorescent light in the center of the room on the ceiling with cool white bulbs, set on a timer for 13 hours on and 11 hours off.

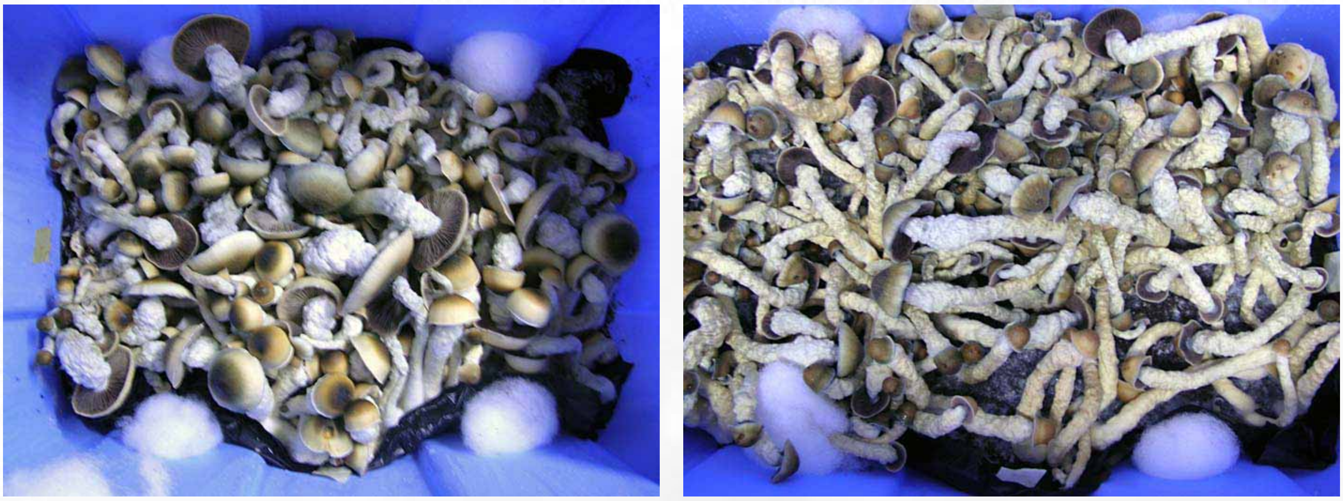
That's it.
No misting, ever.
No fanning, ever.
No patching or any opening of the tub at all, until harvest that is...
The holes are placed so as to promote swirling of air inside of the tub.
The poly-fil is used to trap humidity inside that the casing naturally produces.
It's a wonderful fruiting environment.

Table of Contents

STAGE SIX: Harvest, Dunking a Bulk Substrate and Later Flushes

Pinning is a problem to show you.
See these monotubs never opened, and I couldn't photograph the pinset.
The lids are translucent to start, and with a touch of condensation they turn pretty much opaque.
So sorry folks, right now I have no pinset shots of these tubs.
Let's just say the pinsets were acceptable, but not overwhelming.

Here are some pictures of the fruits:



Each tub on their first flush, nothing too special really.

Nice color on the gills on this one.

Typical flush for one tub, six ounces cracker dry.

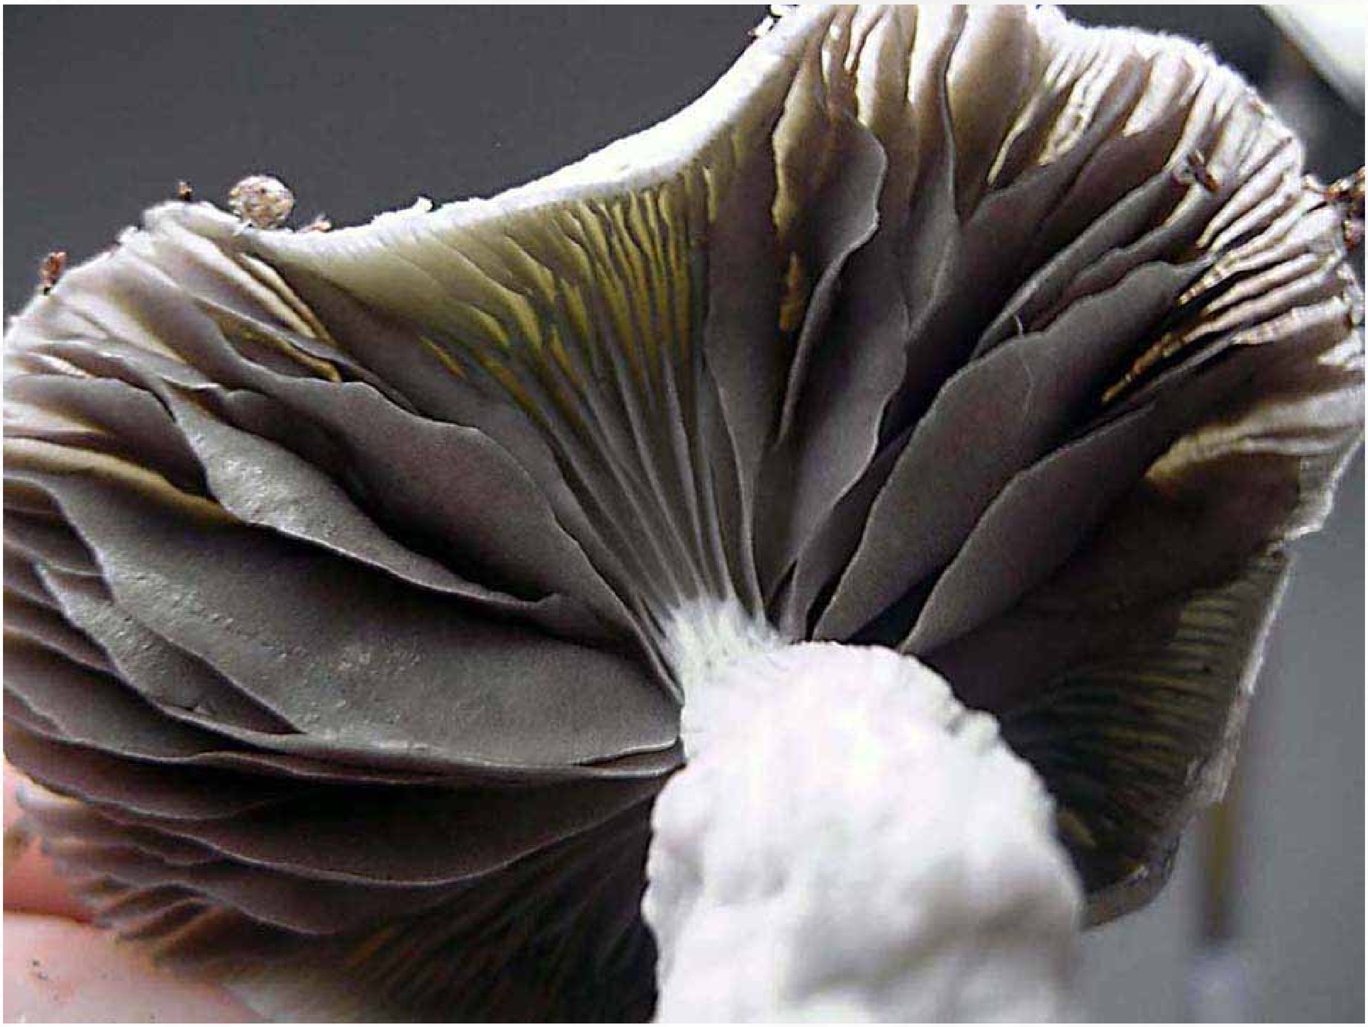
Some pictures of Second Flush Fruits for you:

A nice handful of solid fruits and a nice family of brothers and sisters.

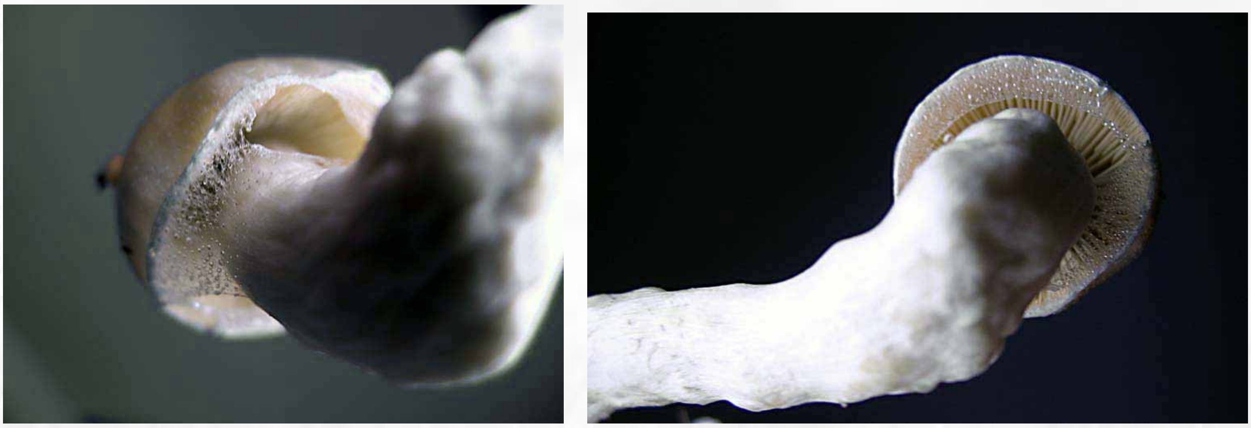
My dehydrator was laughing at me.

But I got them dry.

Other Penis Envy pictures of mine for you:



Gill mutation.



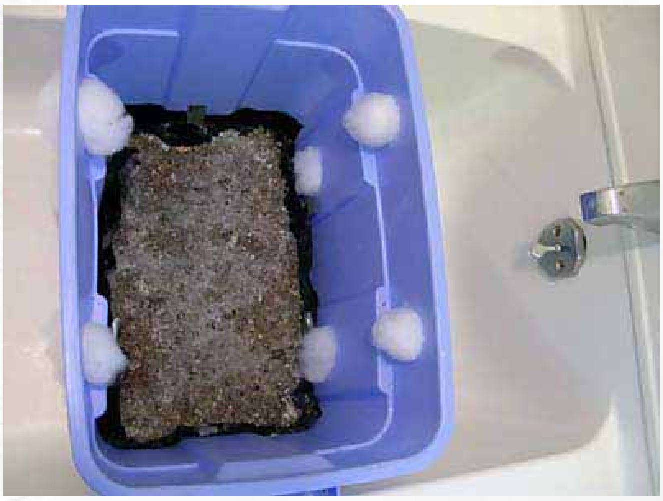
The minuscule veil.

The single and double penises.

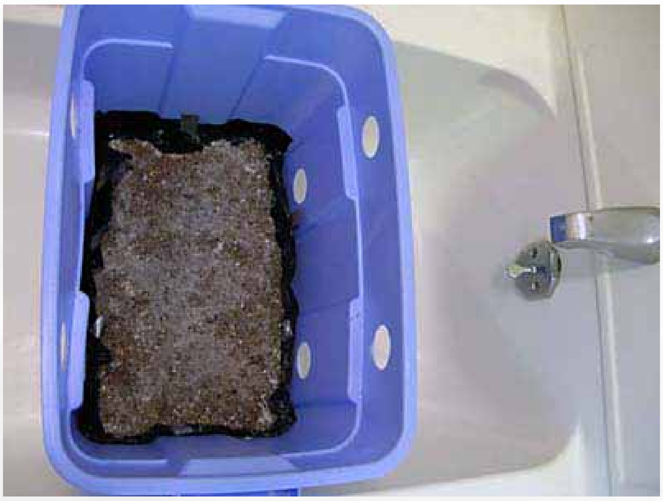
Super dense stipes on these pe pe's.

Nice shots from a bag.

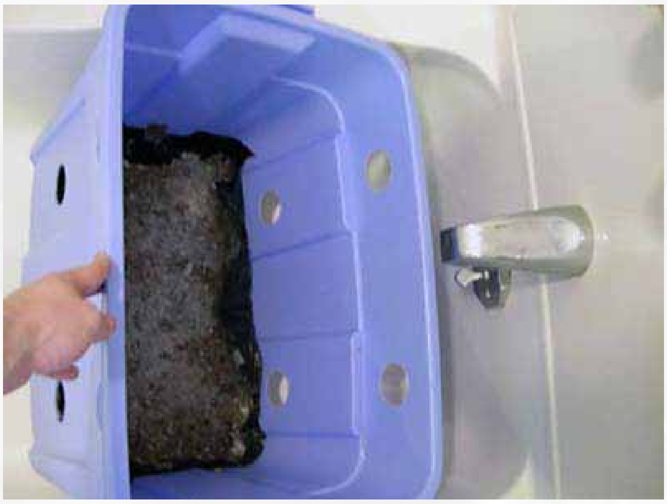
After the harvest, it was time to dunk the substrates and get them ready for a second flush, this is how I did that:



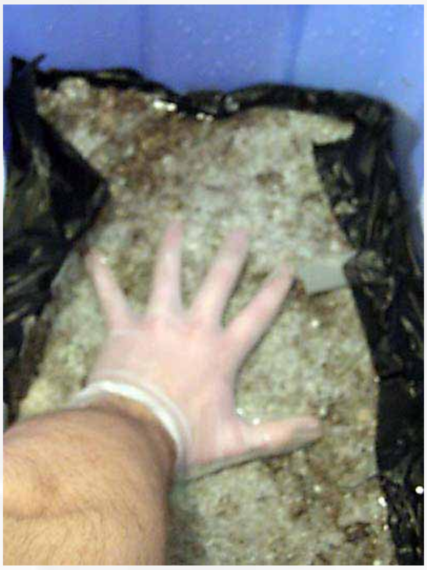
I placed the tub into the bathtub.



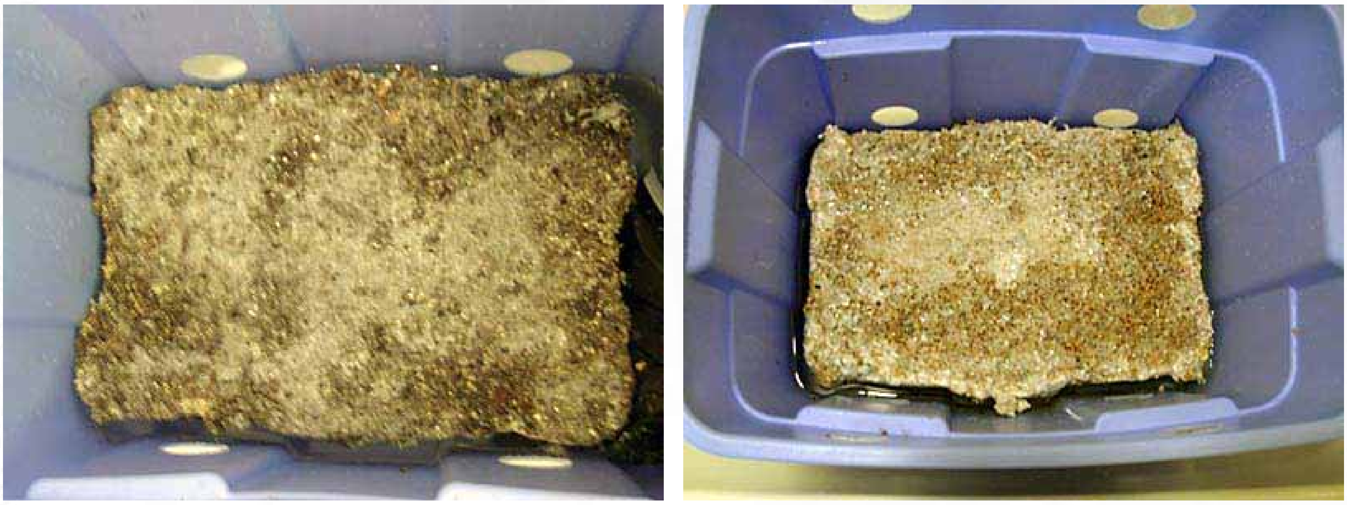
I removed the poly-fil from the holes and set it aside.



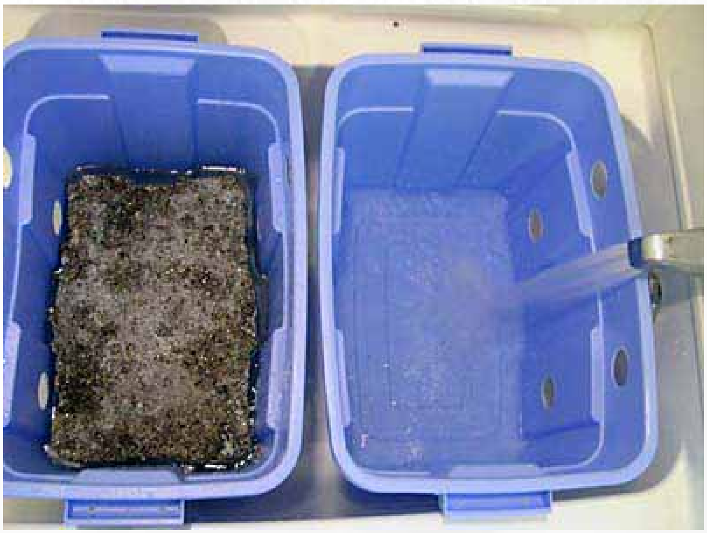
I tilted the tub and carefully filled it with water up to the holes.



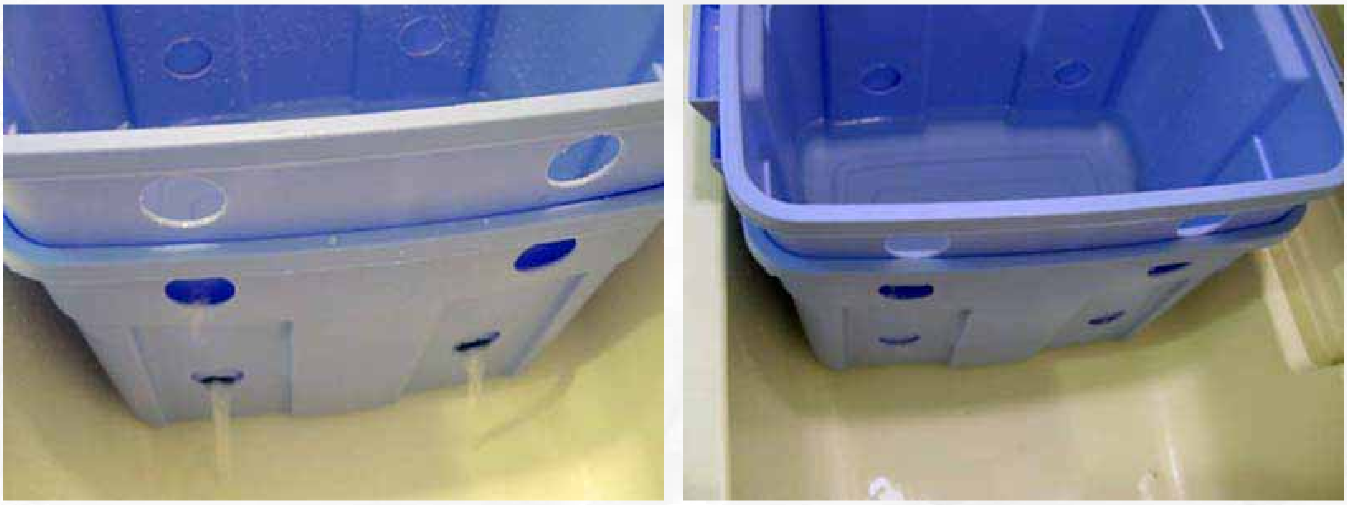
I gently submerged the substrate and loosened the bag around the sides.



I removed the bag gently.



I filled another tub with about two inches of water.



I carefully put the water filled tub on/in the tub with the substrate.
This top tub was an effective and even weight to hold the substrate under water.
Notice that some water ran out of the bottom holes, that was fine.

I positioned the tubs under the faucet and turned the water on slow.

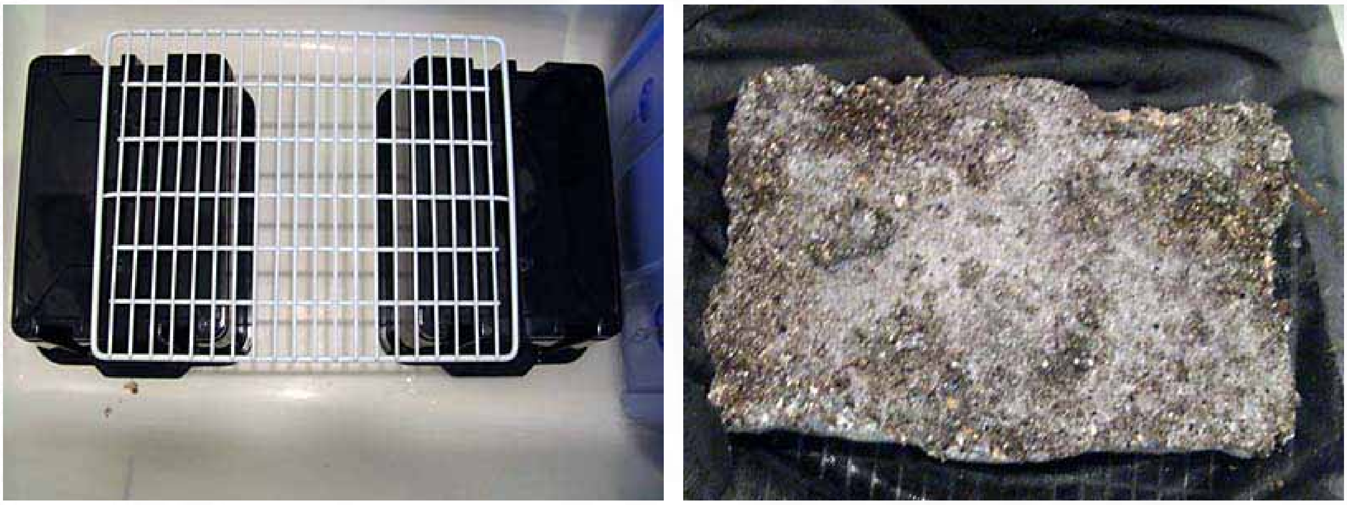
I let the water run into and out of the bottom tub for 4 hours.
After the four hour dunking, I shut the water off.
This used about as much water as a typical shower would have.

I very carefully removed the top tub as to not spill any water onto the substrate.

I emptied the top tub and set it aside.
Now it was time to remove and drain the substrate.

I taped two of the bottom holes with duct tape.
This would be temporary.

I tilted the tub again and filled it as much as I could.
I cut a piece of house screen six inches longer and wider than the substrate.
I used the screen to easily lift the substrate out of the bottom tub.



I placed the substrate and screen on to a wire shelf on top of some trays to drain.

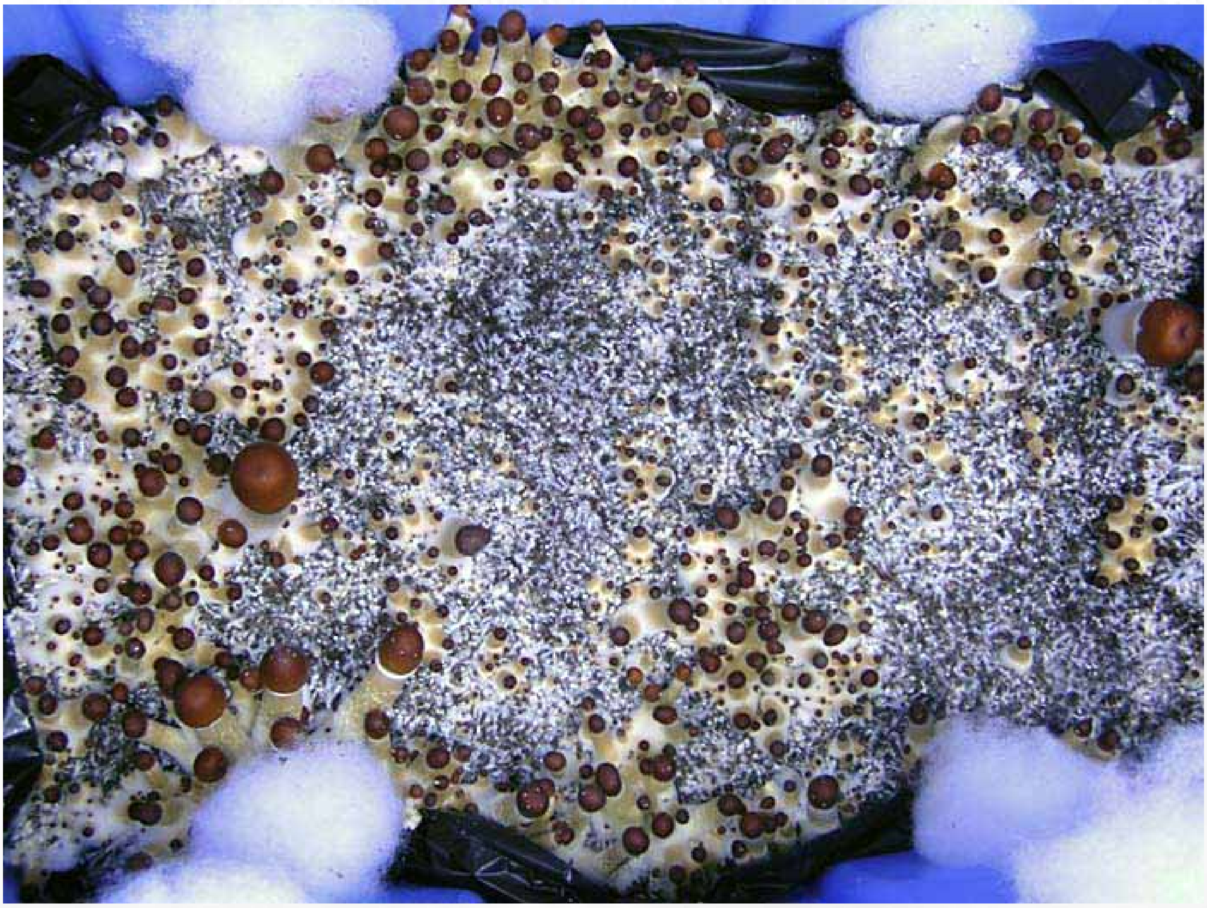
I let the substrate drain for four hours.

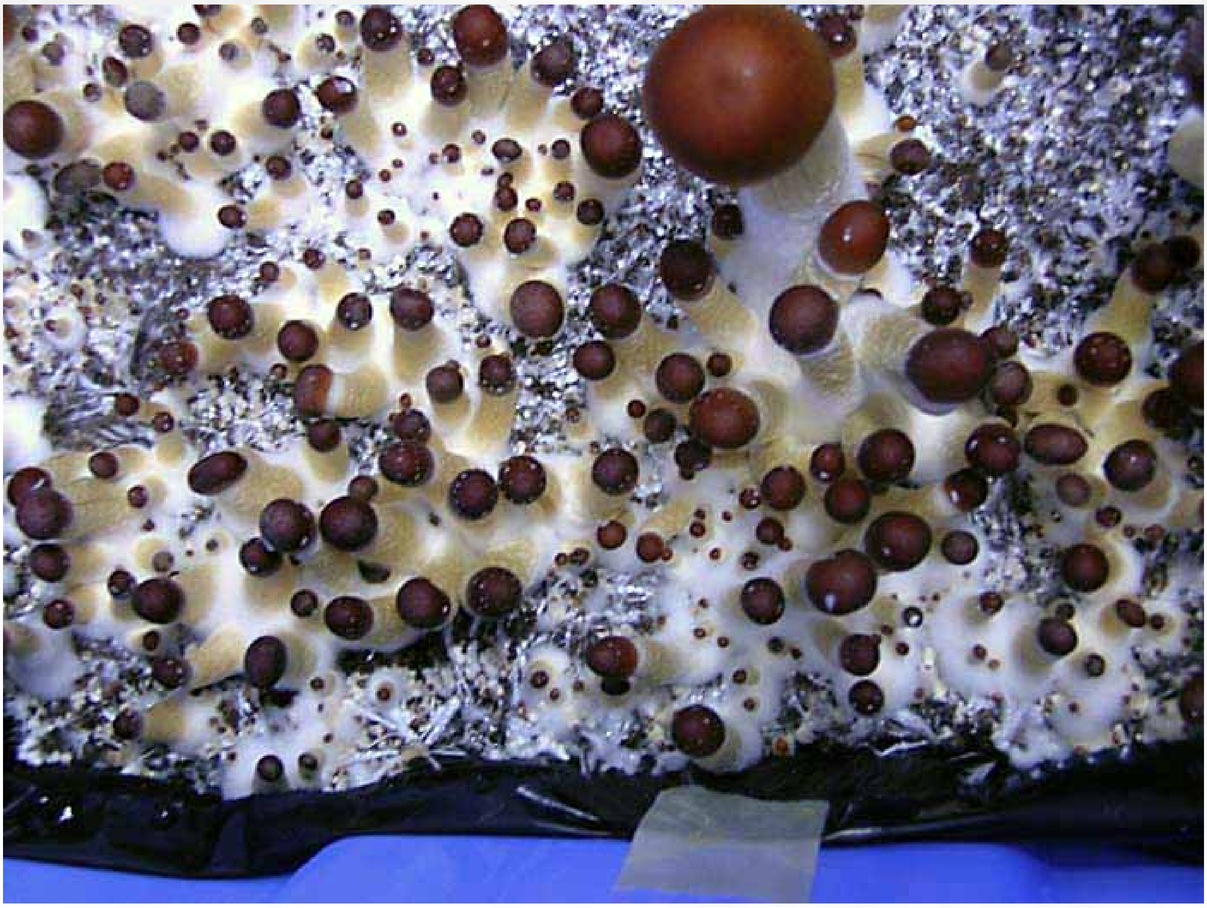
While the substrate was draining, I cleaned the monotub
very, very well and replaced the poly-fil in the holes.
I sealed the lid and set it by the bathtub for easy access when ready.

I slowly and easily shimmied a new plastic bag under and around the substrate.

I placed the substrates back into their clean monotubs and applied a fresh layer of brand new casing material to the substrates.
I then placed the monotubs back into the fruiting room and waited for a second flush.
And the grow is successfully completed.
What to do with the fruits? Make chocolates!

Works with any strain!!





Rye Grass Seed Bag Tek

by

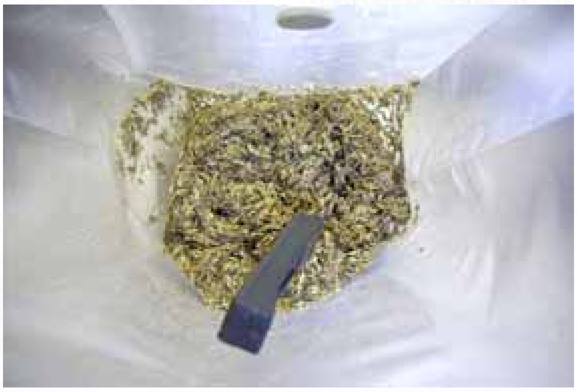
Compiler

original source:
http://cdn.preterhuman.net/texts/drugs/shroomery_grow_archive_2003_10_14/shroomery_grow/www.sporeworks.com/labnotes/ryebagtek.html

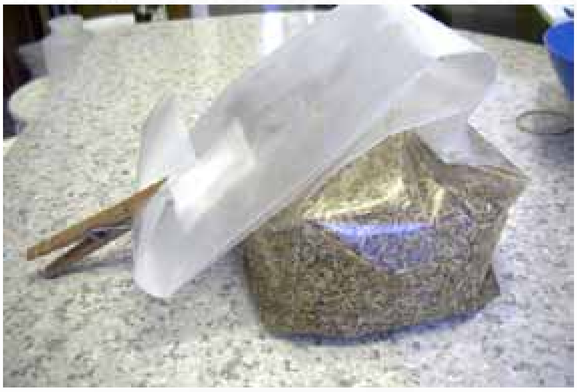
Below you will find instructions for the preparation of rye grass seed in Autoclavable Spawn Bags. The bags we are using for this demonstration contain filter patches and our new self-healing injector site. For these instructions we will be filling 3 bags and sterilizing them in a #915 All-American Pressure Cooker.

Fill 3 Autoclavable Spawn Bags with 500 gm of Rye Grass Seed.

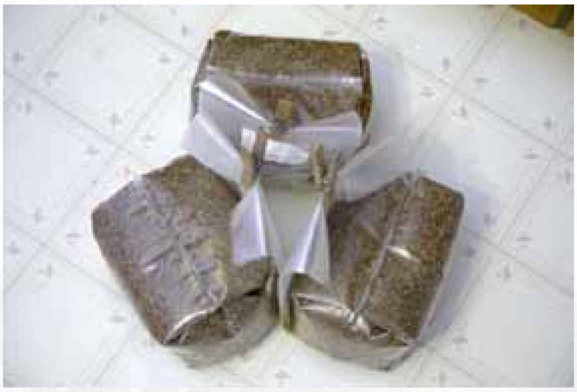
Add 500 ml of water to each bag.



Mix well.

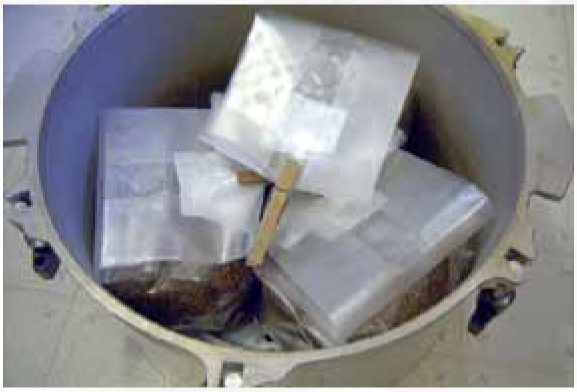


Fold over top of bags and hold closed with a clothespin.



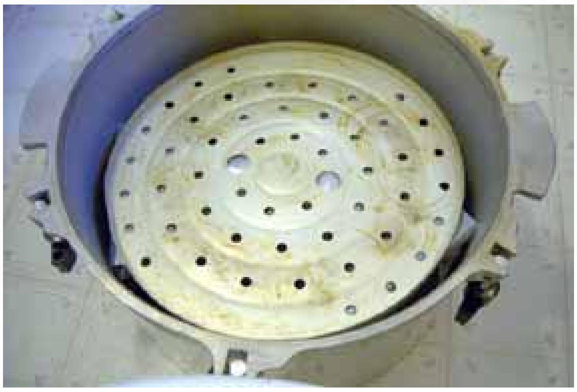
Flip bags over but keep opening at top like in photo to right.

Let sit like this for 8-10 hours or overnight. Rotate bags back to the normal upright position and fold the top down.



Now load 3 bags into a #915 All-American Pressure Cooker.

Add 3000 ml water to cooker.



Place extra bottom rack on top of the bags. This prevents the bags from blocking the vents of the cooker.

Put the lid on your cooker and secure. Turn on the heat to the range and set on high.

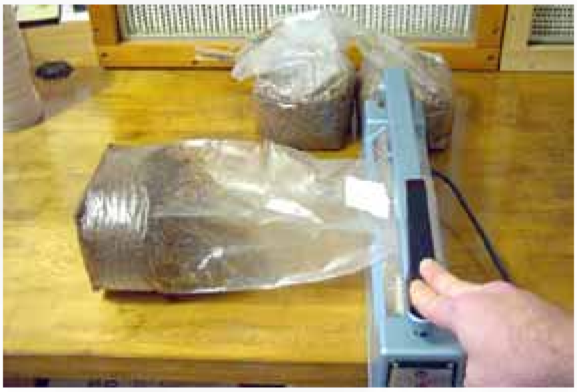
Let the steam vent until the pressure gauge is near 5 pounds pressure. This will ensure you that all air has been forced out of the unit.
Place the rocker on the vent pipe and turn down the heat to medium-high. This will vary with your particular range.

Pressure will slowly build until it reaches 15 pounds and then it will escape from the rocker. At this time turn the heat down to medium or so, just enough to maintain the pressure without making too much noise.
Once it reaches 15 pounds hold it there for 2 hours then turn off heat. Do not move the cooker. To many, 2 hours is overkill but I prefer double sterilization times for grain products.

Now is a good time to clean the work area where the bags are unloaded from the cooker. When the pressure has dropped to less than 5 pounds, the cooker can be moved, with care, to rest until opened.

This demonstration will be done in front of a HEPA (High Efficiency Particulate Air) filter system. A good still-air chamber or glove box will also work but contamination is more likely. It can be done.
Make sure you have washed your hands before proceeding.
Remove the rocker weight and open the pressure cooker.

Remove the 3 bags and let cool overnight or until less than 80 degrees (F).



Once cool the bags can be sealed with an impulse sealer.

The bags are now ready for inoculation.

Using your culture syringe, gently insert the needle through the small injector disk. Squirt approximately 2-4 ccs of spore solution into the rye grass seed. Slowly remove needle and the injection site will seal itself (If you are using bags without injector sites, insert needle through the side of the bag and tape over the hole once needle is removed).

Care for bags and store at proper incubation temps as species requires.

Late casing

The Method of Late Casing and Why it's a Good Idea

by

Fahtster

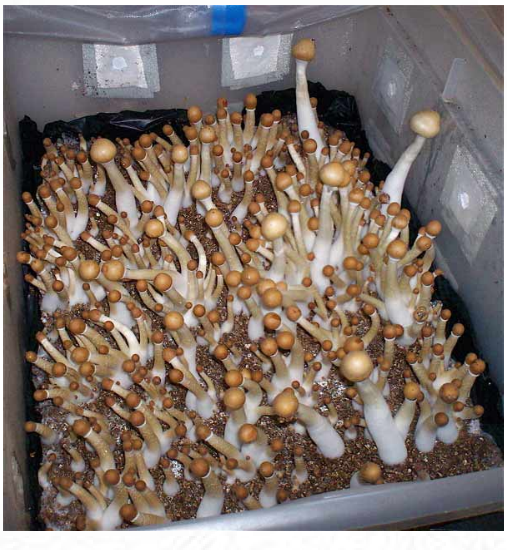
original source: http://www.shroomery.org/11382/Late-casing

I've been using a method called late casing... It's basically very simple and just how it sounds; applying the casing only after knotting has started and a few small pins start forming... so far it's been working great. I'm sure it'll have many rebuttals, but I say give it a try for yourself and see what ya think.. I know youz use hyphae's casing strategy and from what I can see, it also works great... this is just another way about it. Disclaimer: all of this is IMO and experience you can use whatever method you find fit, but I just want you to listen to why I think it's a good idea:

1. If you keep a casing layer off the top of the substrate and expose the sub to light from the time you lay it out, you are initiating knotting on the entirety of the top of the substrate. This will ultimately give you more fruits, at least some more fruits compared to the alternative. When you cover the sub with a casing layer, you are cutting off light penetration to some of the sub.

2. (a) The casing layer should not be colonized at all.. I don't care what anyone says.. that's not what it's for. It's not to hydrate the sub either, that just seems ridiculous to me. it does slow the release of evaporating water from the top of the substrate but while that's an important part it's a bit different than supplying the sub with hydration. The casing is to trap small air pockets of moist air to encourage developing pins and knots.. If the casing layer is colonized, the substrate cannot breathe like it should be able to.

(b) The substrate doesn't use the casing layer after the fruits have developed passed small pins. The fruits themselves act as the fruiting environment. If you think of an uncased bin, does it have a casing layer? The answer is actually yes; the entire rest of the bin is the fruiting environment... when you apply a casing layer, you are basically shrinking that fruiting environment down to the 1/2 inch directly above the substrate. This encourages the knots to form into pins and those pins to go on to develop into small mushrooms.. But then what happens after the fruits grow above the casing layer? That's when the fruits themselves become the fruiting environment for each other... kind of a one hand washes the other situation. I mean think about it.. if you put one cake in the middle of a 54 qt bin by itself, do you think that would do as well as if you put 24 cakes in that bin? no, because the cakes use the heat and perspiration of the cakes surrounding them as a fruiting environment. The same reason that the chronic tek works so well.. it's a cake in a small environment. Here's an example of what I mean...



notice in that pic how the casing layer is barely colonized if at all. The substrate at this point has stopped using the casing layer in the sense that the fruits are using it.. but the casing layer is using it in the sense that the casing is slowing the evaporation of water from the top of the substrate. And since the casing layer was added after the sub switched from the colonizing stage to the fruiting stage, the casing layer is not being consumed which helps the sub breathe. This also keeps the sub from spending vital energy on colonizing the casing. I know you've all noticed that once your bins' fruits reach a certain height, the bins are considerably warmer and moister inside. This is because the fruits are making that environment; basically helping themselves grow. So if you take a look at that pic, the actual casing layer (or fruiting environment) is from the top of the sub to about 4.5 inches above it.. the whole length of the fruits themselves. (sorry for the redundancy, just trying to really hit that home).

3. Another reason that this is a good idea is the length of time that the casing material is exposed to the substrate is greatly reduced. This in turns reduces the amount of risk the casing layer imposes on the substrate in harboring contamination. In example...

the amount of time it took this bin to get from here (right when the sub started pinning and the casing was applied)

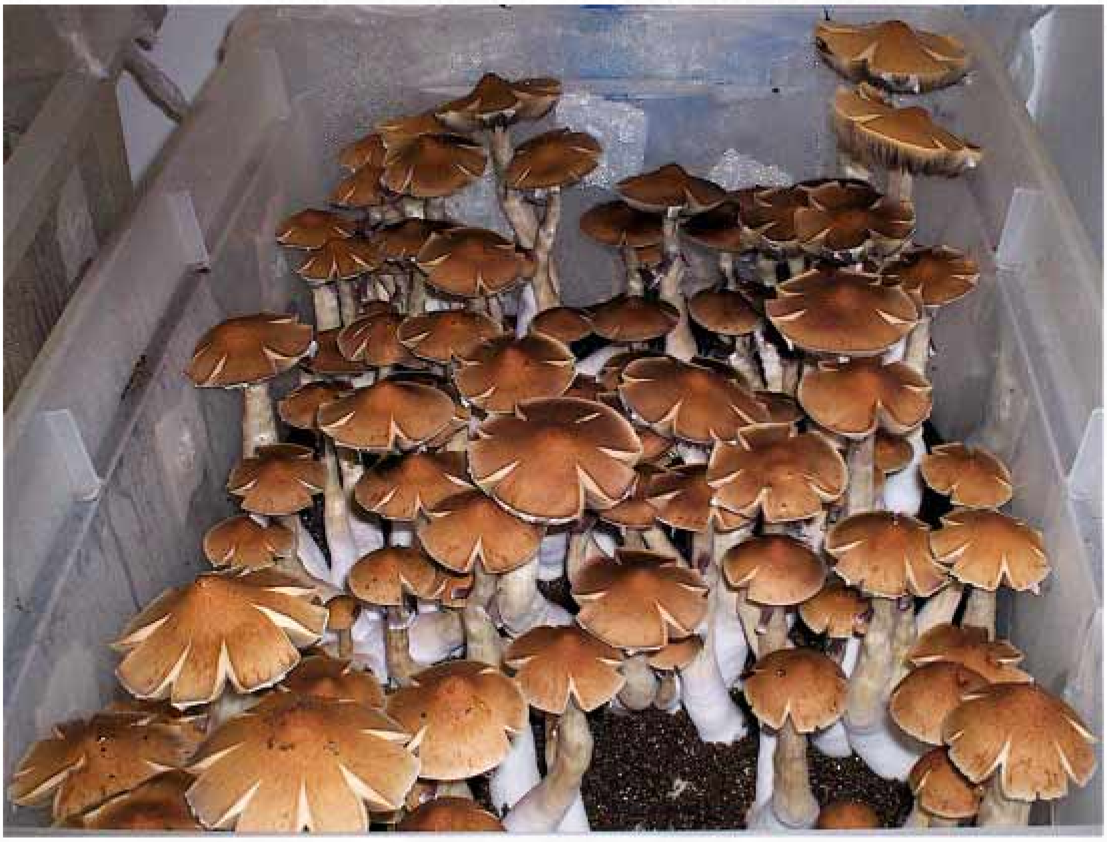
to looking like this...

was a mere four days. And since the time is so short, there should be no reason to add water to the casing after you first apply it.

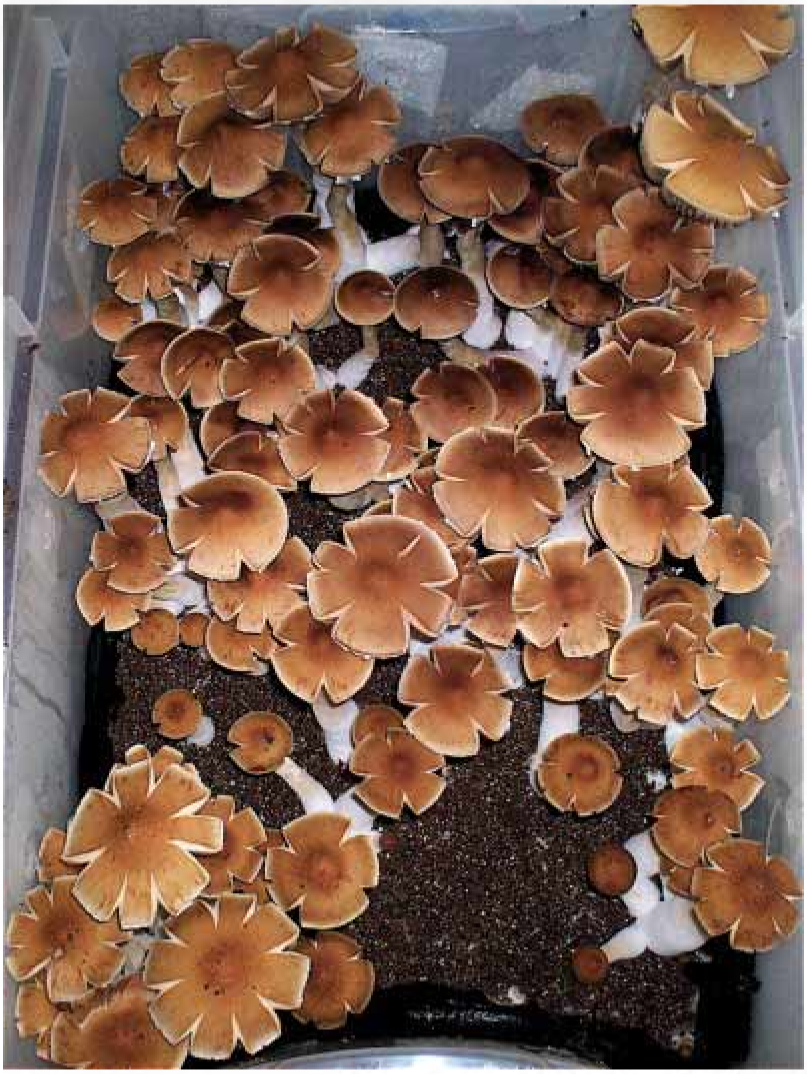
Here's other bins that have been late cased: all are 54 Qt bins except for the last tex bin, that's just a shorter version of the 54 qt.

that same bin in the first pic (SA's) only a couple days later...

The other two HB bins..



And a Tex popcorn verm rez bin that was also late cased...



Now, I'm strictly speaking of the bulk and grain casing methods and not for cakes. I actually do use the DECing's for water retention and cake hydration and not the usual method of a casing that the fruits grow "up" through.

I would love to hear any opinions and ideas about this and they are more than welcome. I just ask that you keep in respectful. Thanks for taking the time to check this out.

Here is also another thread you should check out on casing... it's the most standard way of casing... lots of good info here

Rez effect

by

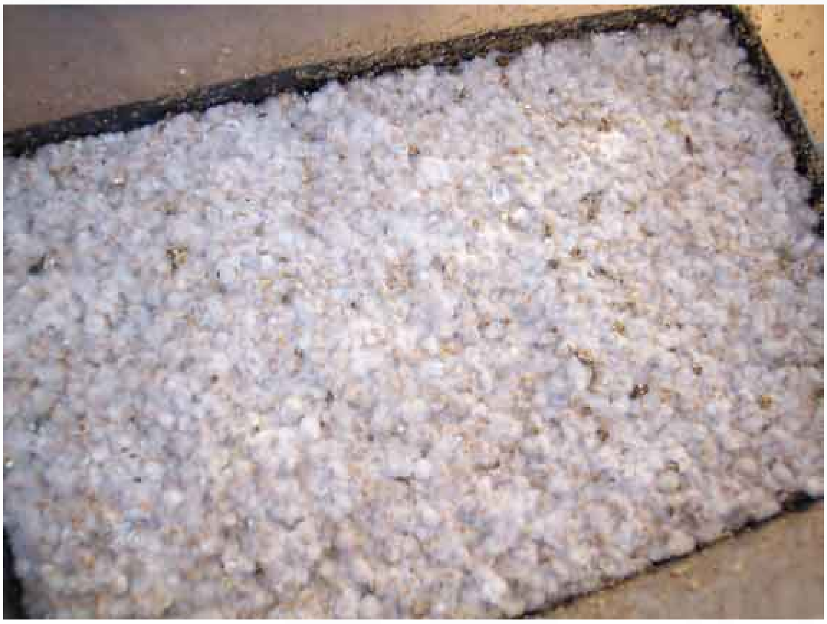
mockeylock

original source: http://www.rollitup.org/t/first-time-shroom-grower-pf-tek.107399/page-18#post-1651991

I know I'm new here and thanks for having me...I am rather experienced, however, and definitely know a thing or two about cultivation....
I've noticed just poking around, that most folks on this site are going with the PF tek. That's fine and all...it helps let you see the life cycle of cubes and gives you a good idea of how all this works.
But, man alive! Some of you are spending so much time, effort, and money setting up automated chambers with bubblers, humidity gauges, the whole works. With little to show for your efforts....
So I just wanted to give some ideas how to simplify and reap the benefits, so first off here's the Rez-Effect Tek which gives bulk-type results without pasteurization or anything besides wbs and vermiculite!
First off, get to know whole grains...so easy! They colonize faster since you can shake the qt. jars and you end up with way more spawn/substrate. This grow used 4 qts...this is 3 of 'em.

Next you simply mix into a Tupperware container (this is a 20qt'er) with about equal parts moistened vermiculite...

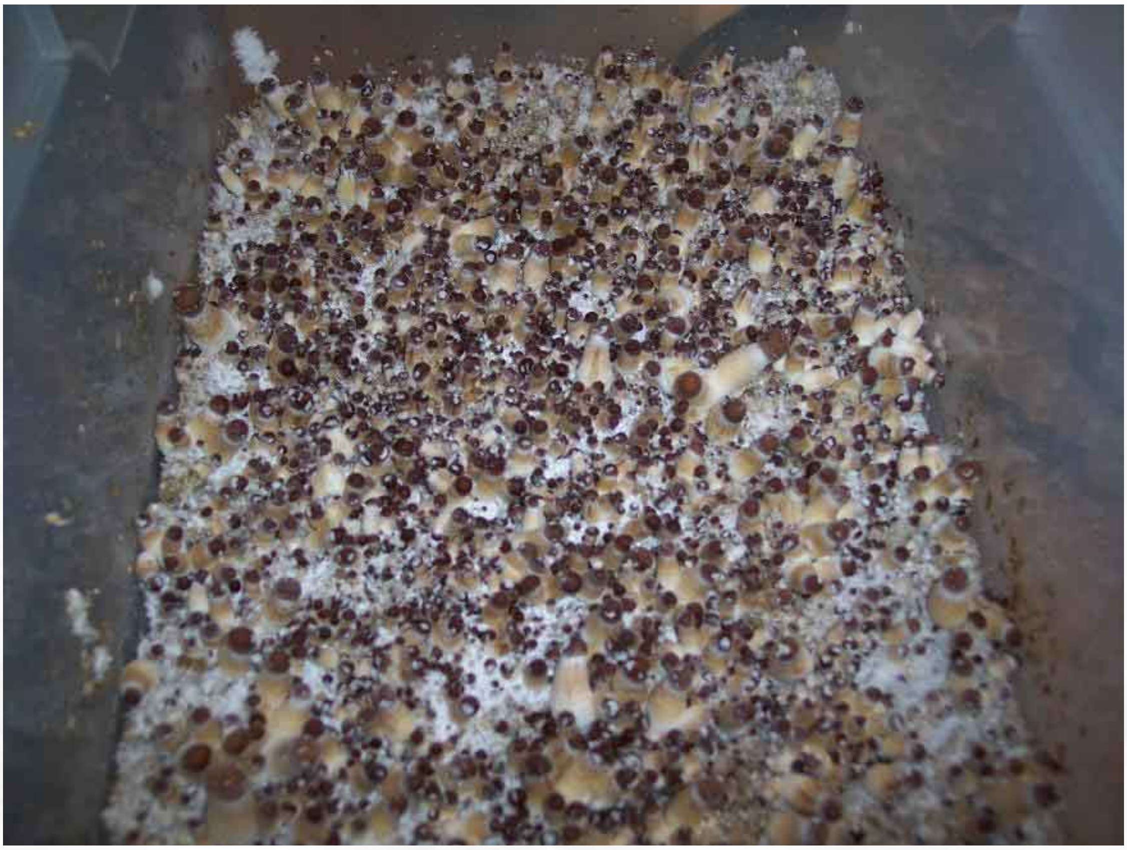
Next, cover with foil and incubate (we're talking about 3 days) until totally colonized.

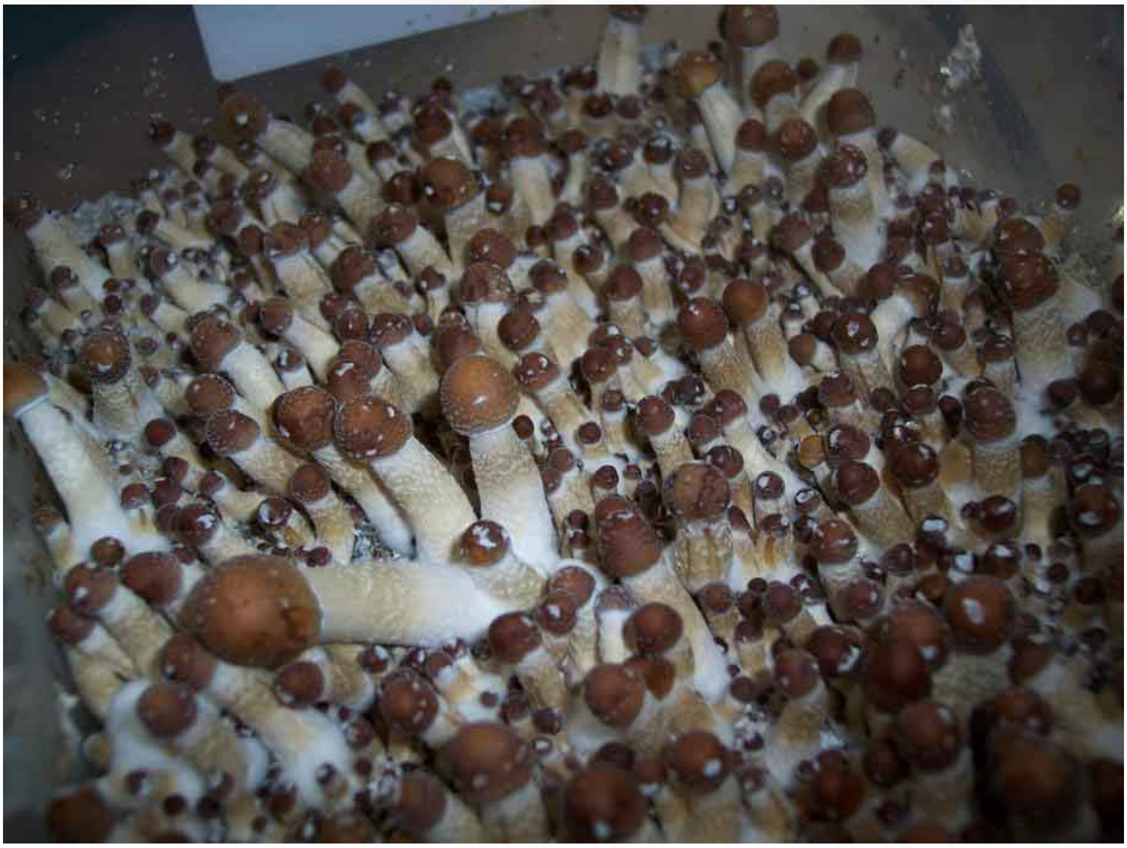


Now I've messed with a lot of casing mixtures. I've crushed Oyster shells with a hammer, lime, peat moss, coir, you name it.

You know what I use now? Vermiculite.

So case with whatever you like, recover, and let colonize a bit until you're ready to fruit. This time around it took forever to pin and the casing was 95% colonized. Bad news? Heh...just watch!





Just fanned a few times a day. This strain was S. American, btw....

From syringe to print using rye

Making The Syringes

1. Well first I fill up a half pint jar with filtered water.
2. Then I like to add 2 or three drops of jet dry to the water (keeps spores from clumping and sticking to the sides of the syringe) and fill the syringes.
3. I put the syringes into a quart jar and put them in the pressure cooker so the needle tip faces up. (if they don't face up the water will shoot out when it boils.
4. I wrap 1 shot glass for each syringe in foil, put them in a quart jar and put them in the pressure cooker too.
5. I pressure cook at 15psi for an hour.
6. When it's all still hot as hell I load it all into a glove box that has had the living shit sprayed out of it with Lysol the night before. Spore prints to be used go in too.
7. This part is just a me thing but when it cools I unwrap and use one shot glass for each syringe. Flake off the print into the shot glass the amount of spores your going to use, shoot in the water from one of the syringes and suck it back up with the spores. The amount of spores used is up to you cause at this point I go overboard again.

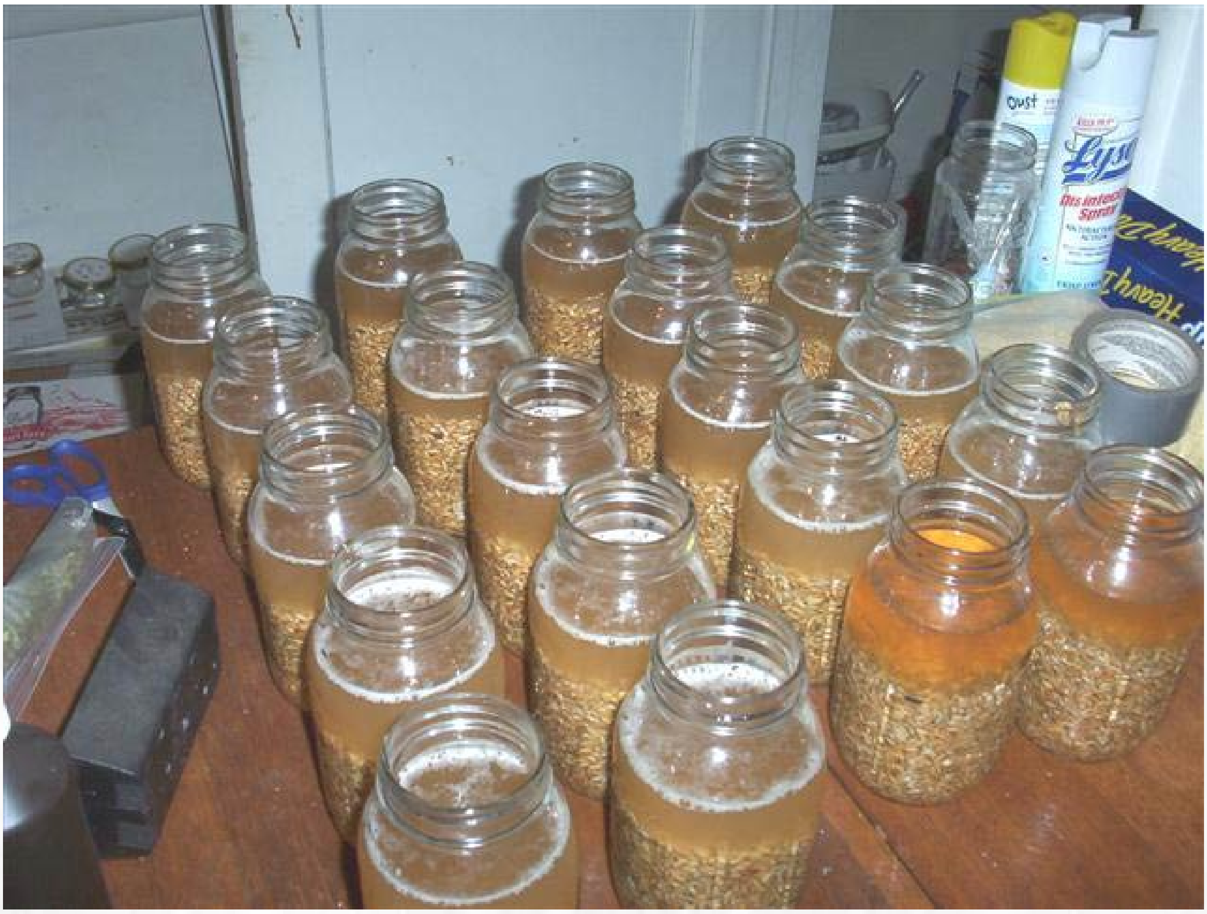
I know there is a lot of steps in this and it's a lot of overkill but it does leave little room for contaminations.

Preparing the Grain and Jars

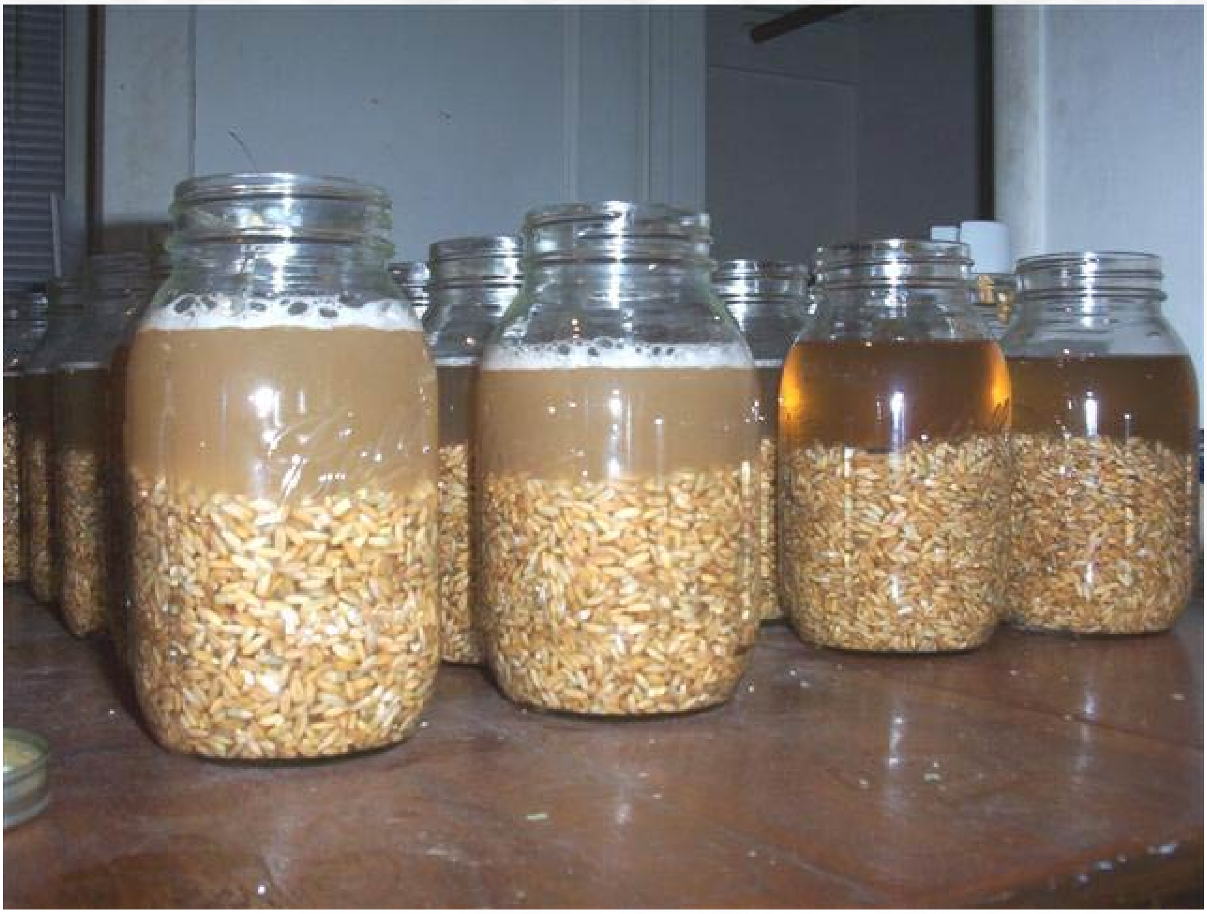
1. First thing I do is put one cup of rye in each quart jar.

2. Put in enough water for the soaking. Alternatively just measure out the grain and let it soak in a big pot (for instance the same pot you are going to use for the simmering later).

I like to soak for 24 hrs. Notice the difference in the color of the water after 24 hrs.



Bacteria endospores have started to germinate.

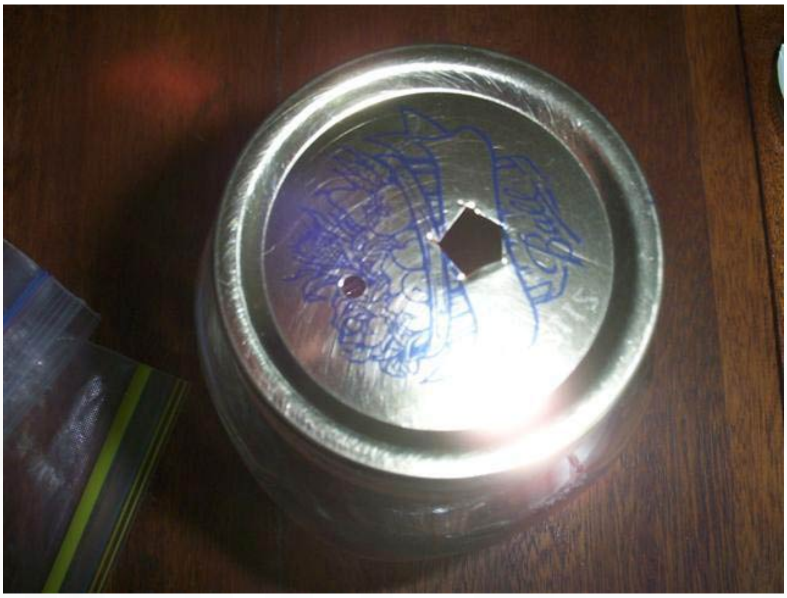


This is the reason we soak the grain. Many believe that this is where water is absorbed by the grain but this is only partially true since a substantial amount of water is absorbed by the grain when it is simmered. The main reason for the soaking is that we are germinating the bacterial endospores because they sometimes can survive the pressure cooking process. NOTE: In hot weather (summer) rye will sometimes begin to sprout before the 24 hour soak is over. This is NOT something you want to hapen. In this case shorten the soak time to 12 or 16 hours.

3. Strain the grain through a colander to get rid of the dirty water.
Put in a pot with plenty of fresh boiling water (roughly double the amount of the grain), reduce the heat and simmer for ~45 min, until the first rye kernels begin to open.

4. Strain the simered grain through a colander. I like to pour 6 gallons through the grain in order to get rid of the starch on the outside of the kernels. (no reason for 6 it's just a me thing). After the rinsing let the grain sit in the collander for ~10 minutes so the excess water can run off. The grain is now ready to be put into jars and pressure cooked.

5. Make 2 holes in the jar lids. One is a breather and one is for the syringe needle.

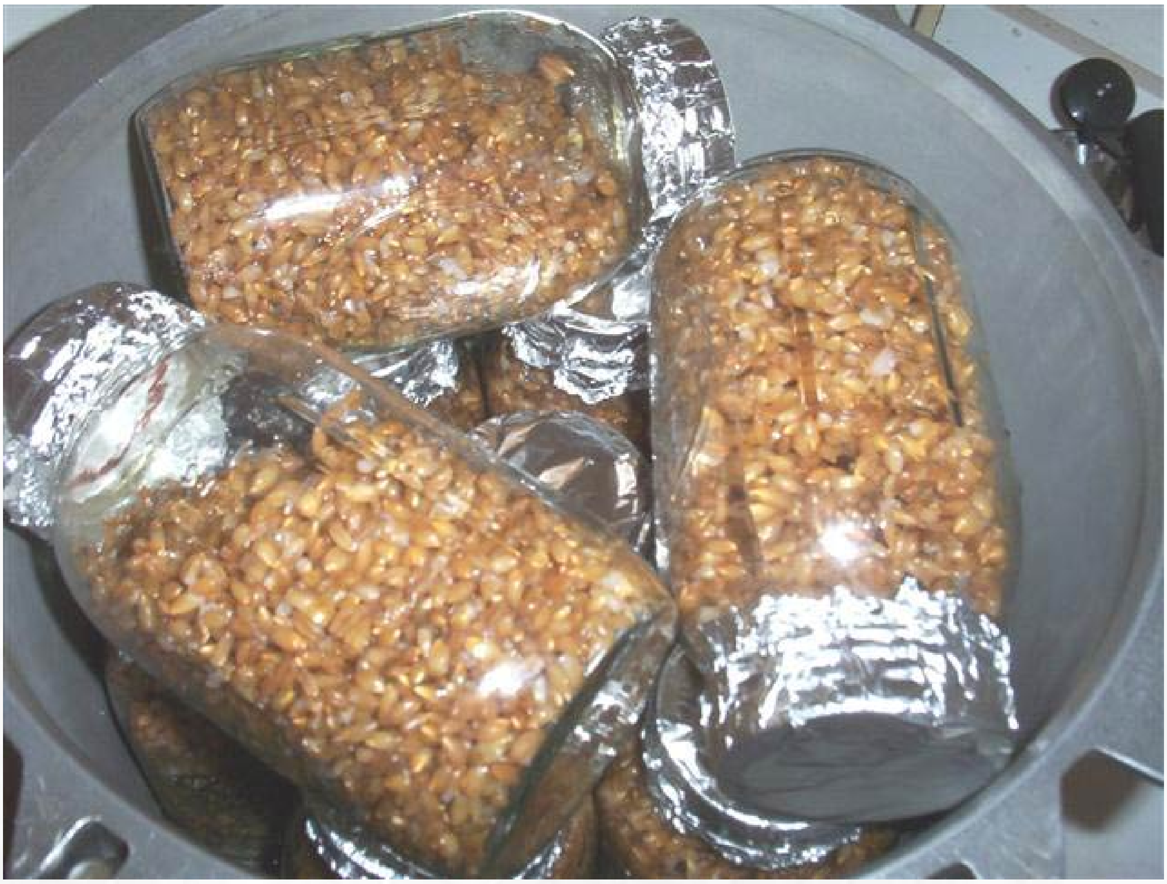


Put a piece of Tyvek over the top, add the ring and some foil and your ready to PC.

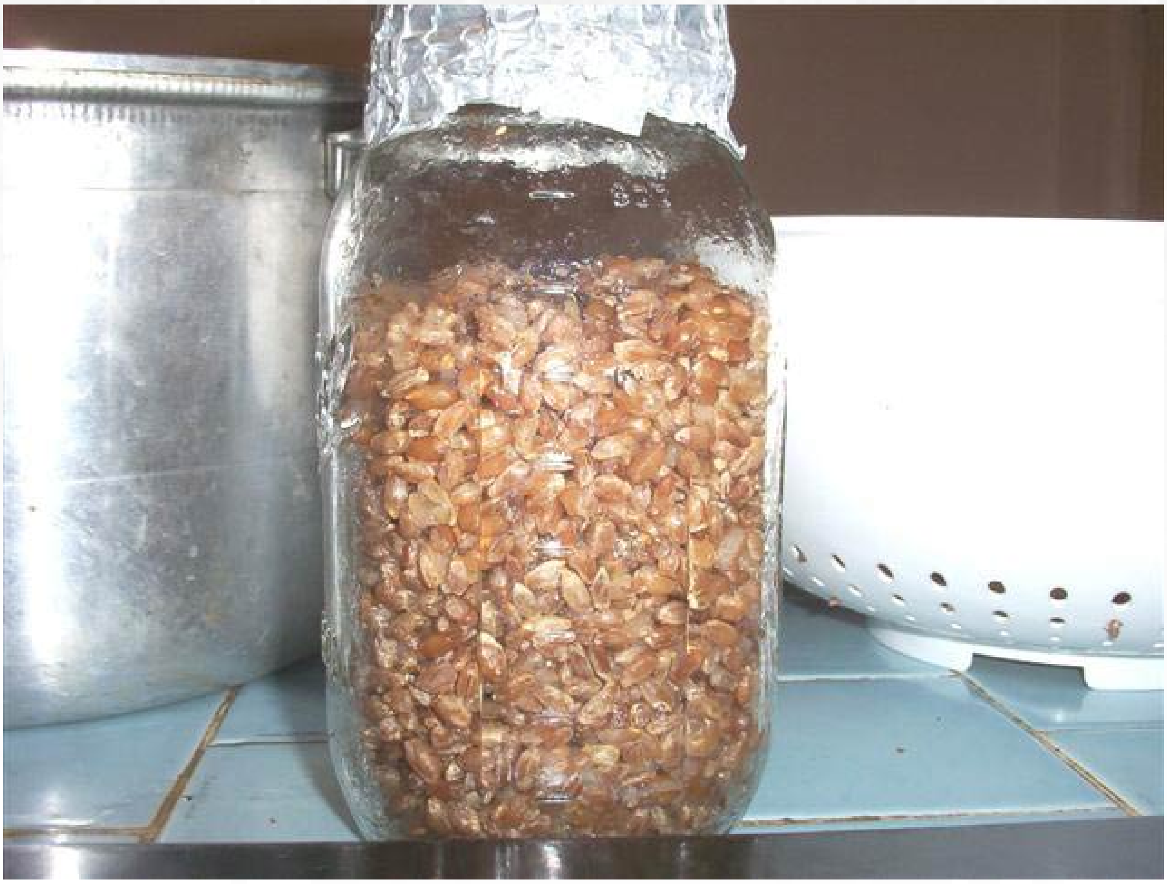
Be sure to leave room in the jars to shake the grain.

Be sure to leave
room at the top
so you can
shake the grain
around.

6. Load the jars into the PC



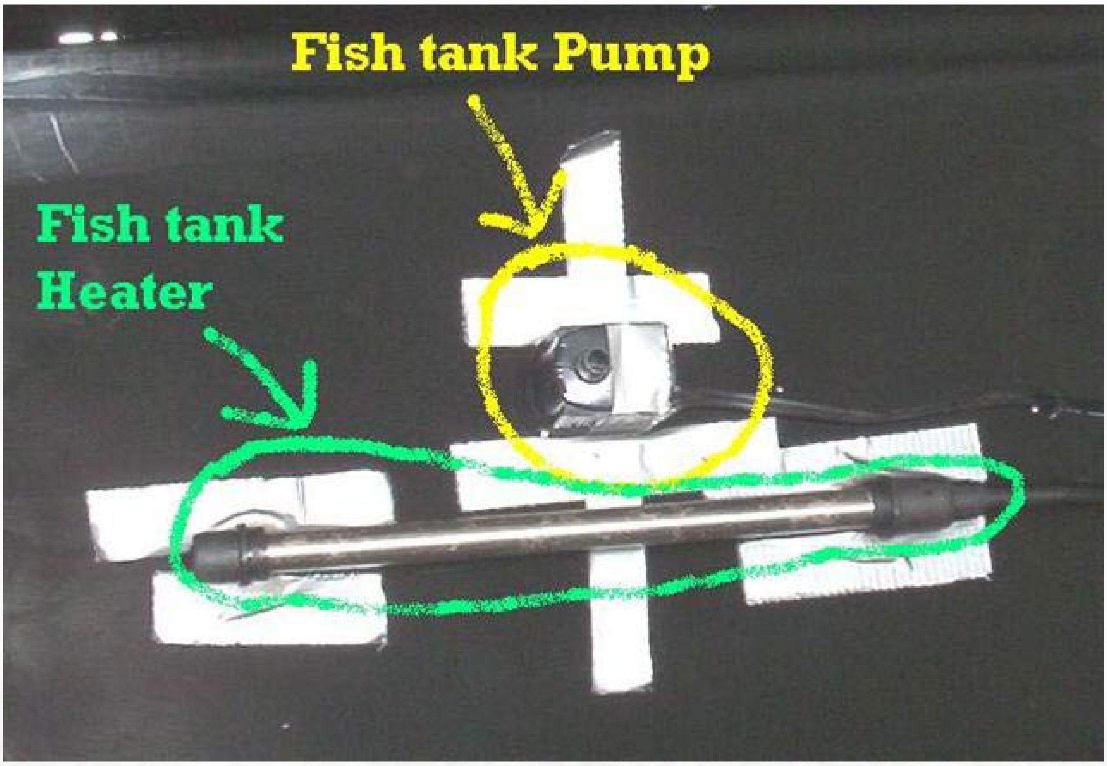
and pressure cook for 1 hour at 15 psi. Here is a finished jar.



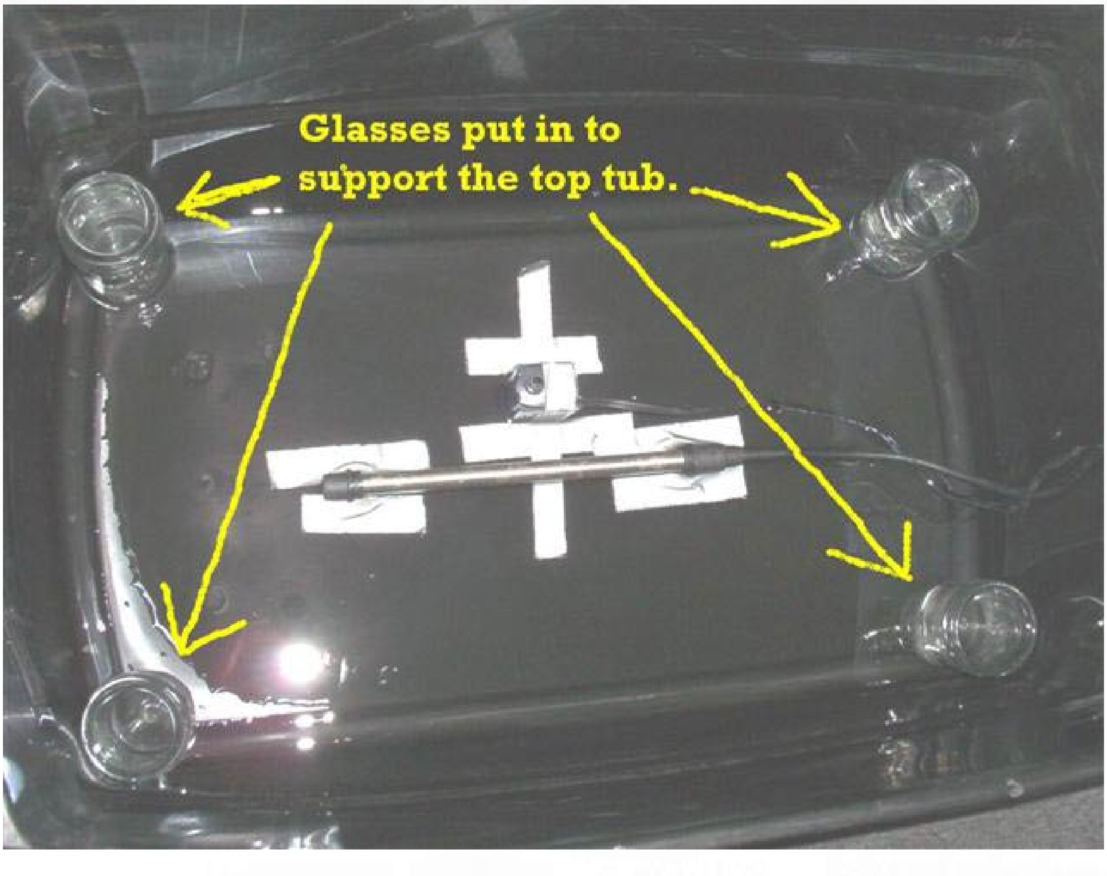
Now your ready for the next step.

Incubator Set Up

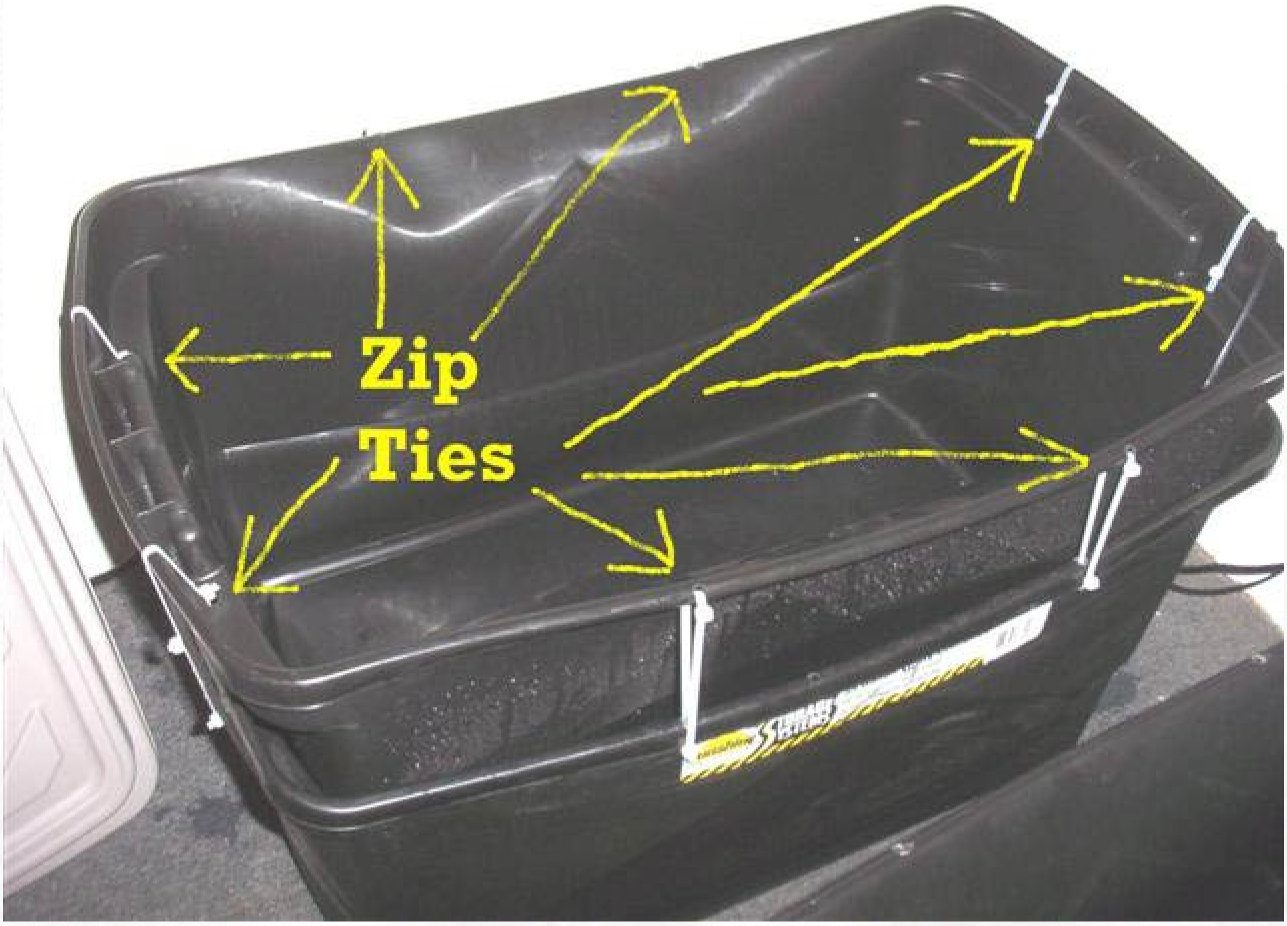
1. First thing get your bottom tub and put in your heater. I also add a water pump to mix the water that way it heats up more evenly but it isn't a necessary item. I got the tape from a boat shop and it has been working for some time. Good stuff for underwater.



2. Next put something (I used tall half pints) in each corner of the tub. This will keep the heater and pump safe from being smashed if I put in to many jars or do something stupid.

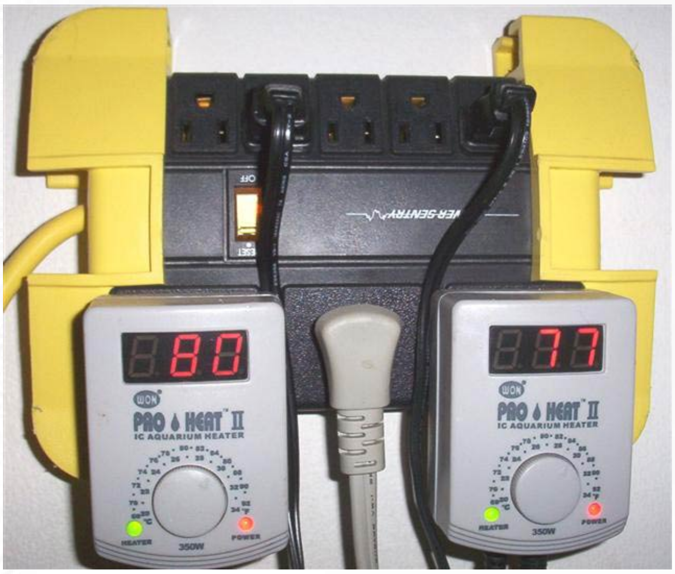


3. Now be sure to set the heater before you put on the top tub. I attach the top tub with zip ties cause the top tub will want to float.



4. Add the water. I like to add as much water as I can before it starts to spill out.

5. If you use the heaters with the external controls set them now to get ready for the jars. Mine use a dial and a sensor that gives the temp inside the chamber rather then the water. It also has a metal bulb rather then a glass one.



80

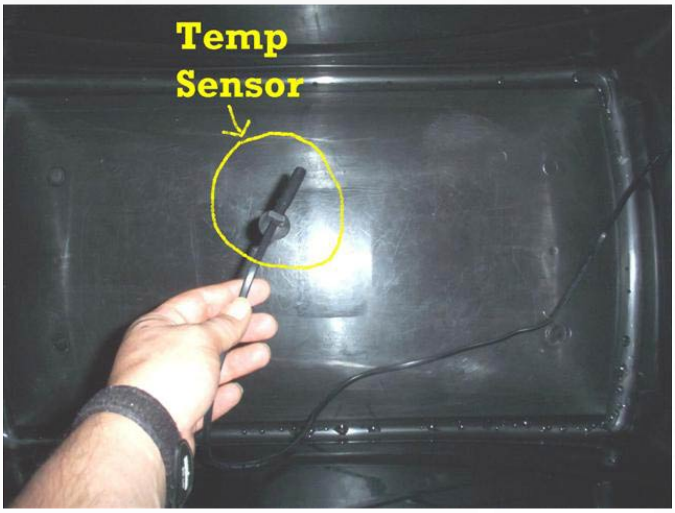
PRO HEAT II
IC AQUARIUM HEATER
PRO HEAT II
IC AQUARIUM HEATER

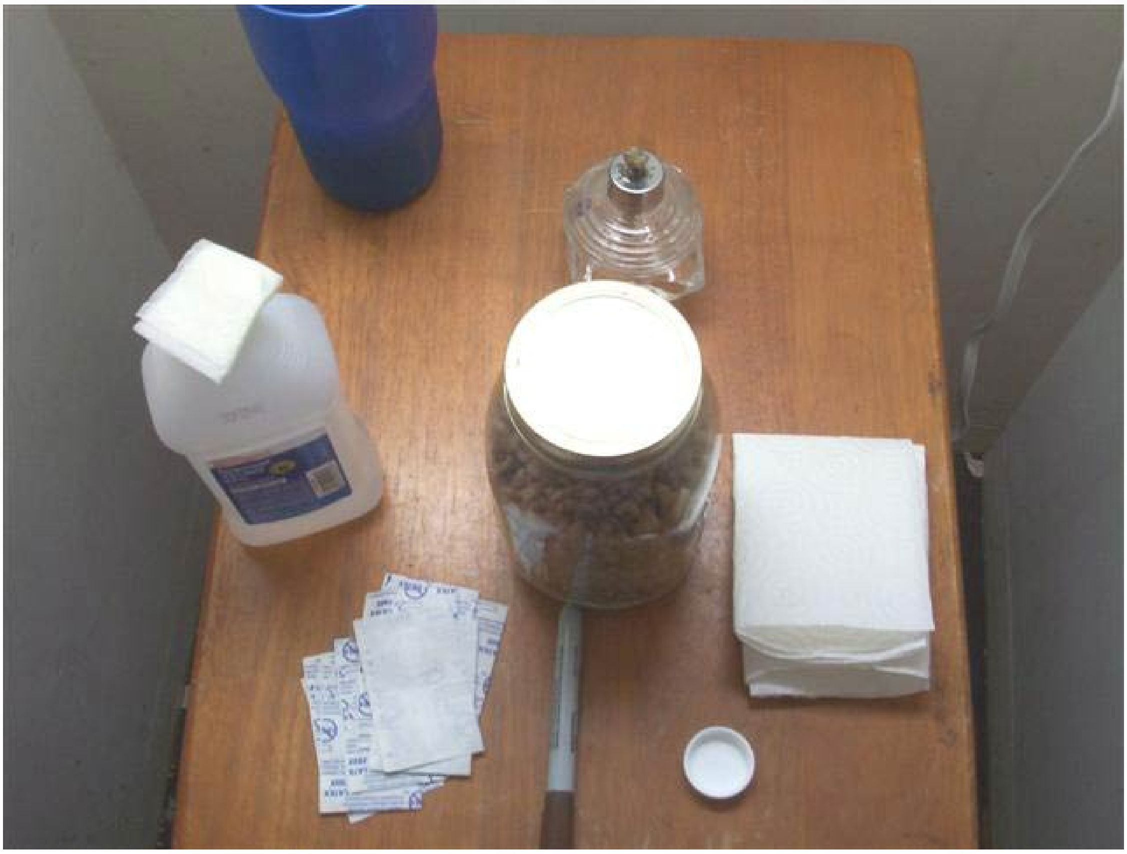


Temp
Sensor

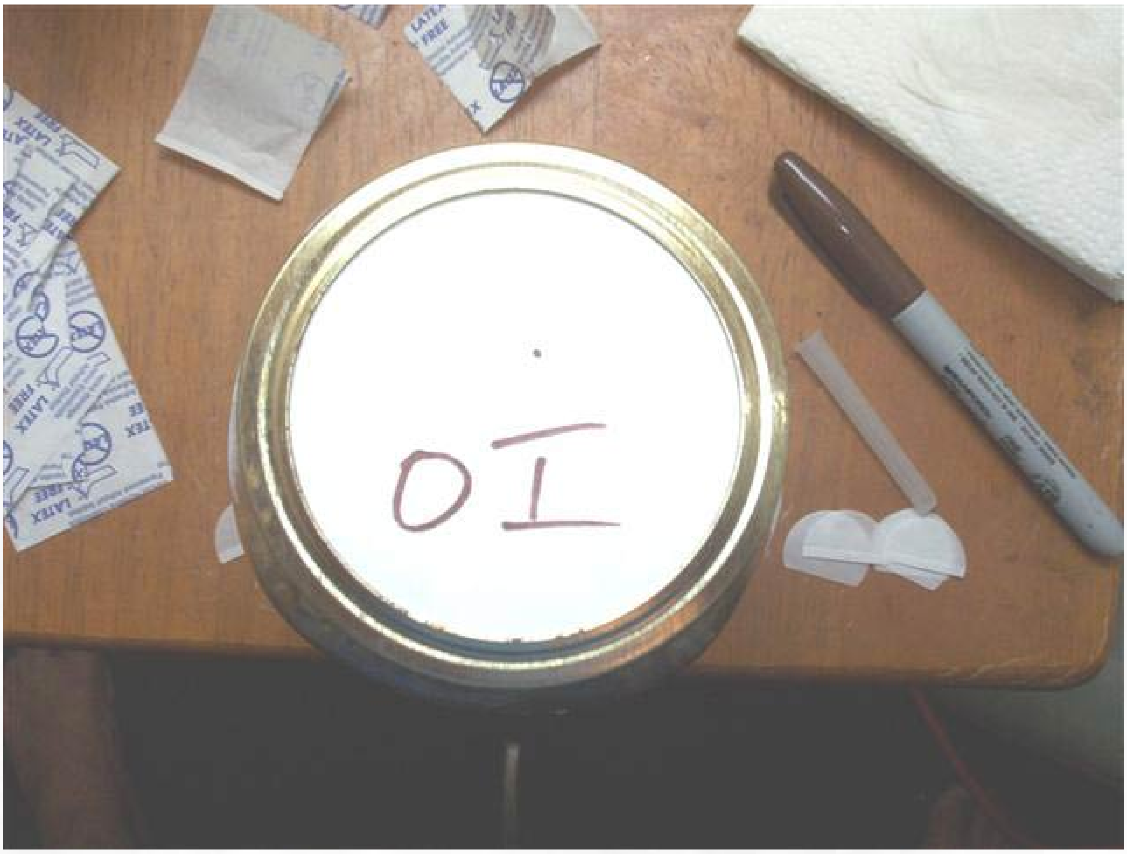
6. Finished.

Inoculation

1. First get your work area ready.



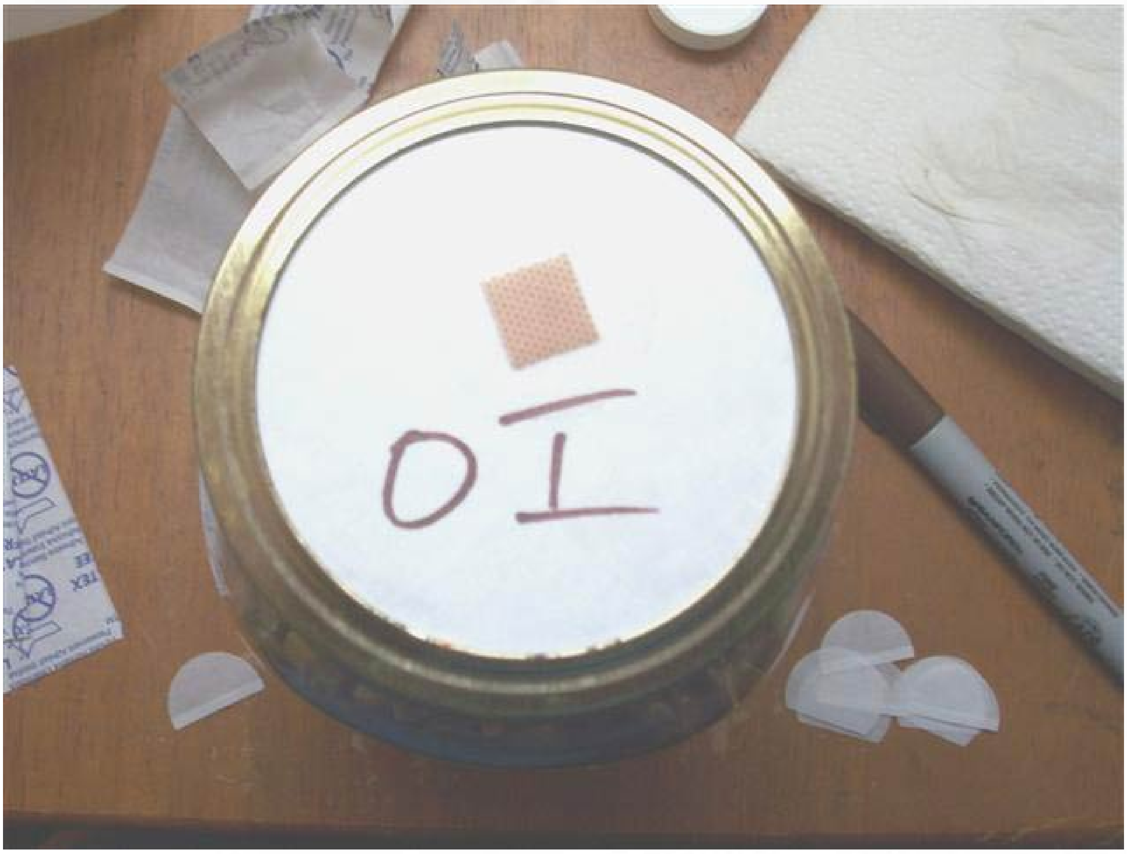
2. One of the reasons I like Tyvek is cause you can write on it



3. I like to heat the needle tip then cool it with a alcohol wipe.

4. Inoculate the grain. I like to use 2.5 cc per quart.

5. I like to cover the inoculation hole with a band-aid. I like em cause they come sterile.

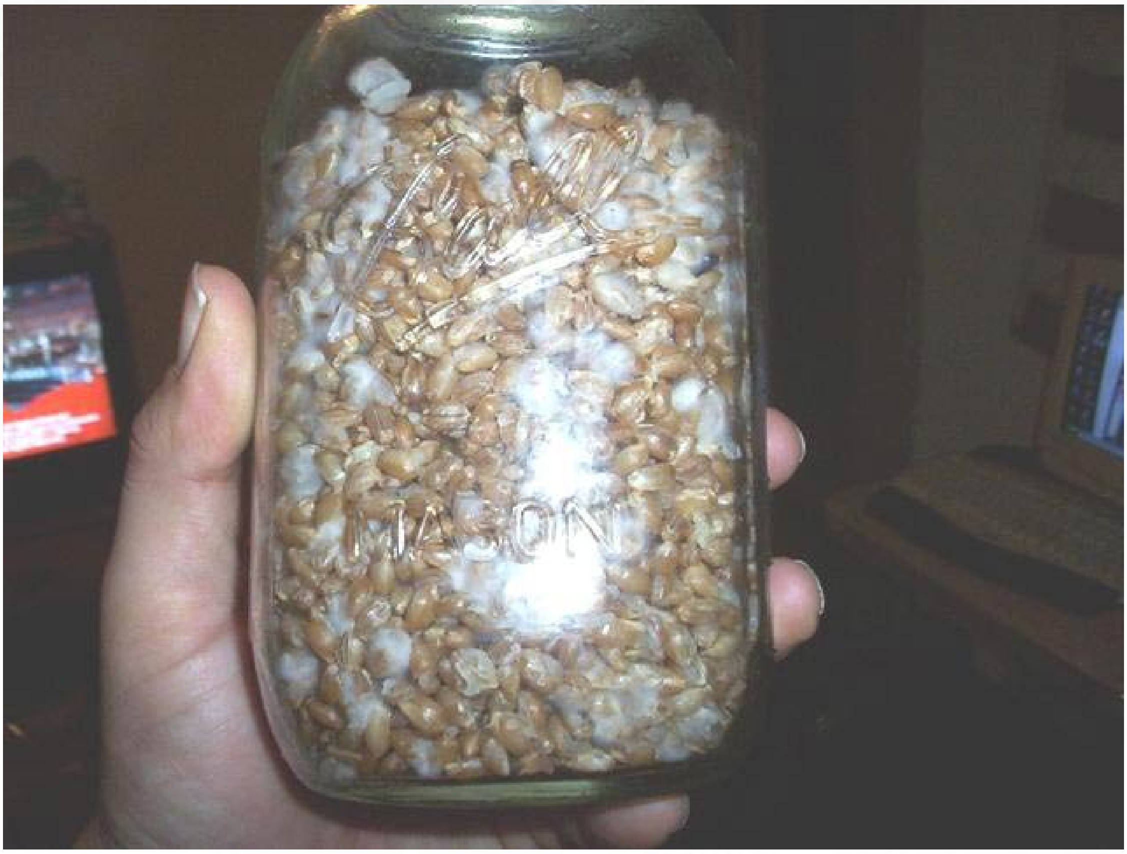


6. Shake up the jars real good and put em in a 82 F - 27.7C to 86F - 30C incubator.

7. I like to shake the jars again when they are about 25% colonized then once more at about 50% to 75% done.

The Waiting Game

1. This is the hard part, the waiting game. Here is a jar 3 ½ days after being shot up.

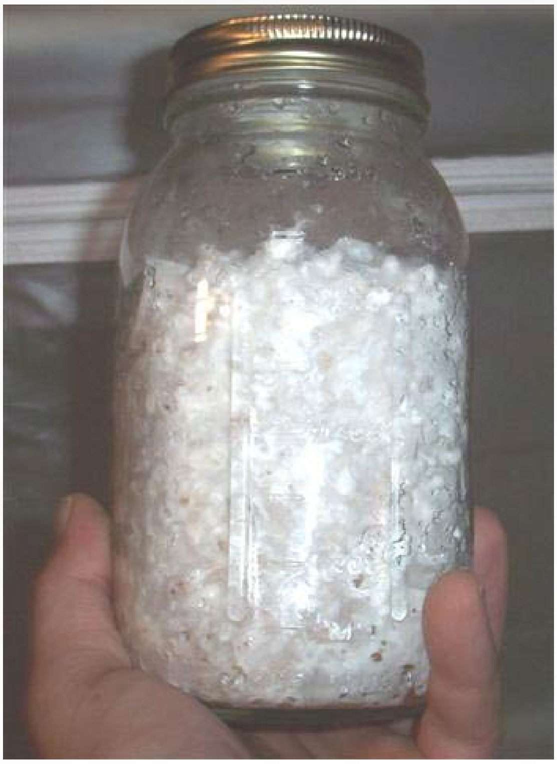


Few days later.

The first part of the waiting game is over time to

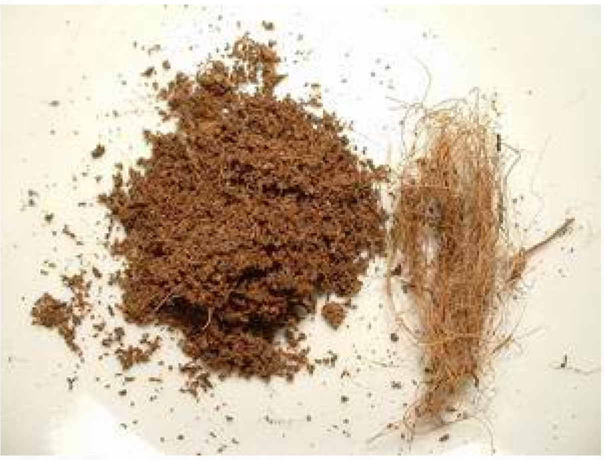
Get The Casing Mix Together

1. Well it's been exactly 9 days and the jars are done.



Time to get the casing supplies.

2. I like coco coir and vermiculite mix. Be sure you get coir and not fiber. Coir is on the left and fiber is on the right.



Coir in the package.

SAVE YOUR REPTILES

3
30 Minutes
4

Vermiculite can be found all over the place and looks like this.

3. Add water to the coir as the directions say. Here is a brick.

Here is one with 4 quarts of water added.

4. Prepare your vermiculite. I just put it in a jar and fill it with water, let it soak,

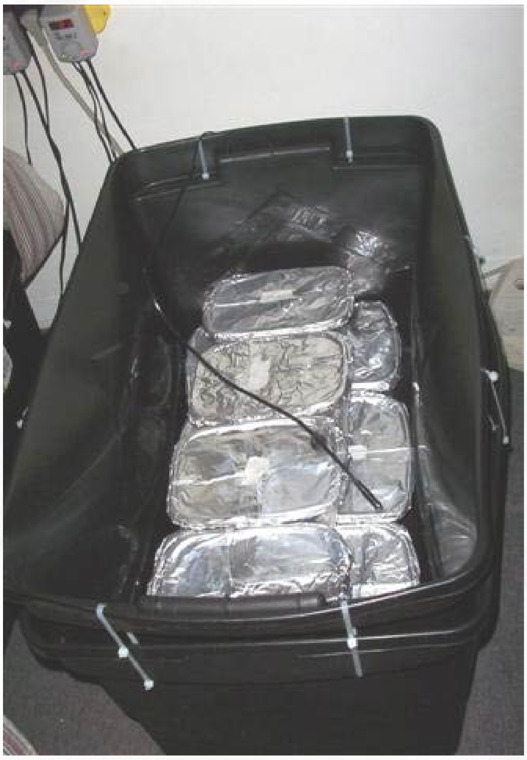
drain then add to a pot.

5. Now mix (I used 2 parts coir to 1 part vermiculite). Here it is when mixed.

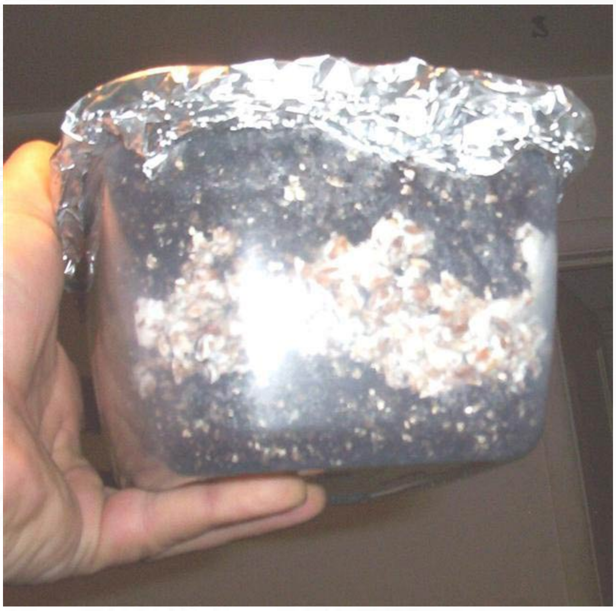
6. Put the mix into jars (I just use the grain jars) and pressure cook for 1 ½ hrs at 15 psi. (Once again just something I do)

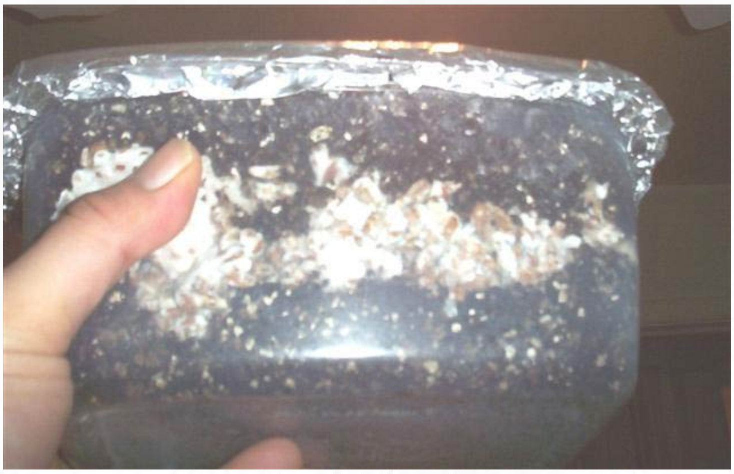
Making The Casing

1. I like to pressure cook everything. I pressure cook the casing layer, the casing containers, the foil that goes over the top, and the spoons and forks I use to do the work.
2. I like to do the work of putting the casing together in a walk in closest that I have. I spray the shit out of the air with oust and wait a few minutes then start the work. (With a face mask)
3. I pour a little (about a half inch) of the casing layer into the container.
4. Now scoop the mycelium out of your jar and put it in the container on top of the bottom casing layer that you put in. Once you have the amount of colonized substrate (these casings will be 1 quart each) that you want to use even it out so it's nice and flat on top.
5. Now add the top casing layer. (In this case ¼ to ½ inch of casing layer) A good rule of thumb is a top casing layer ¼ as thick as the substrate layer.
6. Now cover (I like to use foil) and put into the incubator.



Usually this last 4 to 7 days. A finished casing should look a little like this



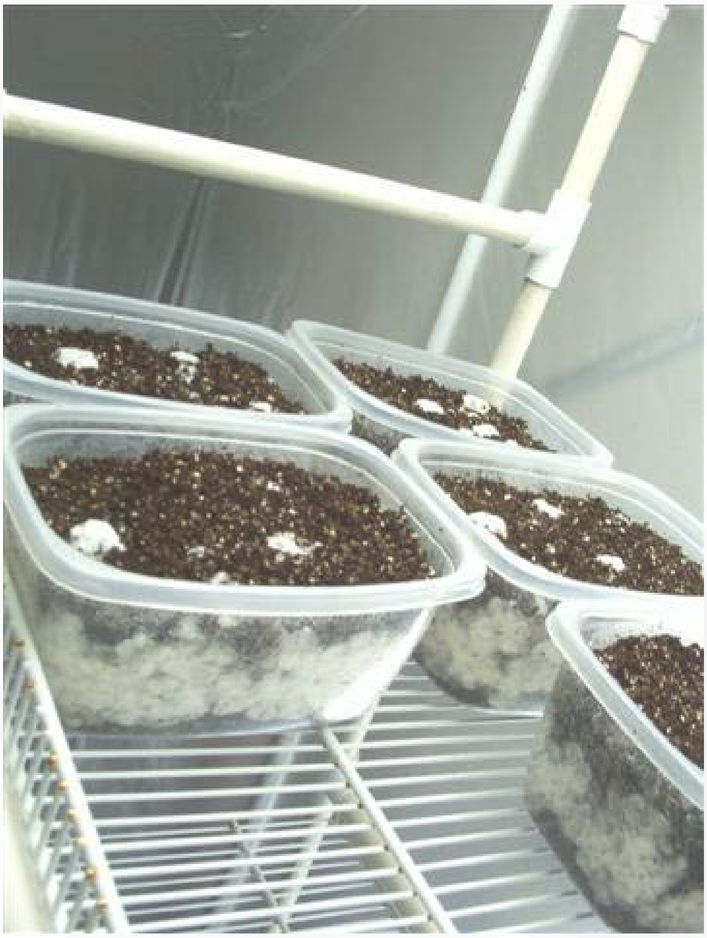


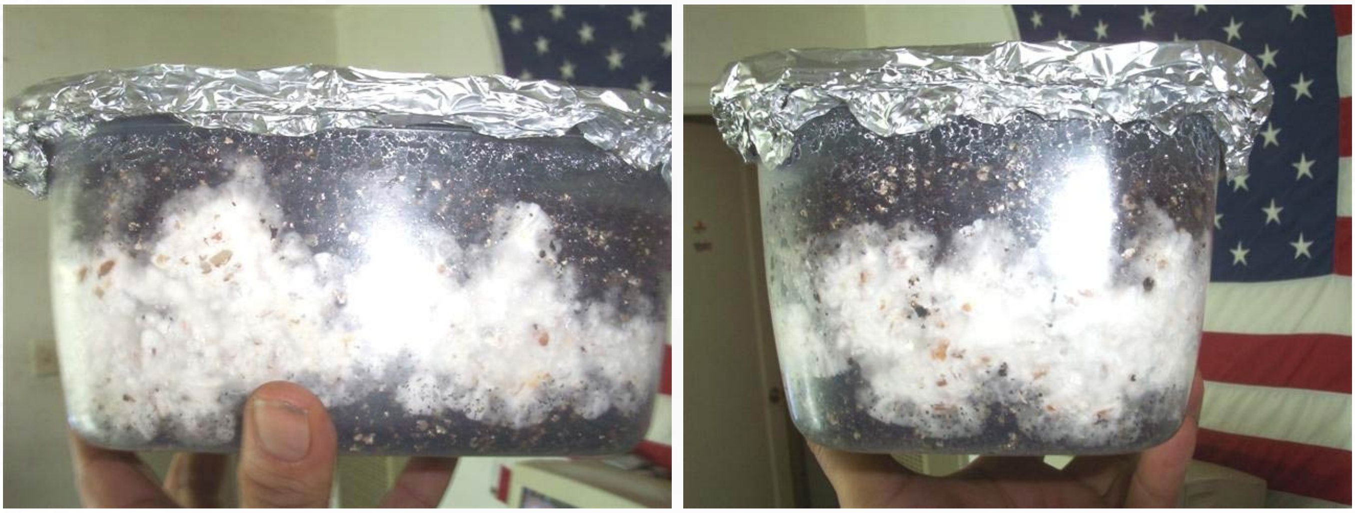
(I suggest covering the sides of clear containers to prevent side pinning. These will be left uncovered for pictures used in this post)

Time to put the casings in.

The Chamber

1. When the mycelium starts to break the casing surface is when I like to put them in the chamber.

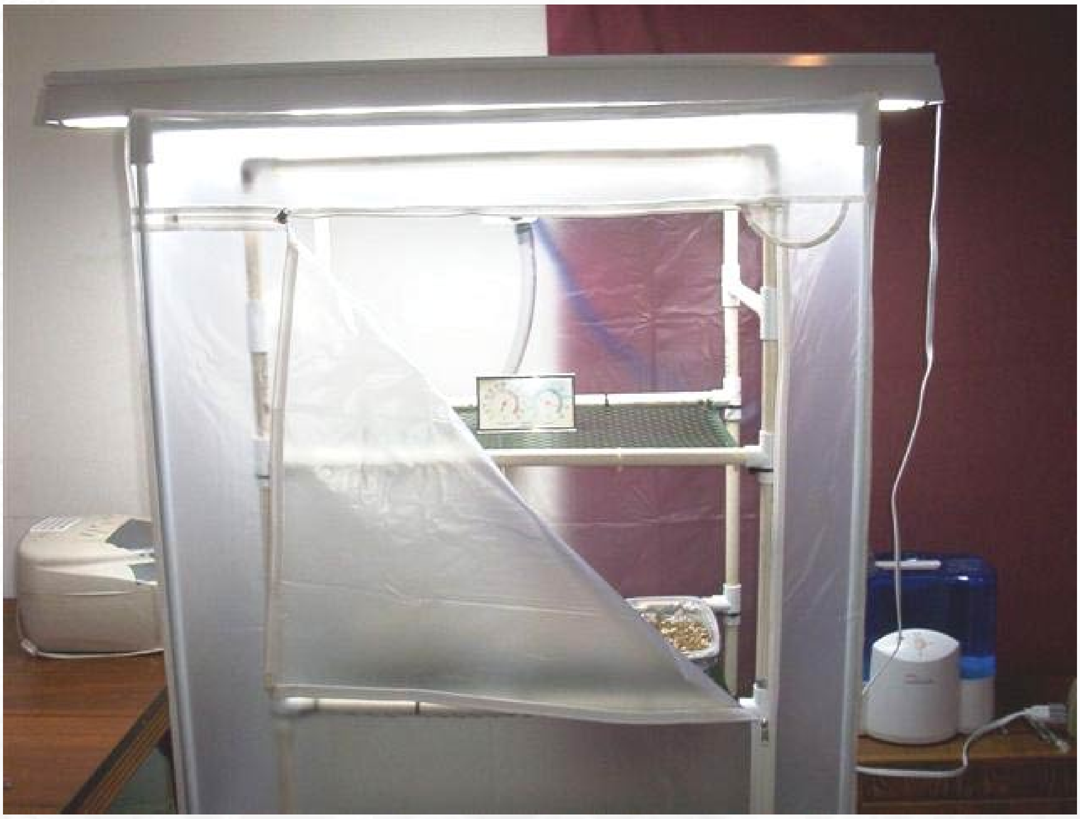




Lots of people like to patch at this time. Myself I've never been one for patching so in the chamber they go.

2. I like to use the tent style chamber that uses the cool mist running all the time and a ultrasonic that comes on every few hours for so many minutes.

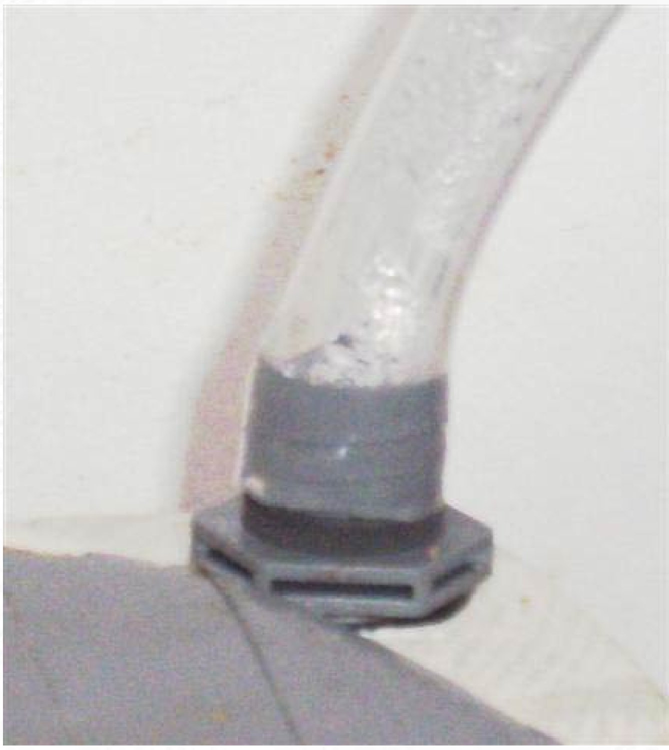
3. This is a Martha Stewart closet and hose set up.

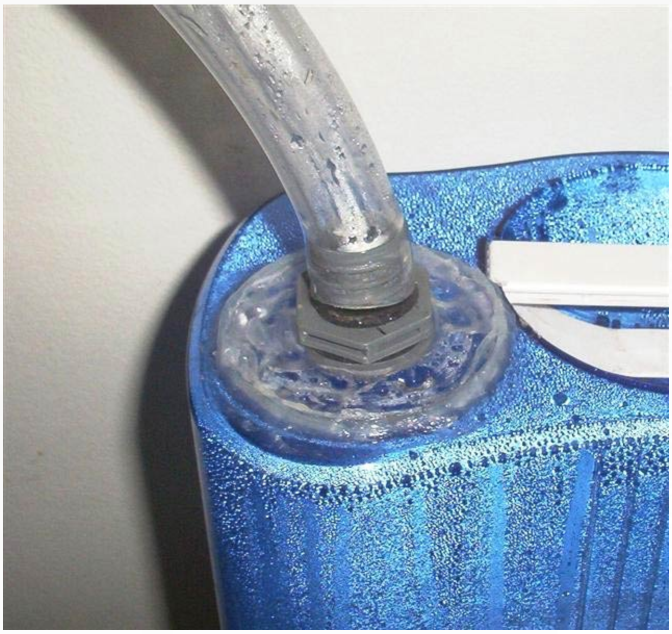


MARTHA STEWART
36"
STATIONARY
storage closet

I use the ultrasonic and cool mist. Very firm believer in air exchange.

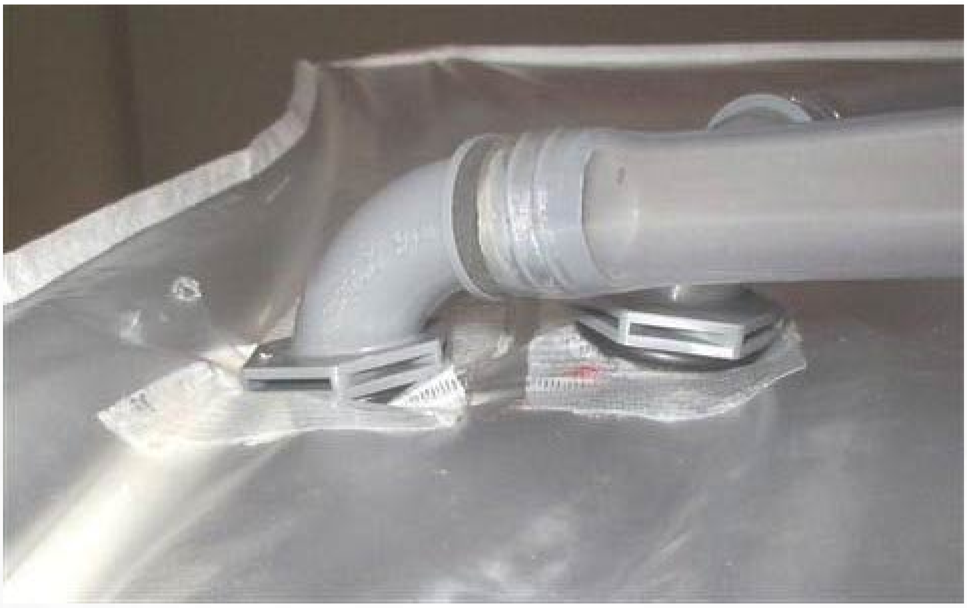
In the electrical Dept of the hardware store I find these.





and on the ultrasonic

Now on the back of the closet I cut the holes for the hose fittings and put tape over them and cut holes threw the tape for the fittings. The reason for the tape is to give the closet plastic a little extra strength when holding the hose weight.



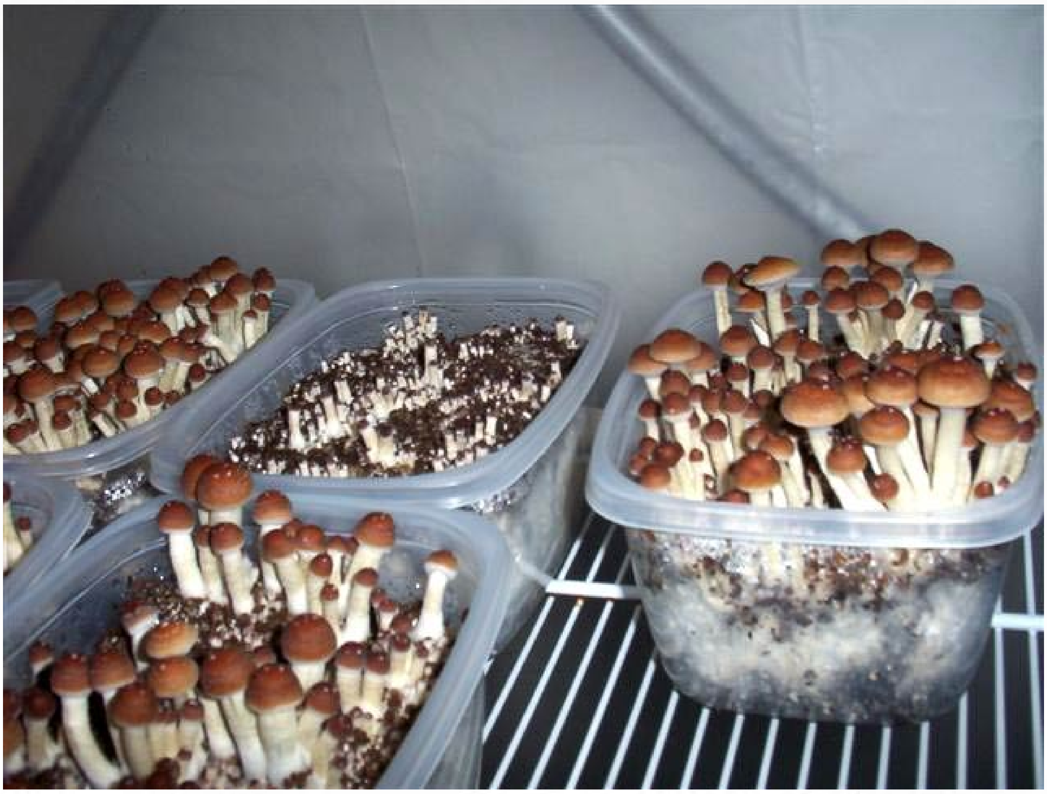
The outlet for the ultrasonic goes above the cool mist outlet that way the mist from the ultrasonic drops into the air stream of the cool mist and mixes better.

4. Now that the casings are in the chamber it's time to wait for pinning.

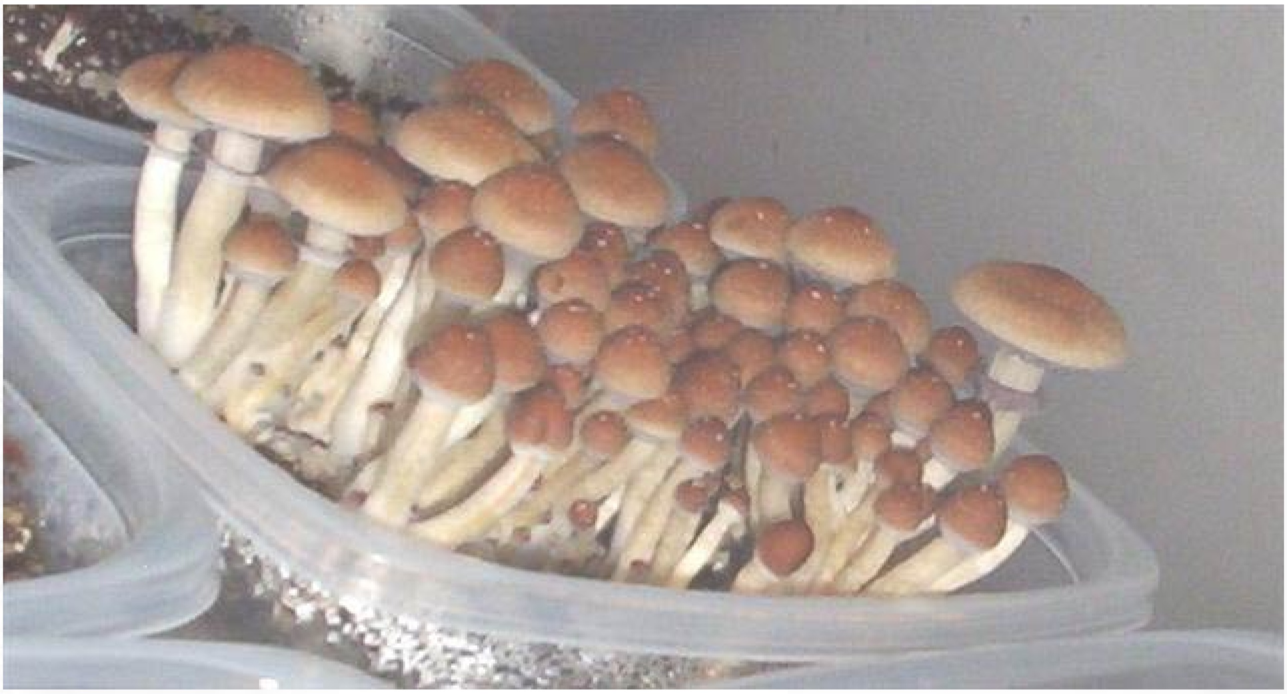
5. If the coir starts to get a little lighter in color it may be starting to get dry. Now is a good time to mist them with some sterile water, it's safe to mist up to the point of pinning.

Well it's been a week and pinning has started.

A few days later.



Well some of the veils are starting to tear



so it's time to think about.

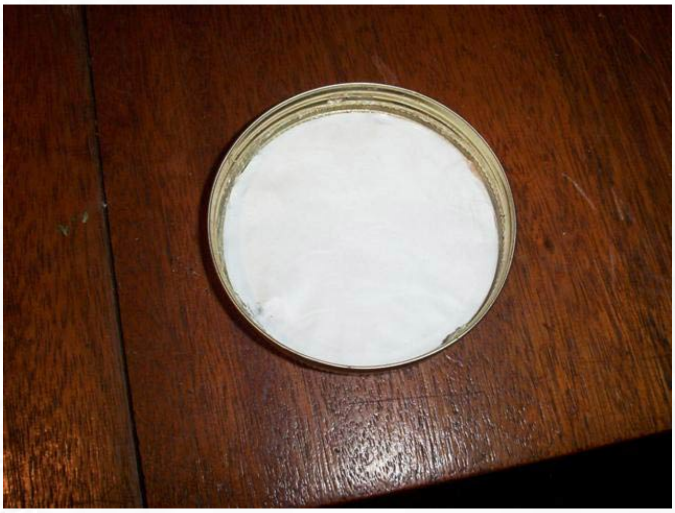
Harvesting and Taking Prints

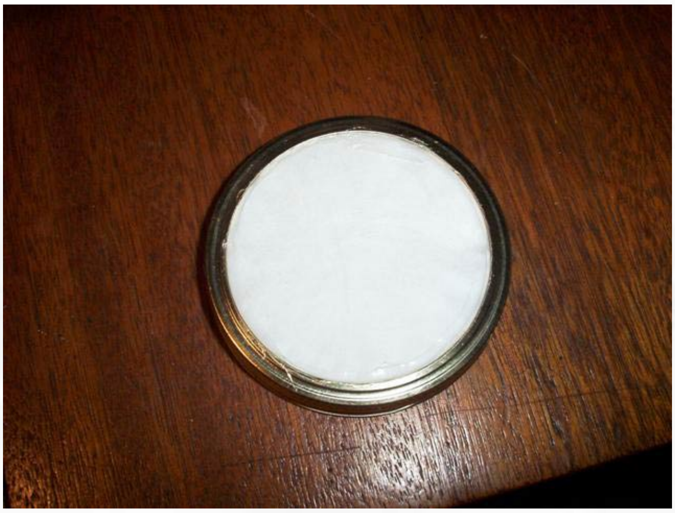
1. Harvesting is easy. Just be sure to remove the whole shroom and leave none behind to rot on the casing.
2. Cover the spots that show cause of the picked shrooms with casing material and spray it down real good with the water H_2O_2 mix.
3. If you dunk your casings now would be the time.

Now I suggest you take your own prints to use.
Well this is how I like to do it. I like to get my foil ready like this.

That way when the print is done you have these flaps to fold over.

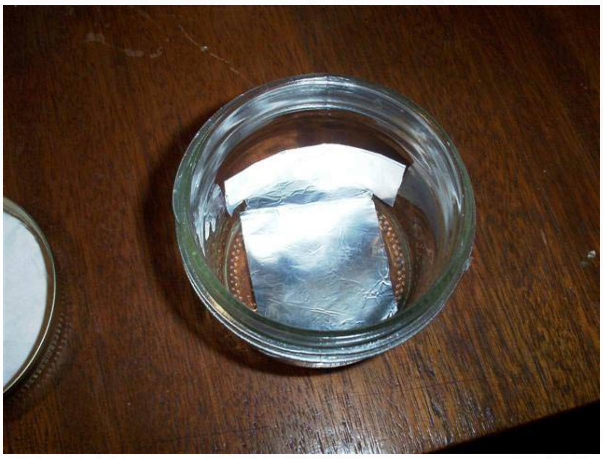
I then get a half pint jar (wide mouth) and prepare it like this. I ditch the disk and silicone in a Tyvek disk.





This will allow the cap to dry a little as sits in the jar. (Which causes more spores to drop and prevents the cap from rotting. Will also allow the prints to dry once the mushroom cap is removed.)

Next put in the foil and cover with the lid.



Put some foil on top and pressure cook for one hour at 15 psi.
Now uncover and wipe off and your little print chamber is ready.
Now take the jar to your mushroom chamber and loosen the top but don't remove it.
I like to put a pin in each of the mushroom caps I'm going to print.

Cut the shroom just below the cap and put it on the foil in the jar as fast as you can. Easy to do since the jar lid is loose.
Put it in a glove box or where you like to do your work.
In 24 hrs open up and take out the cap by the pin (now we know what the pin is for) and put the cap back on.
Let it sit for 24 hrs again to let the spores dry.
Once dry fold up foil and store in a cool dry place.

FAQ

Why do you wrap a shot glass for each syringe? This is more of a me thing but I like one glass for each syringe just in case there is a contamination I can keep it somewhat contained to one syringe.

Why do you soak the grain in separate jars? This is another one of those me things. I like to come by every once and a while and shake up the jars. No idea if it helps but it makes me feel better and I get a good look at all the grain being used.

Why do you pour out the water and fill and shake and pour that out after the grain has soaked? I like to be sure there is nothing bad like a endospore that may not have germinated and to rinse the water the grain was soaking in out of the jar.

When the grain is done simmering why do you rinse it with 6 gallons of water? Well 6 gallons was used for every 10 quarts of substrate prepared for this post. 6 gallons isn't needed but I do suggest rinsing off the grain.

Why do you leave room in the jars to shake the grain? The jars are shaken to spread the spores around and when the mycelium has started to grow to spread it out so colonization is done faster.

When you inoculate the grain you heat the needle tip then cool it with a alcohol wipe, is it needed to do both? No, if you like you can use one or the other.

When you prepare the vermiculite for the casing you soak it in a jar is that the only way to do it. No, that is just a easy way for me to do it. Anything that can hold the vermiculite and water will pretty much work. I like the vermiculite to have as much water in it as possible.

Is pressure cooking the casing layer the only way to sterilize it before using? No, that is just what I like to do and haven't had a contamination problem using it. There are several other ways to do it and they can be found here in the FAQ.

In the post when you put the casing together you have it in a clear container. Yes that was just done for the post. Light should be shielded from the sides of the casing.

When the mycelium starts to break the casing surface is when I like to put them in the chamber. What about patching? I'm not one that feels that patching is all that needed but many people do and how to do it is in the FAQ.

With your chamber you use two humidifiers, is this needed? I think so to get the most out of your shrooms. The cool mist exchanges the air while not dropping the humidity to much and every few hours the ultrasonic comes on to make sure the humidity is high enough. If you use only one, use the cool mist humidifier.

Your print tek uses a lot of steps are there other ways to do it? Yes look in the Grow section and you will find several ways to take prints.

The Azurescens Foundation - Growing Psilocybe azurescens

The story of *Psilocybe azurescens* Stamets & Gartz

Materials

Mushroom spores

Pressure cooking pot

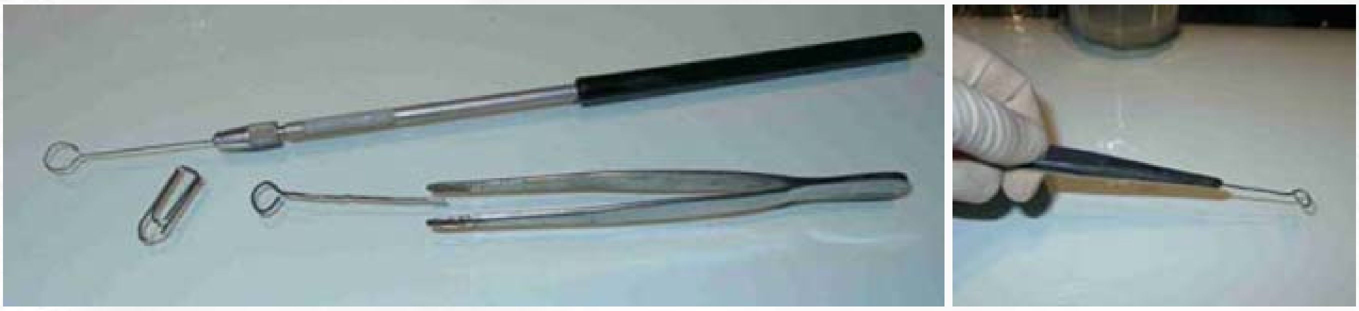
Glass jars

Agar

MALZEXTRAKT

Malt extract

Wood chips (beech, alder, hazelnut,...)

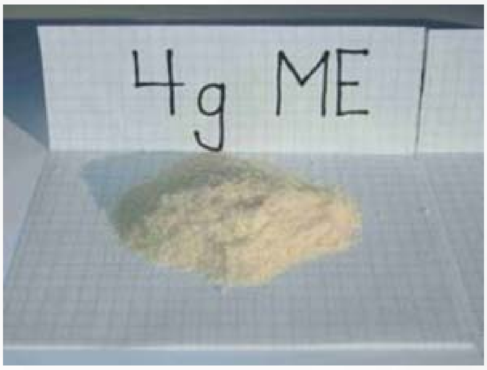


Inoculation instruments: Instead of a professional inoculation loop a pair of tweezers can be used, it is just a bit more tricky to handle.

Preparation of Malt extract Agar

Maltextract agar can easily be prepared in a common kitchen. The most expensive thing needed is a pressure cooking pot. The medium must be sterilised (autoclaved), or you will grow nothing but mold.

To 100 ml water add



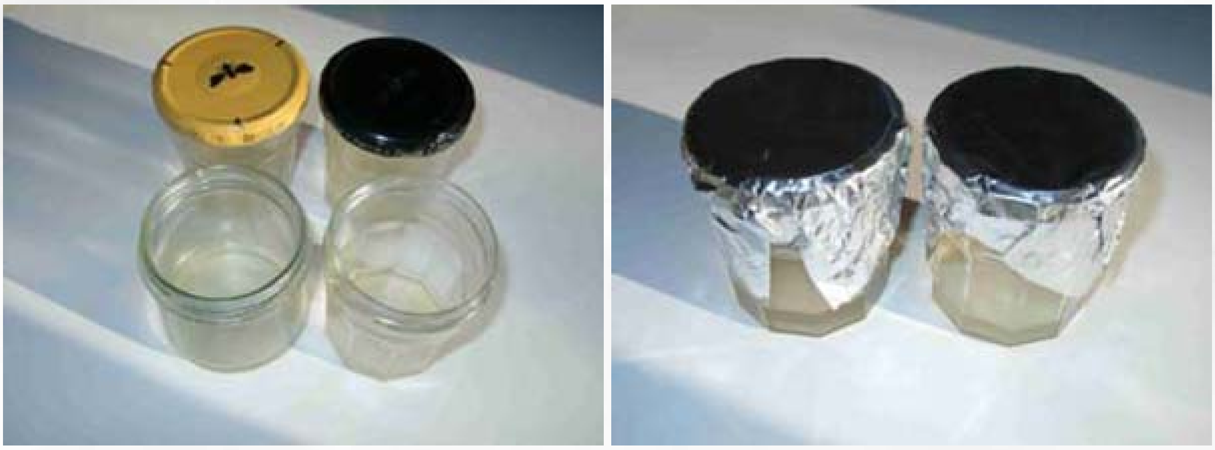
4g maltextract

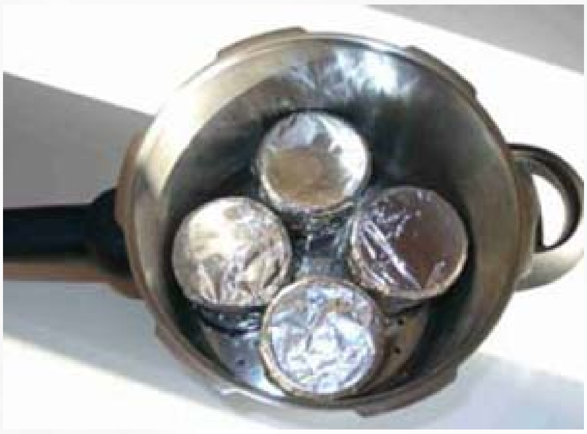
and 2g agar

Bring the liquid to boil to secure all solid particles are solved.

Fill the medium in suitable containers suck as jars of not more than 10cm height (the smaller the better to handle).

Pour about lcm of medium in the jars. The jars are covered with the caps, but do not screw them tight, or the jars will break during cooking!!! The caps can additionally be covered with tin foil to minimize the risk of airborne contamination.





The jars are placed in the pressure cooking pot filled with several cms of water.
Close the pot and slowly bring to boil. When the max. pressure is reached, the temperature in the pot is higher than 121°C.

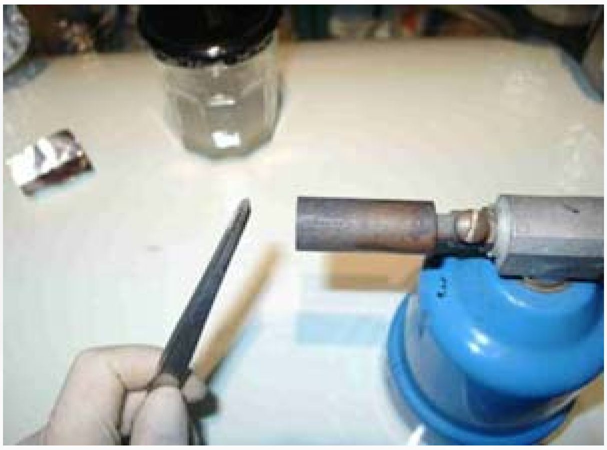
This is hot enough, if maintained for 20 minutes, to kill any spores of mold and bacteria. After this time period let the pot cool to room temperature.

Germination of spores

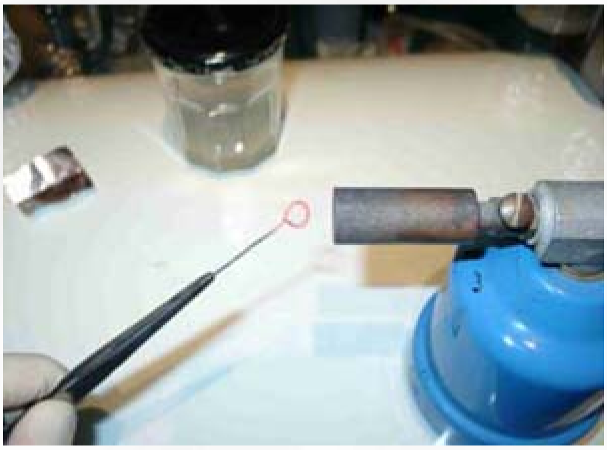
Short: Place some of the mushroom spores on sterile maltextract agar. Let the glass stand at room temperature (18 to 24°C/65 to 75°F). The spores will germ within a few days. Three weeks later the mycelium should be visible as cottony white hairs growing in all directions from where the spores had been placed.

How to transfer spores to maltextract agar in a sterile way:

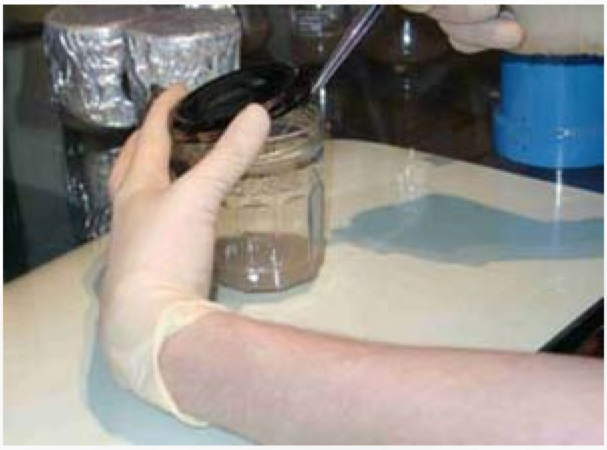
1) The working place is cleaned and sterilized with 70% ethanol.



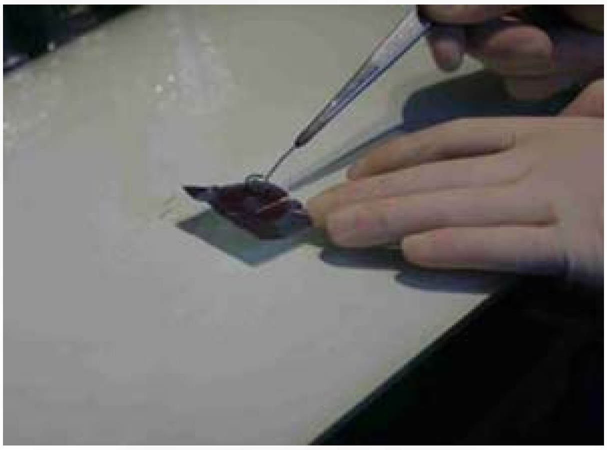
2) If tweezers are used, sterilize them in a gas flame.



3) Glow the inoculation loop, so it is sterile.



4) Cool the loop by placing it on the sterile agar. The spores will stick on the wet loop.

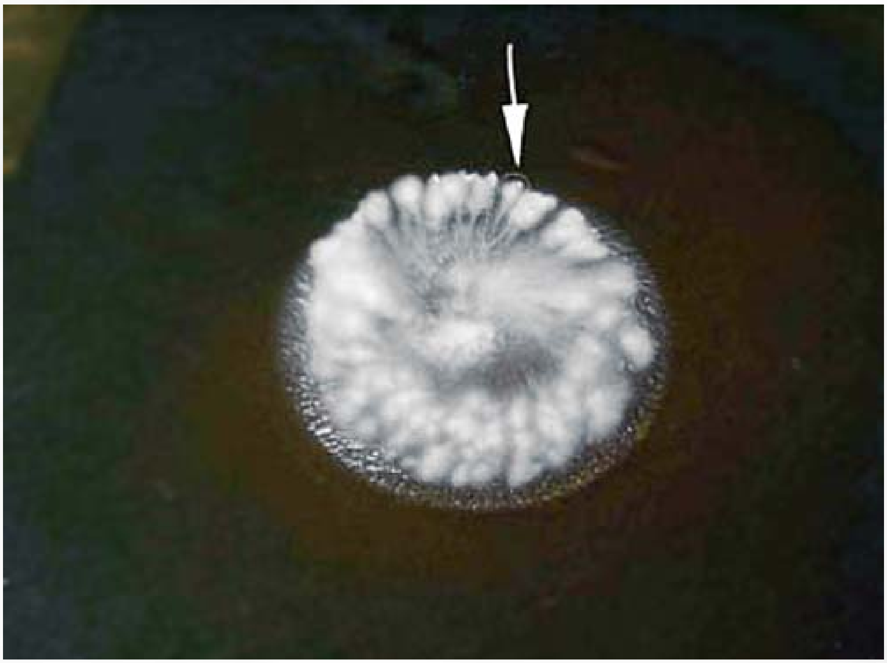


5) Spores are picked with the cooled inoculation loop and are

6) Transferred into the jar with maltextract agar.

Wait about three weeks for the spores to germinate and the mycelium to grow.

Isolation of Pure Mycelium



Mycelium of Psilocybe azurescens about 25 days after germination from spores.

Now it is time to take a little piece of white mycelium and put it in a fresh jar with agar medium.
Instead of an inoculation loop a lancet or similar can be used.
Yon should prefer thick filamentous structures (rhizomorphic mycelium).

Sometimes this isolation of pure medium has to be repeated several times until a really pure culture free of any contaminants is obtained A contamination is anything that grows on your medium that is not the mycelium.
When brought on new agar, the mycelium needs about one day to recover and until new growth can be seen.
Wet sterilized cardboard can be used as a much more selective medium, if serious problems occur in isolation of a pure culture on agar.

Expansion of Mycelium on Wood Substrate

From a pure culture the mycelium can be propagated further. A very good wood substrate are fresh hard wood chips presoaked in water.

Excellent for the expansion of *Psilocybe azurescens*:

Fresh cut hazelnut twigs

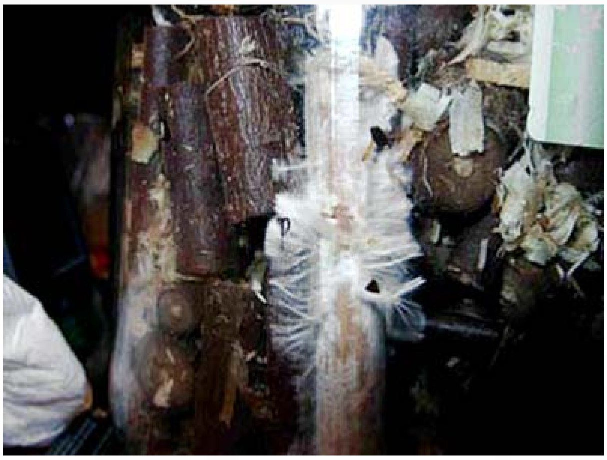
and/or hard wood chips.

Put them in as big glass jars as fit in your pressure cooking pot. The jars should only be filled to two third, this allows you to shake the wood chips in the jars.
The wood should not be sitting in water, and the ideal moisture content is 60 to 65%.

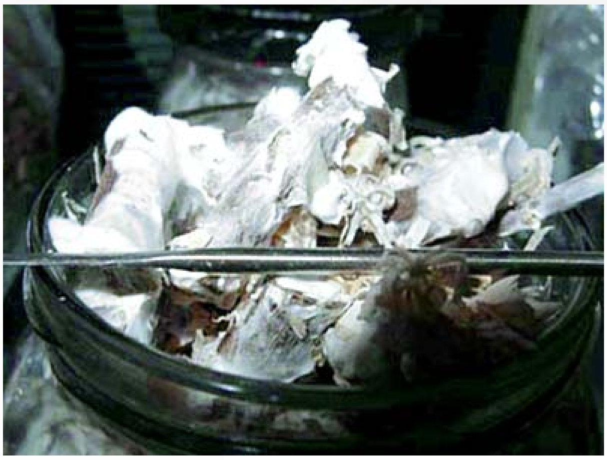
The procedure for sterilization is exactly the same as for the preparation of malt extract agar, except for the cooking time which must be increased to a full hour or more at max. pressure, depending on the container size.
Do not forget that the caps should not be screwed tight during sterilization!!!

As soon as the jars have cooled clown to room temperature they can be inoculated with several pieces of agar culture or if available wood spawn.
Shake the jars to even distribute the agar pieces.
After the shaking the caps are unscrewed a bit to ensure gas circulation and covered with tin foil to prevent airborne contamination.

A few days later growth of the mycelium should be visible.
The jars can then be shaken again to accelerate the expansion of the mycelium. The cultures are ready for the inoculation of more substrate, when they are completely grown through with mycelium.



Hazelnut chips inoculated with beech dowel.



Hazelnut chips ready for inoculation of more wood substrate.

The wood an a the mycelium form a compact mass of a white colour witch produces a characteristic mushroom odor when broken up. This mass of mycelium, suitable for the preparation of an outdoor bed, is called spawn.

Instead of jars, heat resistant polypropylene bags can be used to expand the mycelium to the wished volume, but the risk of contaminations is higher.

Do not use contaminated cultures to inoculate new Substrate!!!
If a jar or a Lag is contaminated, forget it or for the case there is only little contamination, place the spawn outdoor in a half shaded location and check in autumn for mushrooms.

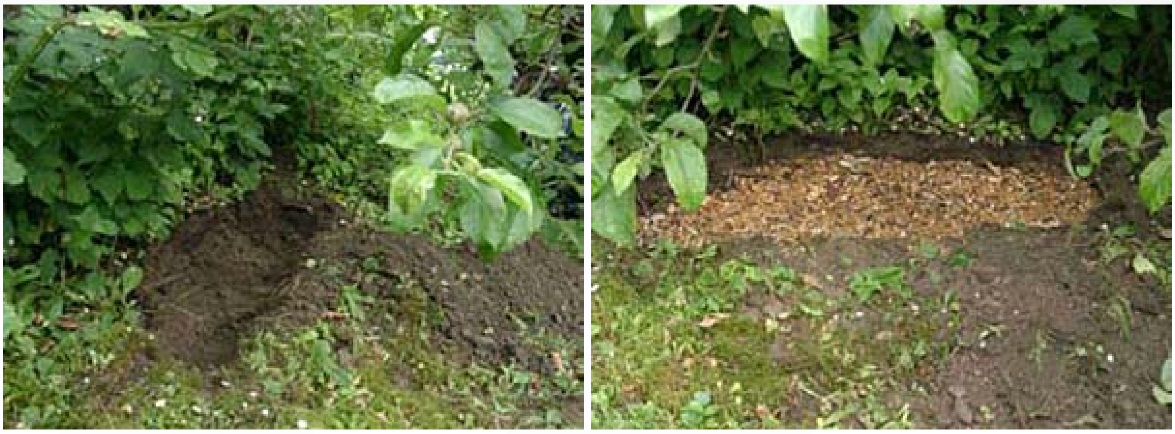
Preparation of an Outdoor Bed

An outdoor bed is nothing else than a 15 to 20cm deep bole m the soil filled with wood substrate.
Once a volume of one to several liters of mycelium on wood substrate has been obtained, the preparation of an outdoor bed is the final step, which will lead to beautiful mushrooms growing in your garden every year in late autumn and this for years.
A mushroom patch can be prepared at every time in the year except if the soil is frozen.
The chance for fructifications in autumn are excellent, if a bed is layed out in spring or even in autumn of the preceding year.
The bed on the pictures was layed out only three months before harvest season and it showed fructifications in the same year, but the result may have been better if the bed had been prepared earlier.
The later the patch is layed out, the more spawn has to be used to secure fructifications in autumn, and the later the mushrooms will appear.
Of course you can also prepare much smaller patches; I saw marvelous mushrooms growing from as little as 0,3 litres of contaminated spawn that bad been discarded in a garden near a compost pile.

Fresh chopped wood chips (preferable beech, alder, hazelnut...)

The wood spawn is added (at least l/5th of total volume) and mixed well with the chips.

A suitable place for the bed is a half shaded location below a shrub like this.

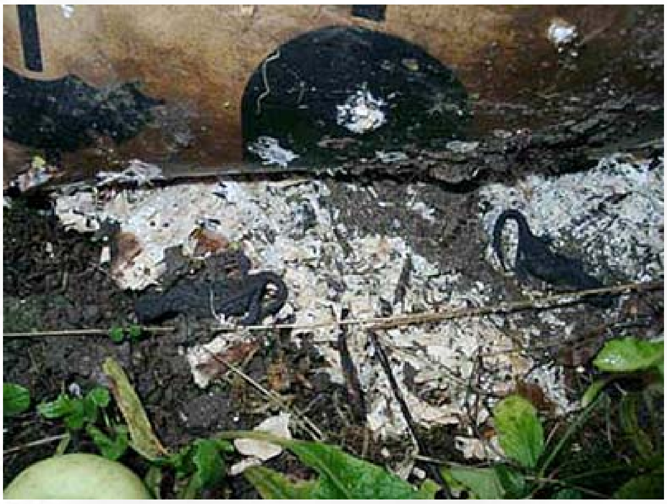


A 15 to 20 cm deep hole is opened and filled with the wood chips/spawn mixture.

The bed is watered with several liters depending on its size. The patch can additionally be covered with wet cardboard and perforated plastic or anything that keeps moisture high.

Do not give to much water! It is better to repeat watering a week later than to give too much first.

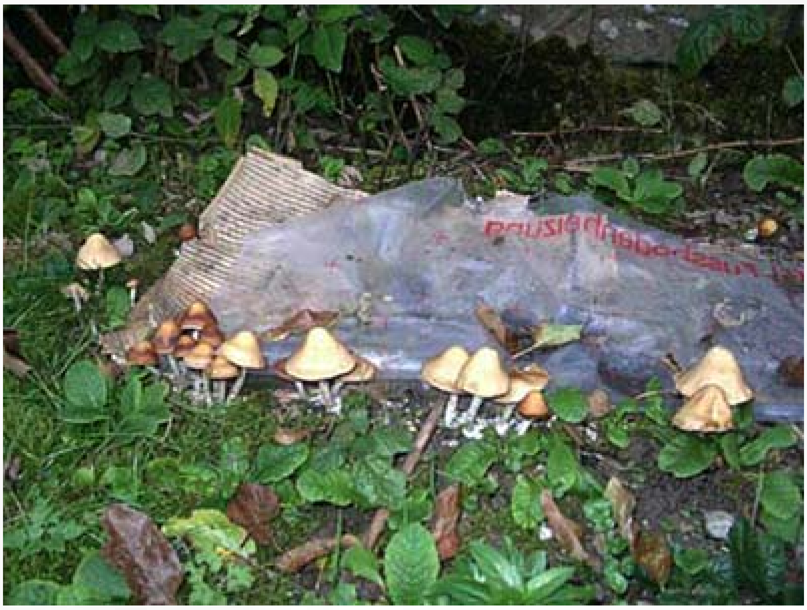
Make sure the bed is humid the first two weeks but not wet, then you will not have to give any more water until September. If you overwater during summer, the mycelium may grow aggressively, but you will probably see no mushrooms in late autumn.



That is the way a mushroom bed may look during summer: Note the white mycelium below and on the cardboard.

Not only mushrooms, but also amphibians like the humid environment.
Here you see ***Salamandra atra*** on a bed of ***Psilocybe azurescens***.

From September on keep the patch wet by watering once or twice a week.
This is not necessary if it is raining a lot, what is not unusual in this season.
In late September to early October, when the temperatures drop to 7°-10°C (45°-50°F), the first mushrooms can be expected, and they grow in usually two flushes about a month apart, until the temperatures drop below zero. Depending on the temperatures, mushrooms may even grow until January. By placing a tent over the bed, the fructification time can be prolonged.



The cardboard, the bed is covered with, is itself used by the mushroom as medium. A new bed of wood chips could be inoculated just by placing the infected cardboard on a small layer of wood chips at the bottom of the new bed, and by covering the cardboard with wood chips.

When the temperatures drop below 0°C the mushrooms stop growing. A layer of new wood chips can be worked in the top of the patch; this is the nutrition for the next year.

Treated that way, a mushroom bed may last for decades and zillions of spores will be set free.

The story of *Psilocybe azurescens* Stamets & Gartz

This species originates from the Columbia river basin near Astoria, Oregon and was first found in 1979. It grows in beds of hardwood or conifer chips in half shaded environments.

It belongs to the so called *Psilocybe cyanescens* complex. This means it is closely related to *Psilocybe cyanescens* and *Psilocybe cyanofibrillosa*.

Psilocybe azurescens is distinguished by its comparatively great size and some microscopic characteristics. But the most exclusive feature of this species is its production of secondary metabolites:

Typical analysis of dried ***Psilocybe azurescens*** (%) (Gartz l995):

mushroom	psilocybin	psilocin	baeocystin
1	1,40	0,31	0,28
2	1,56	0,30	0,32
3	1,68	0,28	0,38
4	1,71	0,34	0,41

These data make clear, that Psilocybe azurescens is able to accumulate as high levels of tryptamine alkaloids as 25 milligram, per gram of dried mushrooms.

With these values it is the mushroom with the highest alkaloid concentrations, of all psilocybin mushrooms known so far.

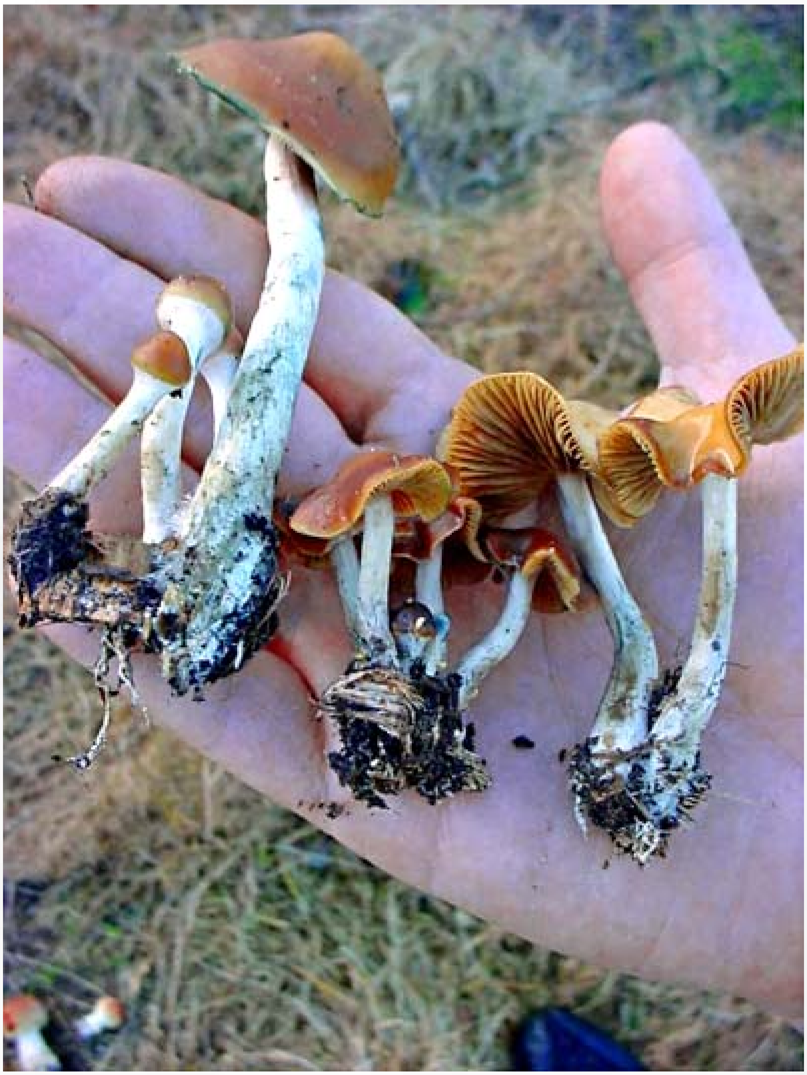
Latin description published by Stamets and Gartz in 1995:

Psilocybe azurescens Stamets & Gartz sp. nov.: Pileo ochreato-brunneo, hygrophano, viscido, pellicula separabili intructo, conico dein convexo, plano 30-100 mm lato, umbonato.
Lamellis sinuato-adnatis, pallidis vel brunneo.
Stipite albo, sricto elongato, 90-200 mm, fibrillis cum strigositate basis caerulescentibus.
Carne caerulescente.
Sporis 13-13.5 x 6.5-8.0 micron Cystidiis fusoid-ventricosis.
Cheilocystidiis 23-28 x 6.5-8.0 micron; pleurocystidiis 23-35 x 9-10 micron.

Cultivation of Caramel Cap Psilocybes with the PF TEK

original source: https://mycotopia.net/topic/7234-cultivation-of-caramel-cap-psilocybes-with-the-pf-tek/

Caramel Cap Psilocybes are mushrooms which belong to the Psilocybe cyanescens species complex: they are closely related to eachother and it is often difficult to separate those in species which exactly can be defined. All Caramel Caps grow on raw uncomposted plant matter, preferably fresh twigs or wood chips, and they typically fruit in the fall when temperatures drop to ten centrigrade and below. Psilocybe azurescens is the most popular Caramel Cap due to its agressive growth, large mushrooms and high alkaloid content.



Psilocybe azurescens (left) and Psilocybe cyanescens (right).

Caramel Caps are quite rare in the wild. In the Netherlands the Psilocybe cyanescens is even specifically listed as an endangered species. Caramel Caps are near to impossible to cultivate indoors but grow easily in semi wild conditions. It are great mushrooms to grow in a shady place in the garden. Until recently there was no good method available to grow these species from spores without the need for sophisticated laboratory equipment. With a few adaptations it is however possible to grow these mushrooms in "PF TEK" style, i.e. by using a spore syringe and without the need of agar cultures, a pressure canner, isolation box etcetera. Such a technique is presented here.

For the "outdoor" parts of this Caramel Caps cultivation technique the text heavily relies on an excellent pdf manual which was published on the internet by "The Azurescens Foundation" in June 2003. A similar technique with equally great pictures can be found at the Erowid site.

Method

For outdoor mushroom cultivation or larger scale cultivation it is recommended to germinate the spores on a substrate of whole grain kernels. The protocol is very similar to the production of "PF Substrate" from brown rice flour and vermiculite. The main difference is that it needs to be boiled two times (a process which is known as tyndallization).

Needed: brown rice, small woodchips (animal bedding), 250ml drinking glasses or jars, tinfoil.

Step 1: boil a cup of grains or brown rice according the directions on the box they came in. A cup of brown rice normally needs to be boiled for 15 minutes in two cups of water. Pour off the water;

Step 2: boil three or four times as much woodchips for half an hour. Pour off the water and mix the rice with the woodchips;

Woodchips plus brown rice substrate.

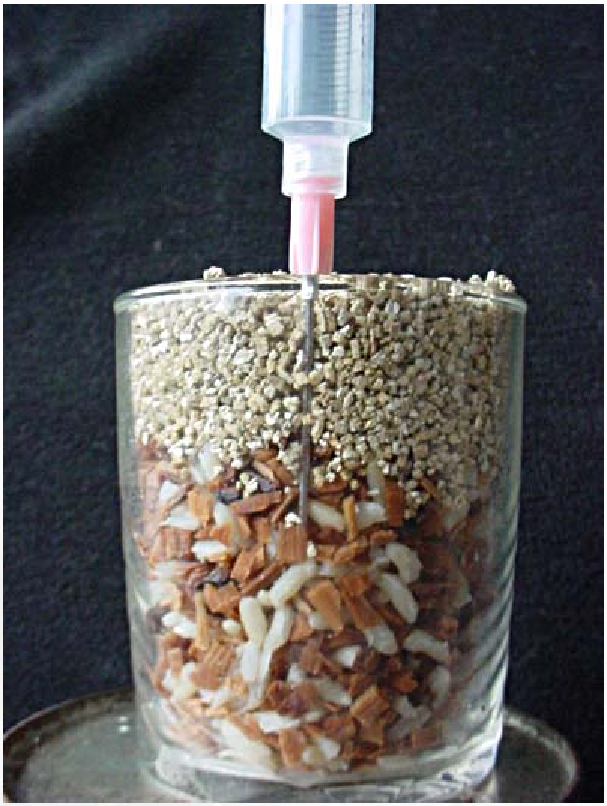
Step 3. Scoop the mixture of grains and woodchips in tall drinking glasses of 250ml until a distance of two fingers from the upper rim of each glass.

Step 4. WAIT 24 HOURS!
Important: the 24 hours waiting period is essential for the sterilization of whole grain mixtures without a pressure canner. This is because only living cells are immediately killed at the temperature of boiling water. But bacterial spores (endospores) are able to survive a boiling period when they are hidden in grains. They germinate in a few hours after the substrate mixture has cooled down. Therefore a double boiling period with a 24 hours pause in between kills contaminants, enables the contaminant spores to grow out (on the condition that the substrate is kept at roomtemperature) and then kills this second generation. This process is called "Tyndallization".

Step 5. Cover the glasses with tinfoil

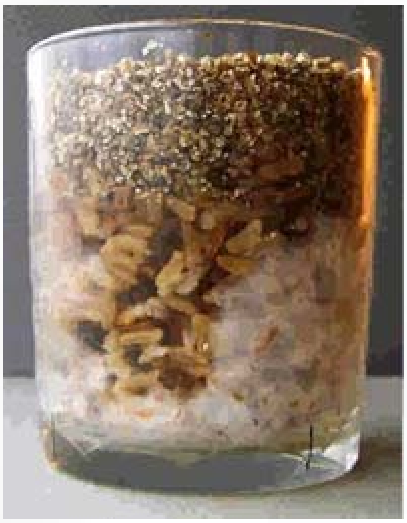
Pan with substrate jars. Photo: Azurescens Foundation.

Step 6: Put the glass(es) or jar(s) in a cooking pot with tight closing lid. Boil the containers in the same way but twice as long as PF Substrate jars: add cold water n the pot until the container(s) are halfway in the water and close the pan with a lid (or plate). Boil the water slowly for 60 minutes. Remove the pan from the gas stove.



Inoculation of rice/wood substrate.

Step 7: wait until the containers are cool to the touch and inoculate by using a spore syringe. The inoculation of azurescens spawn substrate is identical to the inoculation of riceflour substrate: lift the foil, inject the sporewater and replace the foil.



Colonization of rice/wood substrate.

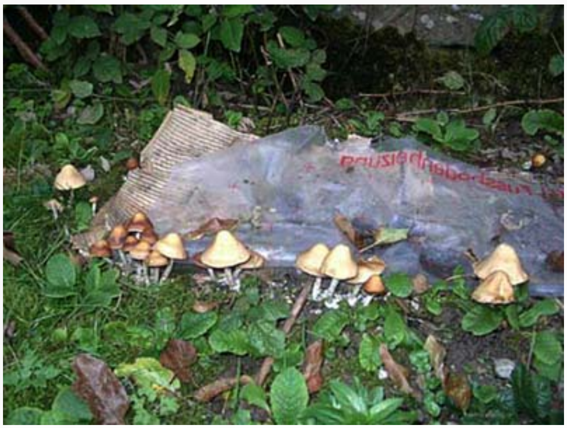
Step 8: again just as in the PF TEK for cubensis, store the inoculated substrate at room temperature. The mycelium will colonize the substrate in about a month (for this picture the tinfoil was temporarily removed).

Left: twigs, right: woodchips (photo: azurescens foundation).

Step 9: as soon as the Caramel Cap woodchip spawn cakes are colonized they can be crumbled and mixed with fresh woodchips (preferably outdoors). The best choice is a mixture of twigs, small chips and sawdust. A single 250ml glass of spawn is enough for several liters of woodchips.

An outdoor woodchips bed in the shade (photo: Azurescens foundation)

Step 10: preparation of an outdoor bed:
An outdoor bed is a 15 to 20cm deep hole in the soil filled with wood substrate. Once a volume of one to several liters of mycelium on wood substrate has been obtained, the preparation of an outdoor bed is the final step, which will lead to beautiful mushrooms growing in your garden every year in late autumn and this for years. A mushroom patch can be prepared at every time in the year except if the soil is frozen. The chance for fructifications in autumn are excellent, if a bed is laid out in spring or even in autumn of the preceding year.



Psilocybe azurescens fruiting and colonizing a sheet of cardboard (photo: Azurescens foundation)

The bed on the pictures was laid out only three months before harvest season and it showed fructifications in

the same year, but the result may have been better if the bed had been prepared earlier. The later the patch is laid out, the more spawn has to be used to secure fructifications in autumn, and the later the mushrooms will appear.
Of course you can also prepare much smaller patches; I saw marvelous mushrooms growing from as little as 0,3 litres of contaminated spawn that had been.
A suitable place for the bed is a half shaded location below a shrub like this.
A 15 to 20 cm deep hole is opened and filled with the wood chips/spawn mixture.
The bed is watered with several liters depending on its size. The patch can additionally be covered with wet cardboard and perforated plastic or anything that keeps moisture high. Do not give to much water! It is better to repeat watering a week later than to give too much first. Make sure the bed is humid the first two weeks but not wet, then you will not have to give any more water until September. If you overwater during summer, the mycelium may grow aggressiveley, but you will probably see no mushrooms in late autumn.

Psilocybe cyanescens fruiting on woodchips in freezing temperatures (photo: PFE)

From september on keep the patch wet by watering once or twice a week.
This is not necessary if it is raining a lot, what is not unusal in this season.
In late september to early october, when the temperatures drop to 7°-10°C (45°-50°F), the first mushrooms can be expected, and they grow in usually two flushes about a month apart, until the temperatures drop below zero. Depending on the temperatures, mushrooms may even grow until january. By placing a tent over the bed, the fructification time can be prolonged. The cardboard, the bed is covered with, is itself used by the mushroom as medium. A new bed of wood chips could be inoculated just by placing the infected cardboard on a small layer of wood chips at the bottom of the new bed, and by covering the cardboard with wood chips. When the temperatures drop below 0°C the mushrooms stop growing. A layer of new wood chips can be worked in the top of the patch; this is the nutrition for the next year. Treated that way, a mushroom bed may last for decades and zillions of spores will be set free.

Psilocybe azurescens fruits upon a thick mycelial mat.

Caramel Cap mycelium cleans up organophosphate pesticides

On October 28, 2004 , the world famous mushroom cultivator Paul Stamets filed a patent for the application of Caramel Cap mycelia for filtering wastewater, breaking down organopesticides and even cleaning up nerve gas residues from military sources(!). The latter two qualities are a directly related to the psilocybin producing capabilities of these species. In all cases the patented technique for the application of mushroom mycelia is quite simple: a wall of mycelium-colonized woodchips is placed around and/or mixed in the contaminated soil. The mushroom mycelium then excrete the phosphotase enzymes which rapidly break down the pollutants.

Paul Stamets writes: "Phosphorylated compounds such as the chemical warfare gases and many organophosphate pesticides have proven particularly resistant to breakdown and bioremediation, as few organisms are equipped with the appropriate dephosphorylating enzymes. Fungi, on the other hand, have a number of enzyme systems and paths for dealing with phosphorylated compounds and are therefore particularly suited for remediation of organophosphates. Preferred species include (...) agarics such as Psilocybe azurescens and Psilocybe cyanescens containing phosphorylated tryptamine compounds and their dephosphorylated analogs. (...) Since both Psilocybe azurescens and Psilocybe cyanescens can possess up to 1-2% psilocybin, a phosphorus rich molecule, and/or psilocin, the product of dephosphorylation of psilocybin, these species can be used to dephosphorylate toxins wherein phosphorus contributes to the toxicity of the pollutant (such as the phosphorylated chemical warfare gases above and organophosphate pesticides). Grassland species such as Psilocybe semilanceata, also rich in psilocybin, may also be preferably employed; such grassland species have the advantageous characteristic of acting as saprophytes, decomposing organic matter, or acting as ectomycorrhizal species, directly benefiting plants via symbiosis, depending upon circumstances. (...) The growth of algae in ponds and lakes can be directly attributed to the phosphorus-rich runoff from agricultural fertilizers and other industrial pollutants. Phosphorus is typically the 'limiting nutrient' of algae growth. By removing phosphorus using mycocloths, mycomats and mycoberms infused or spray hydroseeded with dephosphorylating fungi such as (...) Psilocybe azurescens (...) the over-growth algae can be limited in lakes and ponds, providing cost and ecological saving benefits to fishery ecologies and the watershed."

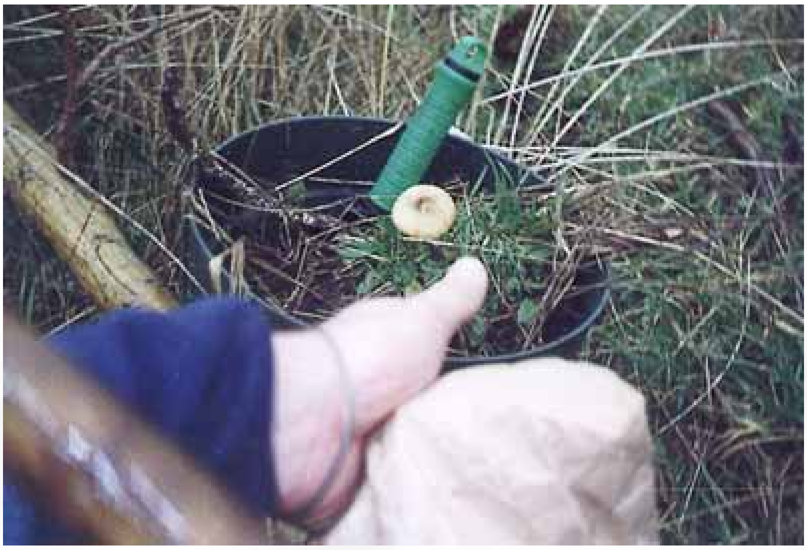
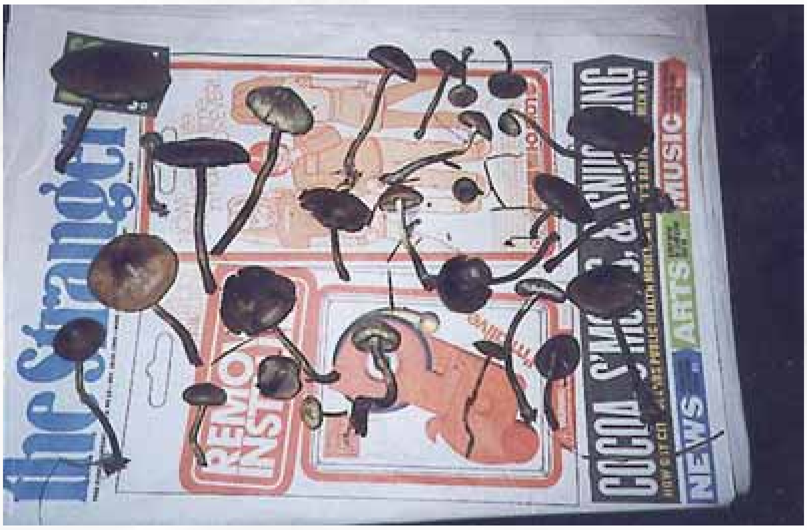
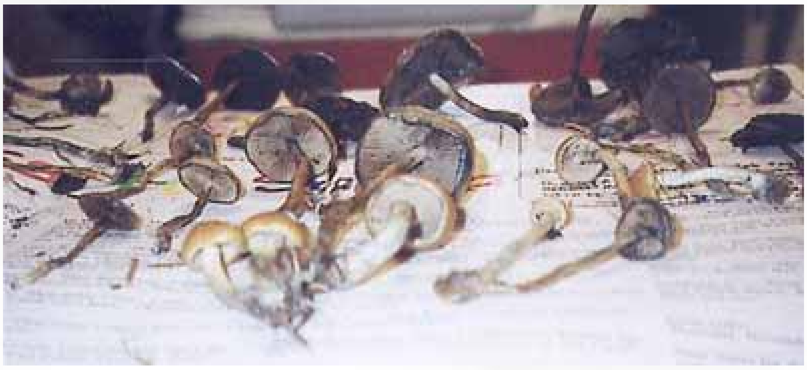
Fruiting report

Psilocybe azurescens (Wild Astoria)

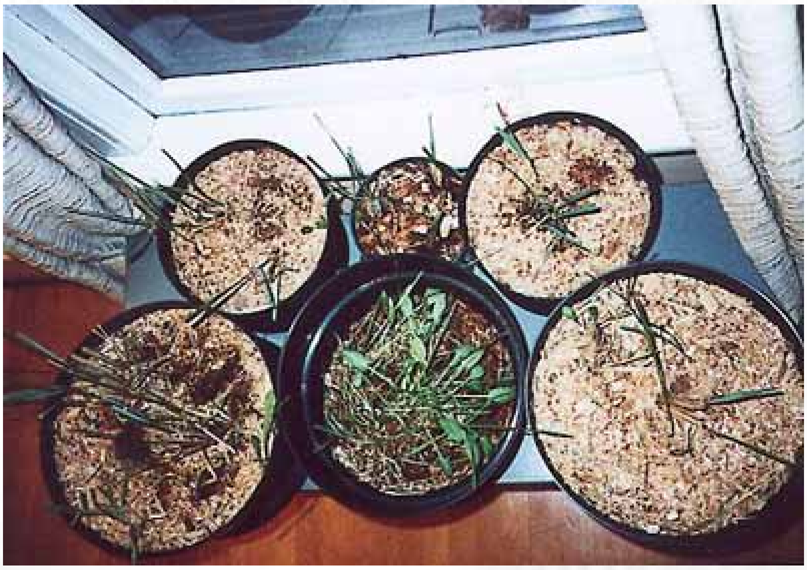
1. Patch collected in Astoria OR 12/19/99. Patch dug up and placed, along with grasses, into large flower pots.







2. Pots brought back to Seattle, WA. Patches were then cleaned up of extra debris and alder woodchips were added. Makeup of pots as follows: Pots filled 3/4 with beach/riparian sand/silt. dune grasses and other plants arranged on sand. Mycelial bits laid on sand surface around grasses. whole thing covered with alder chips and planings.



3. Each pot was watered deeply and placed in a south facing window sill. The pots were sprayed with distilled water every day. note: after two weeks, there were signs of black mold in one of the pots. I cleared the mold out with tweezers and stopped spraying the pots. I noticed lots of mycelium growing at the border between the sand and woodchips. The pots were then watered only once a week, allowing them to dry at the surface. The grass has taken off, as has the weeds. A coast lupine has sprouted as have lots of other weeds.

4. Three of the six pots were taken outside on 2/6/00, 7 weeks after starting. Daytime highs were in the mid-50's, lows in mid-40's. I hope to have Mushrooms growing in flowerpots by mid-March. They should make lovely pictures. After the last flush, the pots will be broken down and planted into prepared beds. These beds will be composed of pits dug out and filled with sand from a nearby river. I will try to recreate the environment of the West Oregon sand dunes and get the Azurescens to take to the Puget Sound environment. A portion of the patch will be dug up and moved every year to a location along the Puget Sound. There are places locally

with sand dunes containing dune grasses that the Azurescens will probably adapt to readily. Within ten years, Psilocybe Azurescens will be a predominant species in the Puget Sound Region.

5. A week after being put outside, a hard frost set in so I pulled the pots back into the house for a few weeks.(2/13/00-2/27/00) All the pots were put out on 2/28/00 along with a batch of P. Cyanescens. As of 4/7/00 there is no sign of activity from any of the pots. The weather has been 1/2 dry 1/2 rainy. Highs have been in the upper 50's to lower 60's, lows from the low 30's to mid 40's. With the weather warming (highs this weekend to near 70 degrees F.) I am fearing that any primordia may abort. Also, the pots go through a period of drying every week. I'll give it another month before I abort the mission and begin work on an outdoor patch. Psilocybe Azurescens.

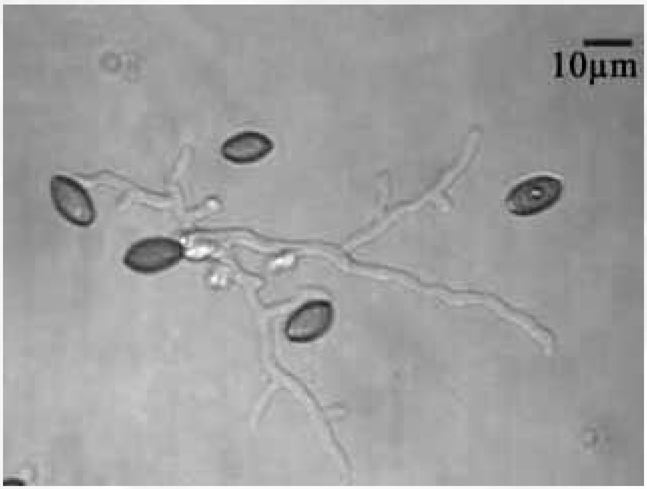
Psilocybe azurescens (Hammond)

by **Amanita**

original source: https://www.erowid.org/plants/mushrooms/mushrooms_cultivation_az2.shtml

Spore germination

Spores from a print were streaked out onto 2% malt agar and incubated in the dark at 25 °C. After 7 days, the healthiest looking rhizomorphic colonies were isolated and transferred to fresh plates, also cultured on agar slants in universal 1 oz glass bottles, for cold storage in the fridge (5.0 °C).



Spores germinating on agar media.

Spawn media

100 ml of organic rye grain and 80 ml of tap water was put in 1 pint glass jars, with synthetic filter discs fitted under the caps, and autoclaved for 20 minutes. Once cooled, 1cm wedges of mycelium were cut from the agar and transferred, 3 to each jar. Lids were replaced, and jars incubated at 25 °C for 7 days. Each jar was shaken to disperse the rapidly spreading mycelium, and then incubated for a further 7 days.

Bulk substrate preparation

Fully colonised grain spawn was then used to inoculate "filter patch spawn bags" . Each bag contained around 1 pound of mixed hardwood sawdust and alder wood shavings/chips. Enough boiling water was added to each bag to fully wet the substrate (approx. 5:4 substrate : water ratio). These substrate bags were left to soak overnight then autoclaved for 20 minutes, and allowed to cool. Around ½ pint of spawn was used to inoculate each bag of substrate and these were left to colonise in a dark cupboard for 2-3 weeks @ about 20 °C. An alternative method for an attempted indoor patch was using a plastic "washing-up" basin with a cased substrate consisting of wood shavings and wheat straw (#1). As you can see, the fungus loves this cellulose rich substrate.

Fully colonised wood/straw substrate.

Preparation of outdoor beds

Patches were placed in different areas of the garden, during the summer around June-July, 1999:

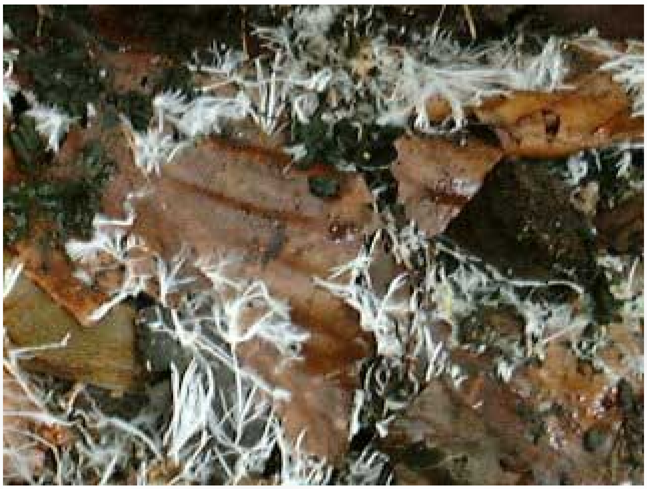
#1. Under Rhododendron bushes, next to grassy lawn
#2. Under a pear tree amongst weeds/shrubbery
#3. Under an ash tree with surrounding gooseberry bushes
#4. In rich woody soil next to a compost heap

Each site was prepared by digging trenches about 6 inches deep, around 2 square feet. The trenches were raked over and lined with a thin layer of moist, well rotted leaf litter/twigs. The colonised woody substrate was broken up and spread out (about 1 bag per patch). The spawn was then covered with another 2 inch layer of rotted leaves/twigs, and finally covered with a thin (1 inch) layer of soil.

Preparation of an outdoor patch (#1).

Establishment of beds

It has now been about 6 weeks since preparing the patches and they are all doing very well. Rhizomorphic mycelium can be observed creeping over leaves, and spreading out into the surrounding leaf litter which comprises the top 2-3 inches of the soil. The weather is cooling down now (August) and it's getting wetter.



Rhizomorphic mycelium spreading over leaf litter.

Pests!

Watch out for slugs, which like to eat mycelium. The best way of getting rid of them is to bait them with bread, and go out at night with a torch and remove them (wearing gloves!). Wood lice were also present and probably feasting on the mycelium. The other pests are squirrels, which discovered the grain and dug a few little holes in the patch under the pear tree (#2), soon after preparing the beds.

Maintenance

The patches were kept well-watered, mostly by rain, although they did encounter some dry periods, which implemented the use of a watering can. There was a light frost at the beginning of October, but the patches were snug under the leaf litter.

Fruiting report

- **#1** developed pinhead primordia, towards the end of October, This was mainly in the area which had been covered by a thin layer of moss, grass and leaves. The mossy turf had recovered and the mycelium could be seen around the grass roots. Over the following two weeks the primordia grew into mushrooms. Translucent caramel caps with whitish stems which have a very strong bluing reaction were bruised; truly an amazing species! They seem to grow very slowly at first, but accelerate as they got bigger.
- **#2** is sparsely colonised at the surface, and not looking very happy. Partially due to animals digging up the grain spawn, and the soil is very clay rich with is not much wood content. The soil might be too moist.
- **#3** under the ash tree, is still looking healthy, and there are plenty of thick rhizomorphic mycelium creeping out. It has a 2 inch covering of leaves, and seems to be retaining moisture well, but no sign of fruiting, yet.
- **#4** also hasn't started to fruit, but the woody ground is very well colonised. The patch was covered with a thin layer of mossy turf: this is keeping it moist, and there is a carpet of rhizomorphic mycelium.

The following images show the development of primordia to "grown-up" mushrooms.

Psilocybe azurescens indoor cultivation

by

abert

original report: http://www.shroomery.org/8702/Psilocybe-azurescens-indoor-cultivation

First I have prepared mycelium on a sterilized wheat grain by inoculating it from mycelium on agar. After the grain was colonized I inoculated alder chips (not sterilized, soaked during 2-3 day in water) with this colonized grain.
The alder chips were dried chips, I bought them in a shop, they are used for smoking fish etc.

ОЛЬХОВАЯ ЩЕПА

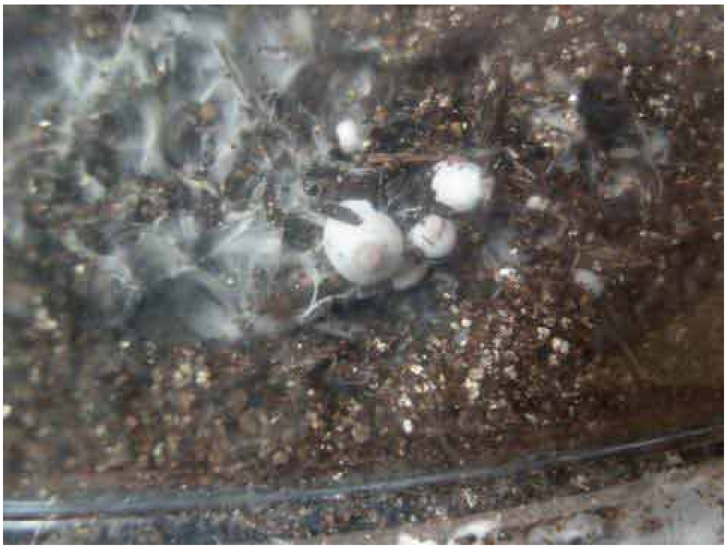
Alder chips were colonized by the mycelium within 1.5 months, at a temperature from 23-25°C. Then I placed the colonized alder chips in a plastic bottle (first case) and put a casing layer on.
The casing layer consisted of composted needles, foliage, sticks etc. from the woods. I removed large fragments so I was left with a homogeneous mass. The casing layer was not sterilized.

After mycelium appeared on the surface of casing layer (temp 23-25°C), I put a layer of wet vermiculite, and placed a bottle in a refrigerator (temp 6-8°C). (My refrigerator has a glass door and fluorescent lamp - such refrigerators are used as a display for wine bottles etc.).

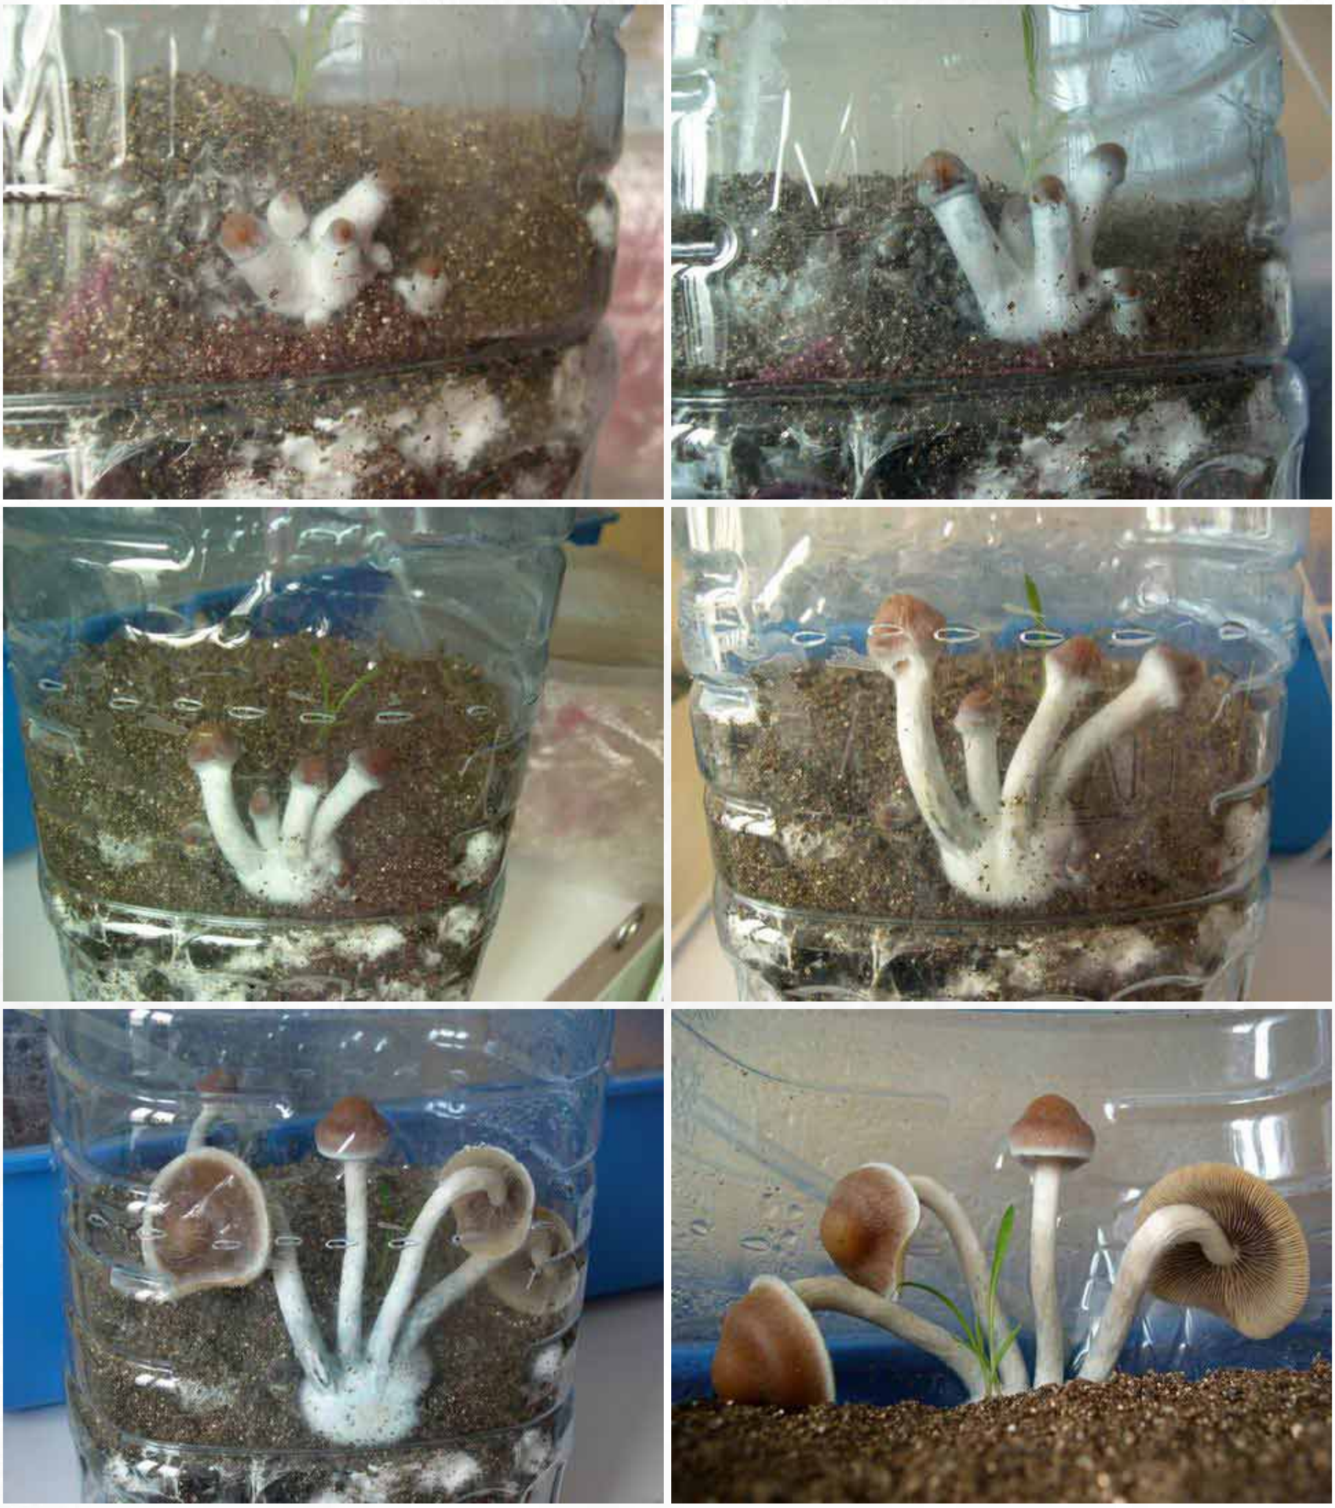
This is my refrigerator.

Regularly (two times per day) I aired and 1 time per 2 days humidified the bottle. 1.5 months later the first mushrooms have appeared.

The first mushrooms did not develop because of shortage of light (I used only natural illumination, through the glass door), but mushrooms on the second flush (that you can see in the pictures) developed normally. I used a fluorescent lamp for 16 hours per day. From occurrence of mushrooms up to harvest 28 days have passed.



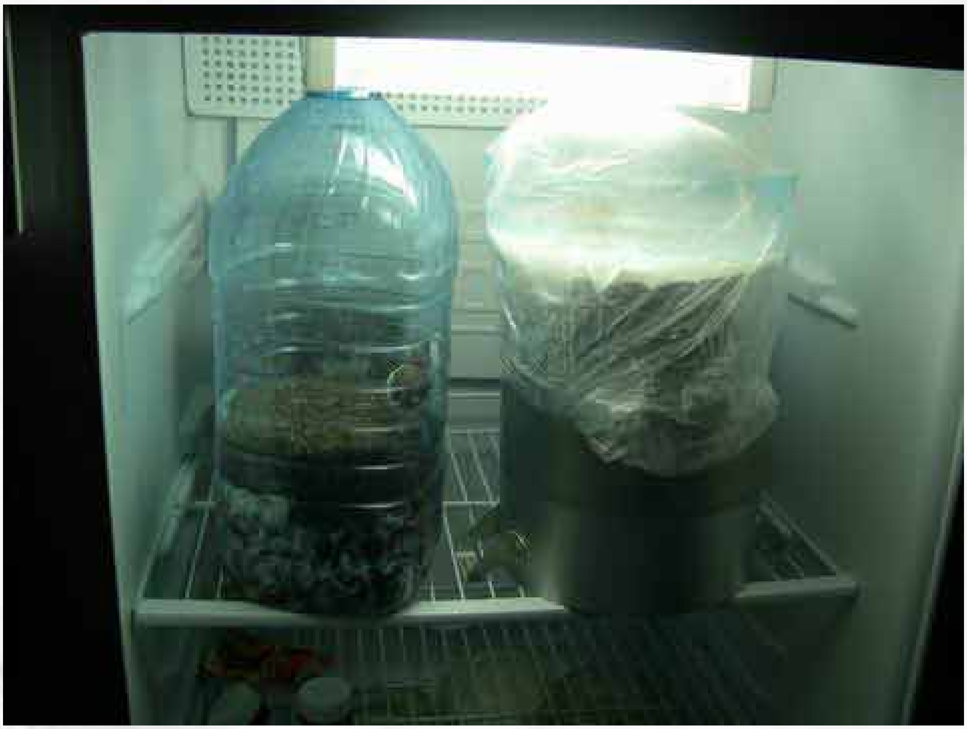
Development of the mushrooms in the bottle.



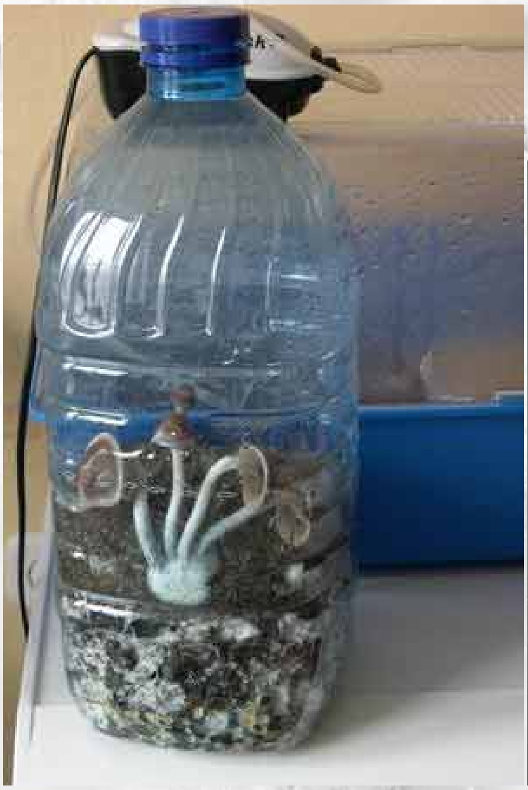
The second container was made in precisely the same way, only one month after the first. What you see in the pictures is the first flush. Using a light from the very beginning, and also having placed the container in the top part of a refrigerator (where temperature is little bit higher: 8-12°C), the development of the mushrooms could be reduced for 2-3 weeks. (2-3 weeks, because I noticed mushrooms when they have appeared above a surface of the casing layer, from this moment up to harvest have passed 2 weeks. But mushrooms needed some time to appear above a surface... let's consider 3-7 days.).

The second container (substrate and casing layer were the same as in the previous case).

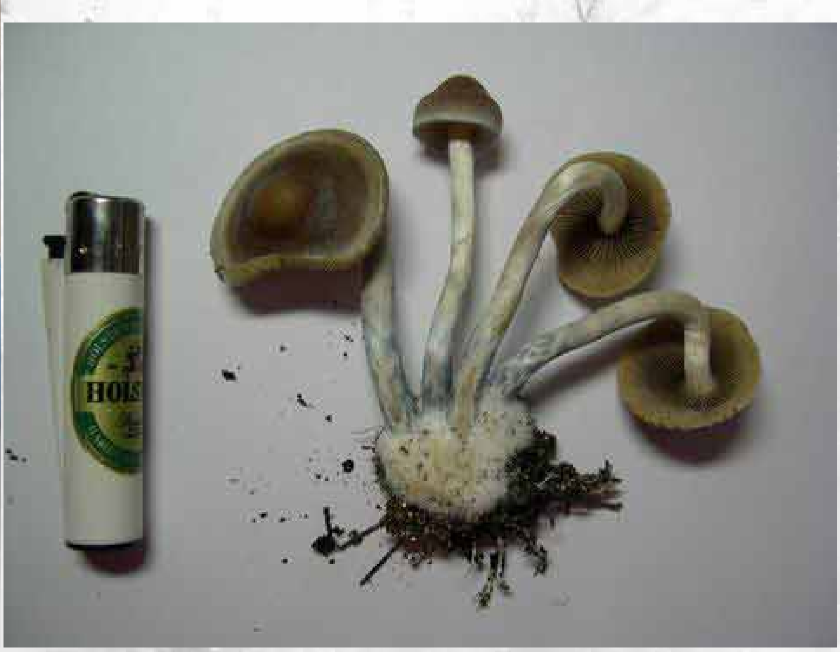
And some more pics.



Two containers, placed on the top shelf, (where it is warmer). Second container placed on a pan (in order to place it higher).



A plastic bottle with mushrooms inside (in full size).



And the harvest.

Growing Panaeolus Tropicalus and Panaeolus Cyanescens

Version 1.0

by

The Hawks Eye

original source: http://mycotopia.net/archives/discus/messages/5/1405.html

This is a document of collected knowledge from our own experience with pans and talking with other growers. Thank you everybody for your input over the years. More to come

Its well known this is not a very easy species of mushroom to grow, but it can be done, and is done quite often. Just count on a little extra work and some TLC.

Ok, for starters, if your using a spore syringe, inoculate your substrate jars of 3:5 ratio of ground brown rice to vermiculite or 2:1 of finch or birdseed to vermiculite. If your using agar with a spore print, then your obviously experienced and we don't need to go into much detail there. After your substrate is inoculated, you will see a very thin and wispy mycelium. Its not thick and rhizomorphic and healthy looking like cubensis mycelium. On agar, it actually looks like contamination its so strange looking. Sometimes very spongy looking, and wispy looking on agar. Strange stuff man. In jars, the mycelium is almost a light grey color, yet off white, and very thin. It almost looks like cobweb mold its so thin. At times it will even grow what appears to be primodorma and pins, but its not. Its just a very strange looking mycelium at this stage. So unless you start seeing strange colors other then white or a light grey, its ok, just go with it.

Typcial colonization of 1/2 pint jars is around 3-4 weeks. Sometimes faster, but allow them to sit a week after full colonization. You'll see why when you break open the jars and pull the substrate out. It breaks apart very easy. Once again its a weak mycelium. Be sure your handa are very clean, as this mycelium easily contaminates.

The next step is to use that substrate as spawn to colonize either dung or compost. Compost is your best bet. Dung is the next choice. A lot of old books recommends straw, well straw also works but it contaminates much easier on straw then dung or compost. This is not just our opinion, but from many growers we've talked with gave up on straw and pan species. So from here, either buy or make some compost, or go out to your local cow/horse/donkey/elephant field and shuck some patties. So you know how your always leaving your girlfriend at home while you go have fun? Well you need a helper, its time to bring her on a field trip This is a great cover up for where you go on those field trips when you disappear Doh!

If you can find farms that have straw or grain fed animals you have some prime realestate to grow those pans on. If you don't know what they are feeding the cows and are not aware of what they are eating, we recommend you kneel down and sniff the patty! A prime pile of dung will have a nice organic aroma to it.

Stay away from fresh steaming patties. You want the ones that are aging a bit. There are to many micro-organisms on the fresh patties that can kill the spores, plus they 're sticky and they stink. You don't want these. There are some great pictures on our website under the panaeolus species of some Manatee County Florida Panaeolus Cyanesecens growing on dung. These are the best pictures we've seen yet showing clarity of how old the dung is when these mushrooms are growing on them.

Ok, so you and your gal are out in the field under the full moon feeling romantic collecting dung. She's happy she's out of the house, your happy because your bucket is full of dung, time for a bud. Your choice, weiser or herb.

The next step is to prepare your dung. Usually its pretty hard when you pick it right. Toss it in a big bucket and poor in a gallon of purified water or more, so its covered in water, and let it sit for day to soften up. Next step, a day later is to pasturize your dung or compost.

Pasturizing is a form of sterilizing the compost or dung in less then boiling water to eliminate many non-beneficial bacteria unhealthy to mushroom mycelia. There are many methods of doing this, but here is what we recommend. Take your dung or compost and put it in an old pillow case, then tie it in a knot. Get a large pot, something like 22-30 quart and fill it with water. We always recommend againts tap water, spend $.50 cents and buy a gallon of filtered drinking water. Fill up your pot of water to about 8-10 inches from the top, turn up the heat on your stove. You want the water temp between 160F-180F, which usually is steaming heavily, but not boiling rapidly. Put in your mother-in-laws pillow case full of dung, push it down a bit, and let the hot water absorb into it. The temp of the water will drop for a while, wait it will build back up. When it does, let it pasturize for a good 45 minutes and turn off the heat. It will take a while to cool down. When its cool enough, take it outside and let it hang for a day to drip water and cool off. Not to worry, the outside air is good and healthy for it . You can let it sit there for several days if you don't have the time to get back to it. When your ready to work, here we go with the next step.

Ok, were assuming your have knowledge of casing your substrate. Take your dung or compost from your MIL's pillow case and take handfulls and squeeze it real hard until the water is barely dripping. You don't want a lot of water in it or it will be to soggy and contaminate to easily. Squeeze it until the water is barely dripping, and place it in your casing container. Get the desired amount for the space your working with. Take those jars of substrate and start gently crumbling them up with your pasturized compost or dung. Mix it well. We recommend about 3 to 4 1/2 pints of subtrate for every 10 lbs of compost. Or, a semi-full pillow of dung or compost, add about 2 1/2 pints of subtrate worth. After its mixed well, then add a casing layer. Pans seem to like hydrated lime in the soil. The 50/50+ mix works well. They grow well with the verm/peat/lime/oyster shell mix. Within 2-3 weeks of casing they should start fruiting. Now all the old school books say they like temps around 70F-75F, well, that is not written in stone. In the tropics where they grow, the temps are much warmer. We've seen them grow at a daytime high of 93F, which means substrate temps of 95-96F, and a LOW of 70-75F. There has not been a lot of information posted about this species that is updated, and we hope what we have given you helps. There is a lot more to come, this document will continue to grow and nothing is written in stone. This species is well worth the time and efforts because the experience from Panaelus species is PHENOMENAL !!!!

The Cultivation of Copelandia cyanescens

Introduction

Copelandia cyanescens is fairly easy to grow and gives a reasonable yield. My specimens were grown from spores supplied by Pacific Exotic Spora. There are different opinions on the taxonomy of species in *Panaeolus* and some mycologists do not recognise *Copelandia* as a genus. The mycelium grows rapidly on malt dung agar (MDA) and fruits abundantly when horse manure is added to grain. Although the fruiting bodies are small they are extremely potent. The *Copelandia* casing layer eventually succumbs to blue mould and must be discarded although it should yield around 40 g of mushrooms (fresh weight) per 100 g rice/horse manure. *Panaeolus cyanescens* (spores from PES) is also very potent but has a weaker mycelium which gives smaller specimens and a much lower yield (10 g per 100 g rice/horse manure). The casing layer also succumbs to blue mould. These tropical species grow at similar temperatures to *Psilocybe cubensis*. Spores of *Copelandia cyanescens* and*Panaeolus cyanescens* are difficult to distinguish. Both are lemon shaped and give black deposits. *Copelandia cyanescens* measure around 9.5 x 11 µ while *Panaeolus cyanescens* are 11 x 12 µ and clump together less (each division in the photomicrograph below is 1.9 µm).

It is my personal view that Hawaiian *Copelandia cyanescens* offers the entheogen user a more enjoyable experience than the more easily cultivated *Psilocybe cubensis*. In fact I would place it in the *premier cru* of psychedelic plants, alongside the indigenous Liberty Cap (*Psilocybe semilanceata*) and the various DMT containing plants.

Making an Inoculation Chamber

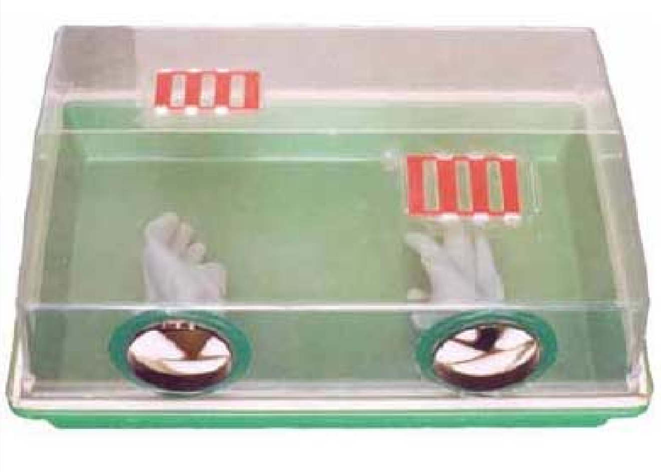
Mushroom mycelium has no hard protective skin, unlike flowering plants, so it is liable to attack by other micro-organisms. In nature each mushroom will produce millions of spores very few of which will reproduce. When working indoors we must therefore first construct an inoculation chamber to ensure sterile conditions. Mushroom laboratories use Laminar Flow Hoods where a powerful fan forces air through a large HEPA filter, but these are very expensive.

My inoculation chamber is based on an idea of Stephen Peele's (see FMRC). A 61 x 39 x 30 cm (24" x 15" x 12") glass aquarium is turned on its side. The exposed edges are rubbed with emery paper to make them less sharp and the narrow strips of glass at the top and bottom of the opening are removed. A sheet of polythene is Sellotaped to the front panel and the bottom left hanging for the operator to put his hands through. Alternatively two vertical slits can be cut in the polythene for this purpose. When exposed material is inside the bottom edge is held in place with tape (it need not be airtight). Hot sterilised items should be placed inside on a mat or plate rather than on the glass and the scalpel blade and tweezer tips must be flamed outside. An angle-poise lamp can be positioned over the aquarium.

A glass aquarium is preferable to a perspex one as it is superior optically and much harder to scratch. Although less portable and larger than necessary, I prefer large aquaria as they allow plenty of room for movement. The inside is misted with a few sprays of a 10% solution of thin (detergent free) bleach each time it is opened when working with exposed material. A plant or cosmetic spray bottle is ideal for this purpose. The spray bottle should be clearly labelled and kept in a safe place - if children are around it is safest to empty it between uses. Cosmetic spray atomisers may eventually block, even when deionised water is used for dilution, due to the chlorine. To extend its life it can be flushed through with water after each use. Gloves must be worn in the aquarium when bleach is present to protect the skin - thin rubber gloves with talcum powder work best. (I use a tissue for swabbing as cotton wool sticks to the rubber.) The inside surface of the aquarium can be wiped clear with the gloves. A mask with a charcoal filter should be worn as chlorine is very irritating to the mucous membranes. Avoid using the aquarium on quality furniture as the bleach spray causes staining of varnish and also stains clothing.

It is also possible to construct a glove box from a plant propagator tray with a perspex lid. Two holes are cut in the lid and washing-up gloves fitted. This model measures 56 x 37 x 22 cm (from B&Q stores). Although this glove box allows less air exchange than the aquarium design, I no longer use it as hand movement is very restricted and the height is inadequate for inoculating Kilner jars.

Aquarium



Glove Box

Horse Manure

Horse manure is a mixture of droppings, urine and straw which is allowed to rot down in a sealed plastic bag to preserve the nutrients. Common *Agaricus* mushrooms are grown commercially on composted horse manure. Various supplements are added and the process is rather complicated. Coprophilous (dung growing) species are less demanding. When used in the garden it is not unusual to see wild mushrooms growing on horse manure. While cubensis fruits abundantly on cased grain, copelandia and panaeolus grow poorly on this medium. Personal hygiene is essential when working with manure as some farm animals harbour the deadly strain of E coli which is frequently in the news. Avoid using kitchen utensils with unsterilised horse manure and wash hands after preparation. I sterilise a small quantity in a Kilner jar which I save for making the MDA below. Alternatively poultry manure pellets can be used.

Spore Germination

MDA (Malt Dung Agar)
For each 8 oz jar:

- 25 ml water
- 0.5 g agar agar
- 0.5 g malt extract (light dried or use 0.5 ml syrup)
- 0.25 g horse manure or poultry manure pellets - copelandia grows poorly on MEA (Malt Extract Agar)

The quantities are not critical but the solution must be contain at least 1.5% agar to solidify. Agar is made from seaweed and is sold as powder or flakes in Health Food shops. It is sometimes labelled "agar agar" to distinguish it from gelatine "agar" which is made from animal sources. Light dried malt extract is available from home brew outlets. Mycelial growth is less vigorous on dark malt extract syrup.

MDA Ingredients - Agar, Malt Extract, Horse Manure

Preparation

Agar Media before Sterilisation

Spraying Aquarium with Bleach Solution

STEP 1
Make up the media as above. Heat the liquid sufficiently in a saucepan to stir in the malt, or use a Pyrex mug in a microwave, then pour into 8 oz jars. It is important to have a reasonable depth of agar for inoculating grain jars later. Thin sections tend to stick to the jar side making inoculation more difficult. Ensure that any media is cleaned from the jar thread to avoid contamination entering later. If an accurate balance is available, it is more precise to add the ingredients separately to each jar as they are difficult to mix in a mug since the manure in not soluble. Add 500 ml of cold water to the pressure cooker. Pressure cookers are normally supplied with a basket and a rest to stand vegetables out of the water. Insert these or some similar utensil in the cooker and place the jars inside it. The lids should not be completely tightened.

STEP 2

Sterilise the jars for 20 minutes at 15 psi (1.05 kg/cm2).

STEP 3

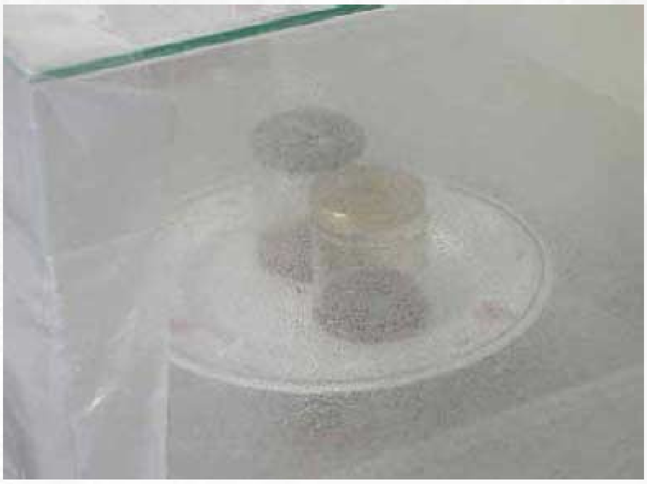
Close all doors and windows to prevent draughts and allow the pressure cooker to depressurise slowly. Depressurising rapidly will cause the media to boil excessively. Spray bleach solution into the aquarium. While wearing a thick pair of gloves remove the lid and place the jars on a plate in the aquarium. Spray more bleach solution. If any lids have come off the jars in the cooker they should be replaced immediately (usually they will be okay). If any lids become seized on by vacuum a flamed screwdriver tip should be used to lift the edge.

STEP 4

Once the media has solidified it can be inoculated (agar solution solidifies at 32°C). Swab a scalpel and tweezers with isopropyl alcohol or surgical spirit and flame the scalpel blade outside the aquarium. Rest them inside on something so that the blade and tweezer tips are not touching anything. Put on the gloves and mask and then pull the spore print partly out of its bag with tweezers inside the aquarium. While holding the print through the bag scrape the scalpel blade tip across the spores. If necessary the print can be placed on a saucer that has been swabbed with isopropyl alcohol (not surgical spirit which leaves a residue). The smallest speck can contain thousands of spores although some prints have to be scraped hard to remove them. Scrape the spores onto the surface of the agar in the centre of each jar. Always open lids as little as possible and close them quickly to reduce the risk of contamination. Do not allow any agar to remain on the spore print as it will attract contaminants. The lids are then tightened.

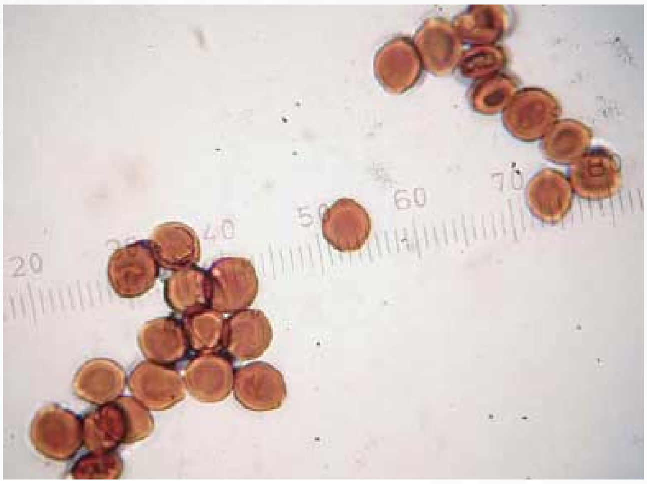
STEP 5

The jars are then incubated in a warm place (the top of an airing cupboard is ideal if you don't yet have a combi boiler). They should be stood upside down to keep moisture off the agar and can be heated up to 27°C. The temperature range can be checked over a period with a max/min thermometer to ensure it is not too hot.

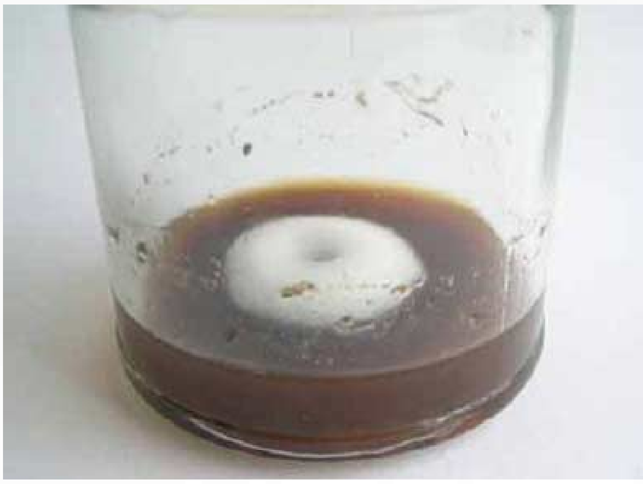


Agar Media Cooling

Scraping Spore Print



Copelandia cyanescens spores



Copelandia cyanescens mycelium on Malt Dung Agar

When working with more than one set of jars each should be labelled with a permanent marker or a Chinagraph pencil. Only write on the glass because permanent marker ink cannot be removed from some lids (ink can be removed from non-porous surfaces with meths). Fresh spores should germinate within a week although older spores can take up to three weeks. In the warm copelandia mycelium should fill a small jar about two weeks after inoculation, although it will not grow to the edge due to the lack of air exchange in the jars. For maximum growth the lids can be fitted with synthetic filter wool (from aquarium shops), although filters are never 100% effective. If liquid was present on the surface of the media the spores may be dispersed and germinate from different points. Any liquid present can be rolled around the side of the jar to remove condensation when viewing. It is essential to inoculate grain with fresh mycelium - in time it flattens and becomes less vigorous.

Copelandia mycelium is white and frequently develops a radial structure. Any coloured mycelia will be moulds from airborne spores. If these appear the media should be disposed of as spores will have been shed inside the jar. A slimy ring around the rim indicates bacterial contamination.

Grain Culture

For each litre Kilner jar:

- 180 g (dry weight) wholegrain rice
- 90 g thoroughly wetted horse manure (or 45 g poultry manure pellets and 45 ml extra water)
- 180 ml water
- 1 g gypsum

Some brands of rice are impossibly sticky. Rice can be tested by rinsing in hot water - if the water remains clear it is suitable. Easy cook rice, also known as parboiled rice, is pressure steamed to modify the starch. Any easy cook brown rice should be okay but Tesco American easy cook brown rice is ideal. Ensure that the ingredients are thoroughly mixed and heat immediately before the gypsum solidifies. The addition of gypsum (calcium sulphate) is particularly useful with rice grain to reduce clumping. Available from craft shops as Plaster of Paris.

STEP 1
Add 1 litre of cold water to the pressure cooker (the larger quantity of water is needed for the longer sterilisation time). Place the filters inside the plastic screw bands and tighten them on the Kilner jars (see Spawn Jar Filters in Resources section). Bring up to pressure with moderate heat and sterilise at 7 psi (0.5 kg/cm^2) maximum for 90 minutes. The pressure must be allowed to drop by itself as releasing it causes a sudden drop in temperature which can crack the jars. Shorter times do not give adequate sterilisation and higher pressure will crack the jars.

STEP 2
Remove the Kilner jars from the pressure cooker wearing thick gloves and check carefully that there are no cracks. Then shake the jars to separate the grains. The jars should be held upside down whilst shaking vigorously to dislodge the grain from the bottom (a little liquid may drip through the filters). It may be necessary to drop the jars upside down on to a floor mat from a couple of inches to dislodge rice grain. Only tighten the lids gently whilst hot as they will tighten as they cool. If the jars are allowed to cool without shaking they will need re-heating for a short period.

STEP 3
Allow the grain jars to cool completely before inoculating in the aquarium. A large section of agar must be used for grain in order to maximise the number of inoculations. I use two quarters of a small jar culture to inoculate each Kilner jar. Use bleach misting, gloves and mask. Cut the culture into quarters and spear them with a flamed scalpel to transfer them to the jars. One fully colonised small jar will adequately inoculate up to 4 Kilner jars - ideally all the jars should be inoculated at the same time. Open the jar lids as little as possible when transferring the media. Tighten the screw bands and shake the Kilner jars thoroughly in all directions to inoculate the grains. Label the jars with a permanent marker or Chinagraph pencil.

STEP 4
Incubate the grain jars in a warm place. They can be stored on their sides provided that the grain does not obstruct the filters, as mycelium grows quicker in less dense grain and it is less susceptible to Wet Spot. If the agar quarter has stuck culture side to the glass the jar may need re-shaking after the mycelium has grown through to the exposed surface. The mycelium will disappear on shaking but recover in a couple of days. In the warm the spawn should be ready in about a week. The grains will be stuck together with a fine white growth. A little moisture may be present as a waste product of the mycelium. Avoid re-shaking the jar if there are uncolonised patches (less likely with rice) as this encourages Wet Spot which thrives in anaerobic conditions. If green mould spots appear or the jar smells bad when the lid is removed due to Wet Spot, dispose of the grain. Wet Spot can often be smelt through the filter - filters are never 100% effective.

Laying Out Spawn

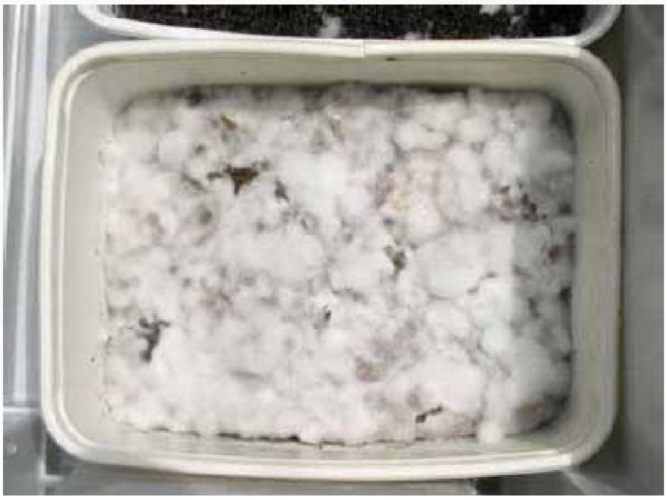
Some growers simply case the grain in the jars. This requires a large number of Kilner jars and the mushrooms are difficult to pick. Laying out the grain is more convenient and gives a better yield. A 2 litre ice cream tub (19 x 15 cm) or a similar sized sandwich box base makes a suitable container. This is then placed inside a larger container with water to maintain a humid atmosphere.

STEP 1
The tub should be stood for a half-hour in a warm bleach solution (keep the lid on to prevent fumes) and then rinsed before use. This will kill any mould spores surviving from previous use. Boiling water is also effective but deforms the tub.

STEP 2
A tablespoon should be placed in a mug of boiling water for a few moments, shaken dry and allowed to cool. The jars should be well shaken to separate the grains before pouring into the tub. Any large lumps should be put back into the jar with the spoon and re-shaken. The last grains may have to be dug out. The spawn is levelled off by pressing it with the spoon. Using the 2 litre ice cream tub should give about 40 mm depth of spawn. In hot weather the grain can sometimes dry out and not spawn after re-shaking. It may recover if the bottom of the tub is covered with a thin layer of wetted vermiculite.

STEP 3
A plastic box with transparent lid or cover should be bleached as above and rinsed. The bottom surface is covered with water and the tub stood inside it. (The water is changed every fortnight - always use cold tap water as the chlorine will help keep it fresh.) The lid is placed on the box to maintain high humidity - alternatively a polythene sheet can be taped over the top. Condensation will form on this lid. If too much condensation forms and drips onto the grain, the lid can be opened slightly to reduce the humidity. A fine white mycelium will completely cover the grain after a day or two with copelandia and cubensis. If a few grains remain uncolonised the spawn can still be cased normally. If the grain is cased before the mycelium reappears, foul smelling Wet Spot will develop and the spawn will be lost.

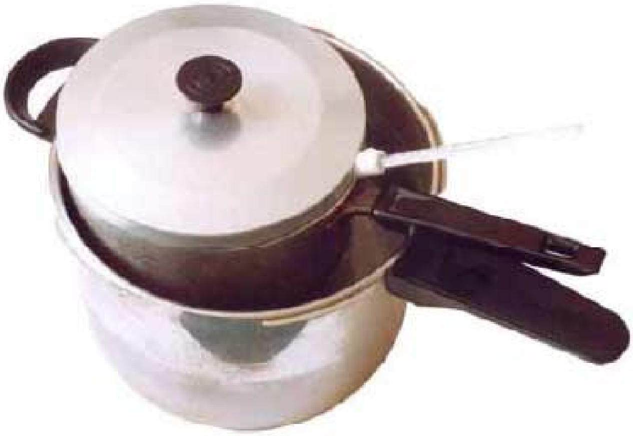
Copelandia cyanescens spawn on rice/horse manure



Spawn ready for casing

SPHAGNUM MOSS PEAT
GARDEN LIME

Casing Ingredients



Pasteurisation Apparatus

Casing and Cropping

Peat mixed with chalk (calcium carbonate) or lime (calcium oxide) is used for casing in *Agaricus* cultivation. Moss (Sphagnum) peat is the type preferred - the heavier sedge peat is unsuitable. It is usually sold in 60-80 litre or larger size bags. Moss peat has a low pH value that is too acidic to be used alone. It also has a low nutritive value. A quantity of chalk or lime is added to buffer the acidity, making the pH value more neutral. Moss peat and garden lime powder should be used in the ratio 2:1 by weight (8:1 by volume) for copelandia. For easy mixing the dry ingredients can be placed in a sealed container and shaken.

Moss peat compost makes an excellent casing for cubensis and unlike raw peat is available in small quantities. It is less acid than raw peat and has nutrients added. Garden retailers describe this product as compost although it has no connection with garden or mushroom compost.

Dry casing is sprayed to achieve an even moistness and then pasteurised. Pasteurisation is preferable to sterilisation because it preserves benign micro-organisms which delay contamination by the lower fungi. Sterilisation is adequate for copelandia although it is not recommended for slow growing species such as *Psilocybe cyanescens*. Untreated peat/lime and compost casings become contaminated very quickly by *Trichoderma*. I find that cubensis pins quicker and more abundantly on compost than on peat/lime. I use peat/lime with copelandia as I have found compost to be susceptible to Cobweb mould (*Dactylium*) when it is not rapidly colonised by mushroom mycelium.

STEP 1
Place sufficient pre-mixed peat/lime casing in a saucepan and wet until moist. I use a chip pan which has a gap in the lid for the basket handle, through which a winemaking/homebrew thermometer fits. The thermometer should touch the base of the saucepan and a piece of paper towel should be wrapped around it to prevent steam escaping from the hole. The pressure cooker base is filled with hot water so that the saucepan floats on the surface - see above. (Placing the thermometer in the water is adequate if a suitable saucepan is not available.) Alternatively the saucepan can be placed in any large pan. If it is too heavy to float, it can be stood on the pressure cooker's upturned perforated basket. The casing is pasteurised for an hour at 71-82°C (160-180°F). It is advisable to turn off the heat before the temperature reaches the lower limit as it will continue to rise for some time. If it reaches the upper limit the saucepan should be removed from the water and replaced when it drops to the lower limit. Once the system is stable, only occasional heat will be needed to maintain the casing between these temperatures.

OR

Place the moistened casing into a casserole dish with a lid and microwave until steaming hot.

STEP 2

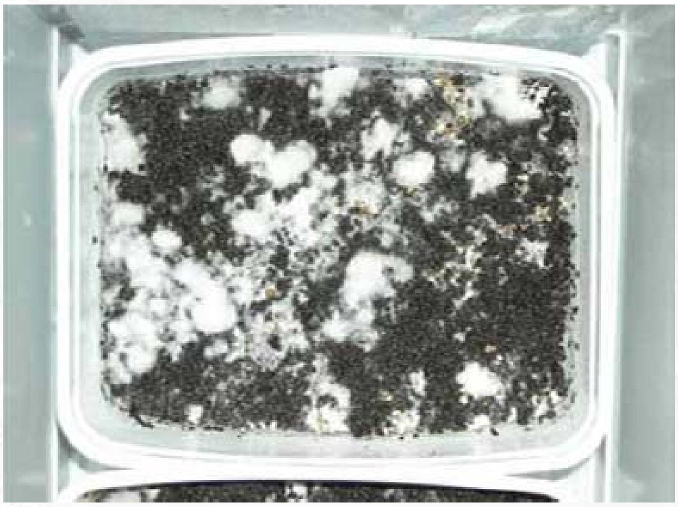
Apply the casing once it has completely cooled and replace in the plastic box with transparent lid. Use just enough to cover the spawn, no more than 10 mm depth. The casing should have an uneven open surface and should not be compressed. A little water should appear when the casing soil is squeezed between thumb and forefinger but it should not be saturated.

STEP 3

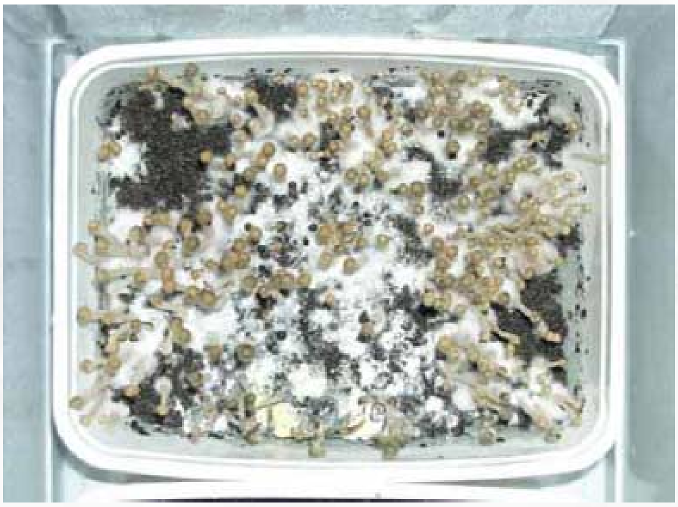
Mycelium should appear on the surface of the casing layer after a few days. If the casing starts to dry it should be sprayed regularly from a height with a fine mist so as not to damage the mycelium. If mycelium does not appear the casing should be completely ruffled up by scraping the surface of the spawn to allow air exchange. In the unlikely event that this fails the casing may need to be thinned. Once mycelium is visible the air should be changed regularly by fanning. Alternatively an aquarium pump tube can be placed inside the box to provide air exchange - place the tube into water to maintain humidity. Mushroom metabolites have a distinctive (not unpleasant) smell. Copelandia primordia (pins) should appear after a week. If the surface becomes completely overlaid with mycelium add more casing.

STEP 4

The stems of copelandia continue growing long after their caps have opened and are tenaciously attached to the casing. Scrape any casing from the bottom of the stems. You will see an instant bluing reaction on the stems after picking. Carefully tip out any liquid from the bottom of the tubs as this will encourage contamination.

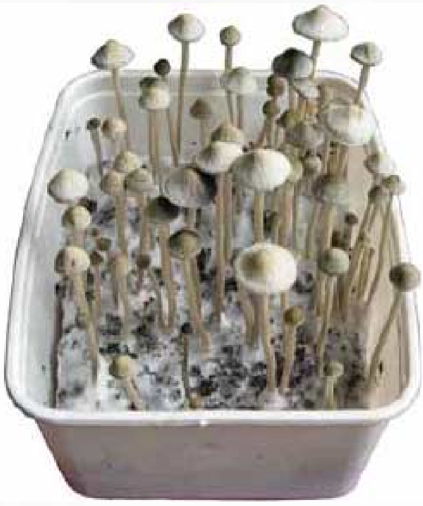


Copelandia cyanescens pins appearing



Six days later

Growing in Humid Box



Mature Specimens

Generally yields are larger in a humid environment. However if the humidity is too high black patches can appear on the caps due to Bacterial Blotch (*Pseudomonas*). Blotch should be wiped off the caps and the humidity reduced by raising or partly removing the lid. Excessive humidity stops the caps opening fully and reduces spore production. Keep the casing moist by spraying when necessary.

Copelandia succumbs to contamination much earlier than cubensis, the spawn and casing turning blue. Growing copelandia is particularly difficult in hot weather when daytime temperatures are much above 20°C. Small patches of contamination and the surrounding area can be sprayed with bleach solution. I have tried replacing contaminated casings in containers and in Kilner jars but they become re-infected because the spawn itself is contaminated.

Fungicides are used by commercial growers. These kill lower fungi while the higher fruiting fungi remain unaffected. Fungicide residues may present health risks so I avoid them. Spraying with pyrethrum is very effective if flies become a problem at fruiting. This natural insecticide is extracted from the pyrethrum daisy and is usually mixed with piperonyl butoxide to make the pyrethrins more effective. These compounds have very low toxicity and are used on edible crops and in medicine.

Airborne spores have been known to cause health problems in the mushroom industry. To reduce exposure the plastic box can be fanned outdoors or the mushrooms picked before the veil breaks. Boiling mushrooms for a few seconds and drinking the cooled water should avoid any allergic reaction - best to repeat to extract everything.

Spore Printing

Select a mature specimen on which the cap has fully opened and remove the stem - copelandia caps develop better when the humidity is reduced by raising or partly removing the lids. Place a strip of white paper on a saucer in the aquarium. Lay the cap onto the paper and cover with a glass, after spraying the inside of the glass with a fine mist. After 24 hours spores should be visible - leave for a couple of days to get a dense print. Remove the glass and cap and allow the print to dry. Once dried it should be folded, placed in a flat re-sealable bag and frozen. Frozen copelandia spore prints remain viable for many years, unlike cubensis, although mycelial cultures will only keep a few months on MDA in a fridge (see DSMZ, Medium 781 for a more elaborate media recipe).

Preserving Mushrooms

The simplest way to preserve mushrooms to dry them thoroughly and then freeze them. I lay them out on a plate in the top of the airing cupboard - psilocybin is destroyed in air at temperatures over 50°C. The mushrooms should be dried hard before being bagged and frozen. Copelandia loses far less potency than cubensis during drying.

Making an Incubator

The traditional home airing cupboard makes an ideal incubator. However they are fast becoming redundant as more efficient combination boilers are being installed which dispense with loft tanks and external boilers. So we can make an incubator by using a plastic box with a flat base and a clear lid, and placing it on a reptile heat mat or a demijohn heater. Inevitably there will be a temperature gradient between the base and top of the box so a spacer is used to prevent the jars touching the hot base and a 12V computer fan is suspended with string - using bolts with spacers looks more professional but is very noisy. The fan is connected to a mains adaptor and can be run at lower voltage to reduce noise further - be careful not to reverse the polarity as these fans have no diode protection. The jars are placed upside down to keep the media dry and a temperature probe is attached with White Tack. Kilner jars are placed on their sides ensuring that the filters are not blocked - the jars are far more susceptible to Wet Spot contamination when placed upright. Up to 27°C is ideal for copelandia agar and grain culture although cased copelandia spawn should not be heated above 21°C as it becomes more susceptible to blue mould - in this case water should be added to the plastic box to maintain high humidity and the fan should be set to its slowest speed to prevent the casing from drying out. Monitor the temperature and use a plug in dimmer or a thermostat, if required. A twin channel thermostat can be used enabling agar and grain to be kept at 27°C in one box while spawn tubs are kept at 21°C in a second box.

Mushrooms and the Law

The UK government has placed all psilocybin containing mushrooms under Class A of the Misuse of Drugs Act from 18 July 2005. Cultivation or sale now carries a maximum sentence of life imprisonment. Sadly our government has little interest in civil liberties and ignores the overwhelming evidence that mushrooms are less harmful for most users than tobacco or excessive drinking. Although no one has been sent to prison yet for mushrooms in the UK, I think it would be prudent to adopt a strategy to minimize our risk exposure. Here's mine:

- Avoid synthetic psychedelics as the risks to the manufacturers and distributors are enormous
- Never sell mushrooms to anyone - encourage them to grow their own
- Only grow and store small quantities
- Be aware that communications can be monitored - use PGP encryption (see PGP Guide) or a Hushmail account for sensitive emails

A Cautionary Note

Psilocybin mushrooms are very powerful. They are probably best avoided if one is not in good spirits as the experience can be overwhelming. They should also be avoided at times of illness as they may suppress the immune system. If you use mushrooms alone and encounter difficulties, an experienced companion can be helpful to sit or take a walk with. If you prefer to wander alone, I would recommend taking a mobile phone, a plastic water bottle and avoiding traffic. Obviously one should never drive or operate machinery whilst under their influence - it is best to avoid driving until the following day as one's own assessment can be deceptive. Be careful not to leave magic mushrooms anywhere where they might be eaten by children and do not use them during pregnancy.

Half a gram of dried copelandia should produce strong effects (dry weight is around 14% of fresh weight). If preferred, a liquid extract can be taken after boiling the mushrooms for a few seconds - best to repeat to extract everything. Taken on an empty stomach the full effects should be reached after an hour and a half and reasonable normality should return after four, although it may not return completely until the following day. Even with higher doses I haven't noticed that the effects last much longer. Taking mushrooms after food tends to cause indigestion and will delay the onset of effects.

In case of adverse effects, have drinking water handy in a plastic cup or bottle. Absolutely no glass. Caffeinated drinks should be avoided as should alcohol, cannabis or any other drugs. Psychotic symptoms can be overwhelming but should improve over time if the person is kept calm, ideally with the minimum of illumination. In this event any future experimentation should be undertaken at a reduced dose.

Resources

Pressure Cooker

Select a model having low and high pressure controls, usually 5 and 15 psi (0.35 and 1.05 kg/cm2), that can hold a pair of litre Kilner jars. I use an old Tower Rapide Chef 4305 which has 7 and 15 psi weights. Any 6 litre Tower model with dual weight settings should do (some only have a 15 psi weight), but check with your jars first for height. Prestige and Tower make larger High Dome aluminium pressure cookers which can be set between 5 and 15 psi by adjusting the heat, but they need watching when sterilising Kilner jars to ensure they don't go over pressure. Argos stores do a good selection. Cooking oil is rubbed around the gasket for lubrication. Large gasketless autoclaves are used commercially (the All-American range is available from Fungi Perfecti). Once sealed autoclaves don't emit steam. The pressure is read off a dial and adjusted by heat.

Spawn Jars

I use traditional preserving jars with filters which are inoculated with agar media. Spawn bags are also available with self healing injection patches for syringes. Buying spore syringes every time is expensive and making your own requires a lot of spore prints. Personally I find jars much easier to work with. (Preserving jars are known as canning jars in the US.) Use a preserving jar with a screw band - see the Kilner jar above. They should be sterilised at 7 psi (0.5 kg/cm2) maximum. At 15 psi they frequently crack. Kilner jars are no longer manufactured although Ball and Leifheit both make screw top preserving jars with the same size mouth. Of course you could use any jar with a metal screw top (PVC caps will deform when sterilised while polypropylene is indestructible). Make a few holes in the lid with a bradawl from the underside so that the burrs don't push against the filter (otherwise too much air would pass through the filter). Autoclave the filter to shrink it, allow to dry and trim with scissors to give a tight fit under the lid. Alternatively a single hole can be made in a metal lid and filled with synthetic filter wool (from aquarium shops).

Spawn Jar Filters

The spawn jars are fitted with autoclavable filters to allow air exchange without micro-organisms entering. I have also grown spawn by removing the rubber sealing rings from glass Kilner lids and tightening the plastic screw band over them to allow some air exchange. (In some American guides the metal sealing disc is inverted and the screw band tightened.) Although the resulting spawn looks healthy the casing becomes contaminated with *Trichoderma* very rapidly. Even if mushrooms are produced the disease free period will be reduced. I wasted a considerable amount of time with this method because the contamination present in the spawn is not visible to the naked eye.

Reusable wide mouth filter discs are available from Fungi Perfecti - they are advertised as 90 mm although the filters are 85 mm in diameter. Initially they are very tight under Kilner screw bands but shrink about 1 mm with use to give a perfect fit. They also fit Ball and Leifheit jars. The filters become stained with use and should be bleached between uses to keep them sterile (this does no harm as they are made from a synthetic material). I soak them in a mild solution in a Kilner jar until clean (use a lid to prevent fumes). The filters should have their surface area restricted to reduce evaporation from the jars. Draw a circle around a 5 pence piece (18 mm diameter) with a pencil and apply gloss paint to the outer area - see above. If the jars are used for slow growing species the filter aperture can be further restricted with tape to prevent the grain drying out prematurely, or the jars can be stored in a humid box.

Panaeolus Cyanescens - Liquid Culture to Fruits

- So, that's all fine and dandy, but how strong are they?

What is all this about?

This grow log is of my first try at Ausi Pan Cyans. The techniques I used in this grow are identical to my successful Ecuadorian cubensis grow of a few months back.

How do they grow compared to cubensis?

Like cubensis Pan Cyans are not too difficult to grow. I would call them a tiny bit more challenging than cubensis but not very much.

They grow slightly faster than cubensis in liquid culture, taking only 2 or 3 days to achieve a very high mycelium density cloud if continuously stirred and inoculated with a few ml of starter liquid culture whereas cubensis takes about 3 or 4 days.

Once in in grain or manure, they are close to the same speed as cubensis but can't hold the substrate as hard or dig through as well because they lack rhizomorphic features. When trying to colonize lots of grain, you really need to either keep shaking the grain every four days or use sufficient liquid culture so you don't need to shake because the mycelium can slow down, lacking the tenacity of cubensis mycelium. The same probably applies to spawning manure (i.e. use lots of spawn).

In the fruiting department, they like a between 75 to the low 80s, which is a little warmer than cubensis requires. The pins won't tolerate 100% relative humidity very well like cubensis can. The fruiting bodies are very tiny compared to cubensis, but there are tons of them. The fruits are much easier to dry than cubensis because they are smaller, but still the yield isn't as great. I believe one could achieve about 30% the yield of a perfect cubensis yield under ideal conditions.

In the strength department they make up for some of the yield shortfall. They will knock your socks off so be careful with these! I write a lot more about strength below, and I recommend you read it if you intend to trip on these. Tripping hard on anything can be dangerous, even deadly if you are in the wrong place, so take it easy at first.

The Grow

Stage 1 - The Liquid Culture

I started with a 4% by weight liquid culture solution. In my case I used 20 grams of sugars for the 500 ml of water. 10 grams of dextrose was added to 10 grams of light malt powder in a few coffee filters, which was then loaded in the coffee machine. I poured about 4 cups of water in the coffee machine, which steamed out about 2 of the cups and drained the other two through the sugars dissolving and filtering the liquid culture solution. The solution was covered with a metal disc lid with holes and cloth medical tape over the holes. Over that was placed a filter disc. I also dropped my Teflon magnetic stir bar in the quart jar and pressure-cooked the whole thing for 25 minutes. After it cooled, I inoculated with very few spores scraped off a spore print, and thus this liquid culture developed slowly given the minute amount of spores used. I have since seen Goliath Pan Cyans develop from 3ccs of liquid starter culture in only 48 hours, making them faster than cubensis. Below is the progression of the culture:

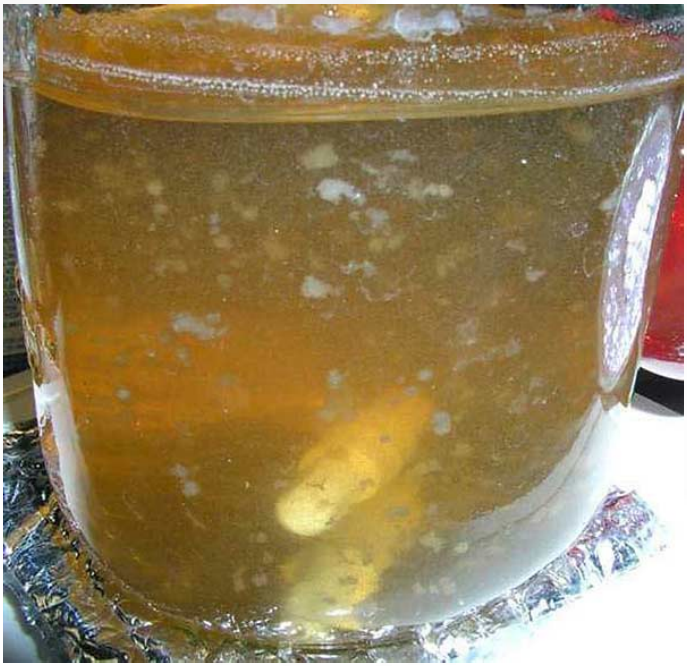
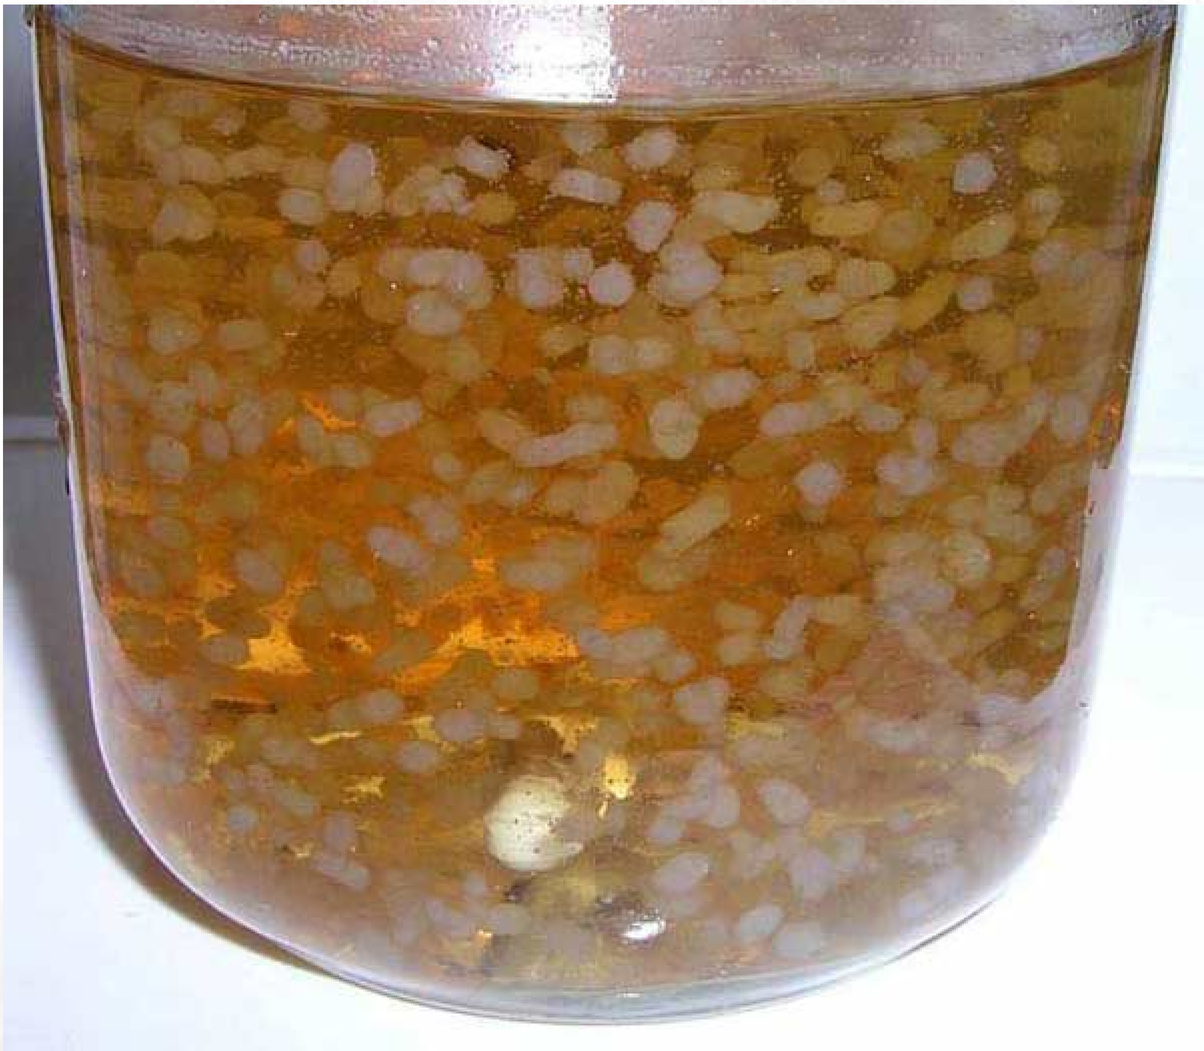
Liquid Culture - Day 3.



Liquid Culture - Day 5.



Liquid Culture - Day 7 (completion). Starting with a few mls of live culture rather than few spores can shorten this stage to around only 48 hours rather than 7 days.

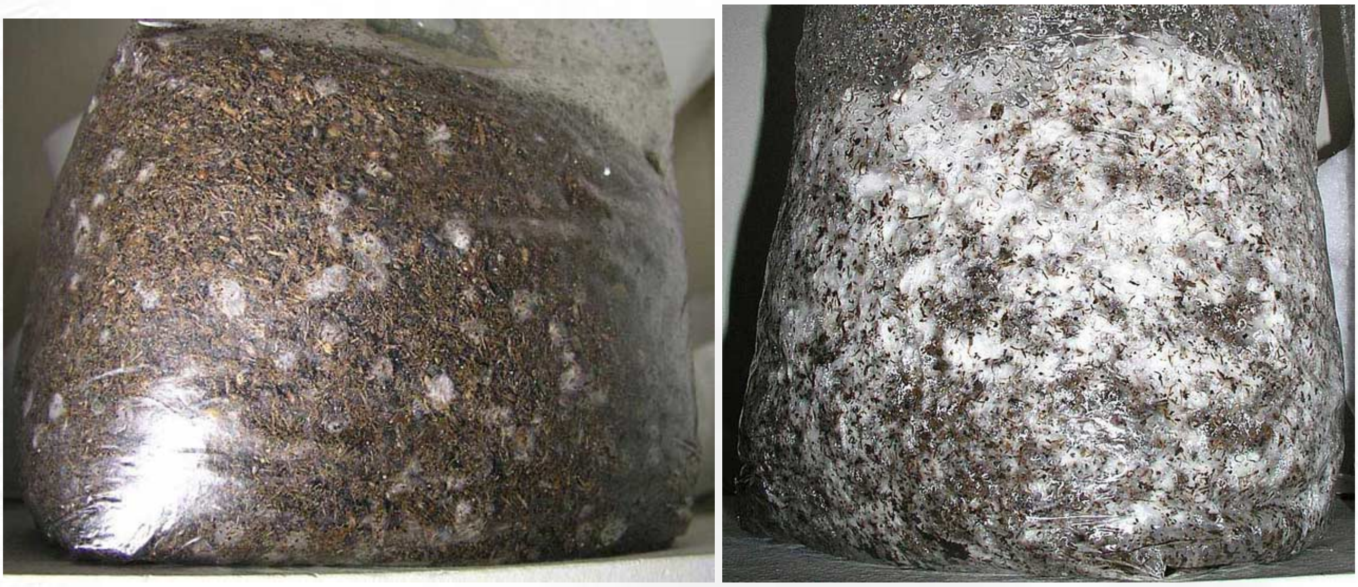
Stage 2 - The Spawn Bags

On the 7th day, the liquid culture was ready for inoculation directly into the fruiting substrate. I use spawn bags to colonize the final fruit out substrate rather than spawn because it's easier and faster. Using a couple or few large spawn bags, one has plenty of room for enough substrate for either small or large bulk grows, so why bother with creating grain spawn? A single large spawn bag holds about one gallon of substrate. In PF terms that about 20 half pins jars of substrate all prepared via a single large liquid culture injection rather than 80 small half pint jar injections.

The fruit out substrate was:

- 6.5 parts Agar's special mushroom compost (via dry weight)
- 2 parts WBS (via dry weight)
- 2 parts rye grass seed (via dry weight)
- 3% Stevia leaf (percentage via volume)
- 0.2% black mustard (percentage via volume)

All was mixed with water to the correct moisture content by feel and then loaded into large spawn bags. The WBS was loaded dry so as to absorb a little moisture during cooking, thus preparing the mix to absorb the liquid culture without getting too wet. I pressure cooked the bags for 4 hours. Once they cooled sufficiently to touch with gloves, I sealed them shut in a dirty bathroom without allowing air in the bag. I then hung the bags up from the top of the plastic in a closet using rubber-footed wood clamps to allow them to cool and draw air in via the filter patch. Once self-inflated and cool, they were removed from the clamps and injected through a tape reinforced area of the bag with 80 ml to 140 ml of liquid culture (I strongly recommend the 140 ml). I immediately sealed the hole with hot glue. Once the hot glue cooled, I kneaded the grains and manure through the plastic to mix in the inoculants and put the bags separated on a shelf to colonize. The bags were remixed one time on the fourth day, but mixing was not needed for the bag that had received the full 140 ml of liquid culture. All bags were well colonized by day 7. Below are pictures of the progression of the bag culture:



Fruiting Substrate Colonizing in Sterile Spawn Bag on Days 2... ...and 7 (completion)

Stage 3 - Laying the trays, Casing, and Casing Incubation

After cutting open the bags, I crumbled up the substrate as required to lay the trays about 2' deep and as evenly as possible. 12-quart dishwash trays are super cheap at Walmart and great for cubensis, but I do NOT recommend 12-quart trays for Pan Cyans. They are far too tall and will encourage air stagnation around the pins. I recommend using a 2' to 4" tall tray of some sort. For example, plant starter trays sold at garden stores would probably work well.

I used the classic 50/50 Tek casing with 10% to 15% coco coir (by volume) added. I laid the casing about 1/3rd inch thick. I do not recommend the addition of coco coir for this mushroom because it will encourage excessive overlay I think which seemed to reduce yields in the Ausi strain. Some folks also don't pH-balance Pan Cyan peat casings. I have no opinion about that as I haven't tried it, but I wouldn't doubt it would work fine. One thing is for certain; do not use hydrated lime for pH-balancing with this mushroom or any other. You are very likely to spike the pH way too high, and while cubensis can take that abuse, this one won't tolerate it. If you can't get pulverized limestone or powder calcium carbonate of some source, just don't use anything.

I put the laid trays in a closet for incubation. I covered the tray with plastic wrap and put a piece of 2" wide masking tape across the center length of the tray over the plastic. With a razor, I cut a slit the entire length of the tape and pulled it apart about 1/4th inch and covered with cloth medical tape. This is to allow some but not excessive gas exchange.

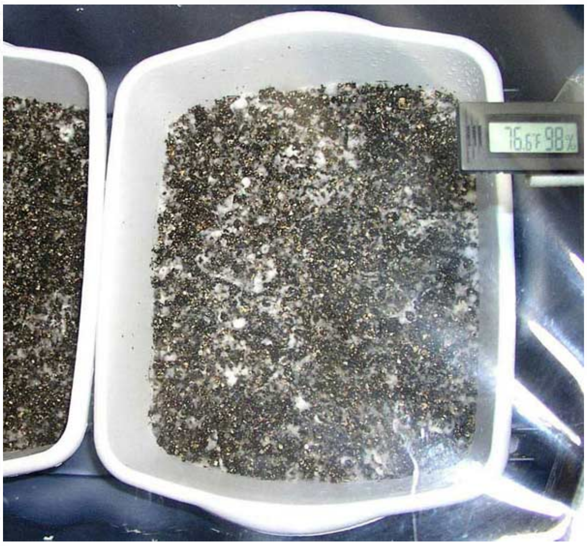
For cubensis with an inch casing, casing incubation is pretty much required, but Pan Cyans can rip through the casing in 24 hours because the casing is so thin. As a result, one can probably skip casing incubation all together with Pan Cyans, but it won't hurt anything. Below is a picture of the tray in the incubation closet. Notice the tray is raised off the shelf to help keep it from overheating. I raised the tray out of habit because with cubensis overheating can be a serious problem, but with Pan Cyans one probably doesn't need to worry about it as the substrate depth is only 2".

24-Hour Casing Incubation.

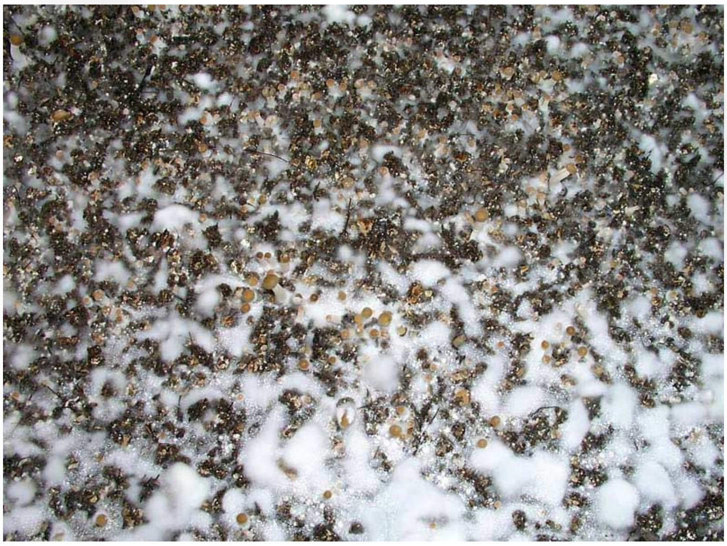
Stage 4 - Fruiting

I incubated the casing for 24 hours and we're off to fruit. At this point, I was only 2 weeks from the ***spore*** injection to the liquid culture, and already I was putting the tray in the fruiting chamber! Now try to beat that! Like I said Pan Cyans are faster than cubensis. Pan Cyans can fruit in the same environment as cubensis with some minor tweaks.

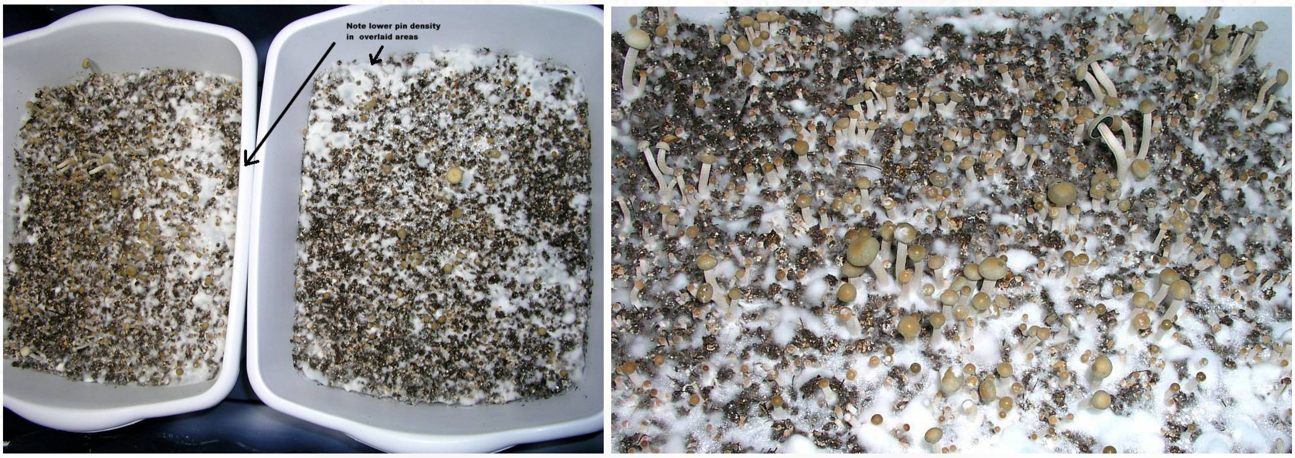
First, you can mist up to the pin formation, but you really must stop watering once the pins start to form. These pins abort easily and misting them will abort them. Once the pins are well set, one should try to reduce the humidity in the chamber to 85% to 95%. Don't allow it to stay up around 100% or else the pins won't mature as they should. Cubensis doesn't seem to mind near 100% humidity all the time--although you risk forming mold in your casing--but these don't like it and you also strongly risk forming mold in the casing. Just crack the lid a little open if you don't have any other way. Fresh air requirements are technically not more than cubensis but they tend to get super tall in high CO2 environments and less stocky. It all depends on what you want. Lastly, keep the chamber a little warmer than cubensis. I recommend 75F to 82F. Below is my fruiting chamber progression.



Day 3 in Fruiting Chamber.

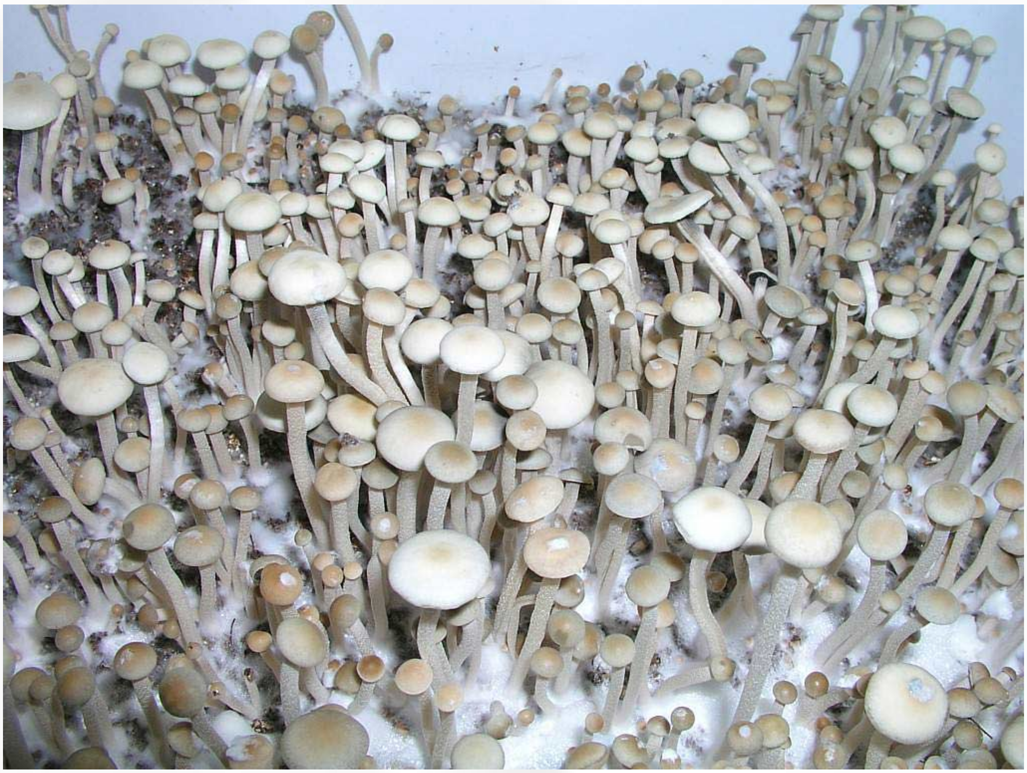


Day 8 in Fruiting Chamber.

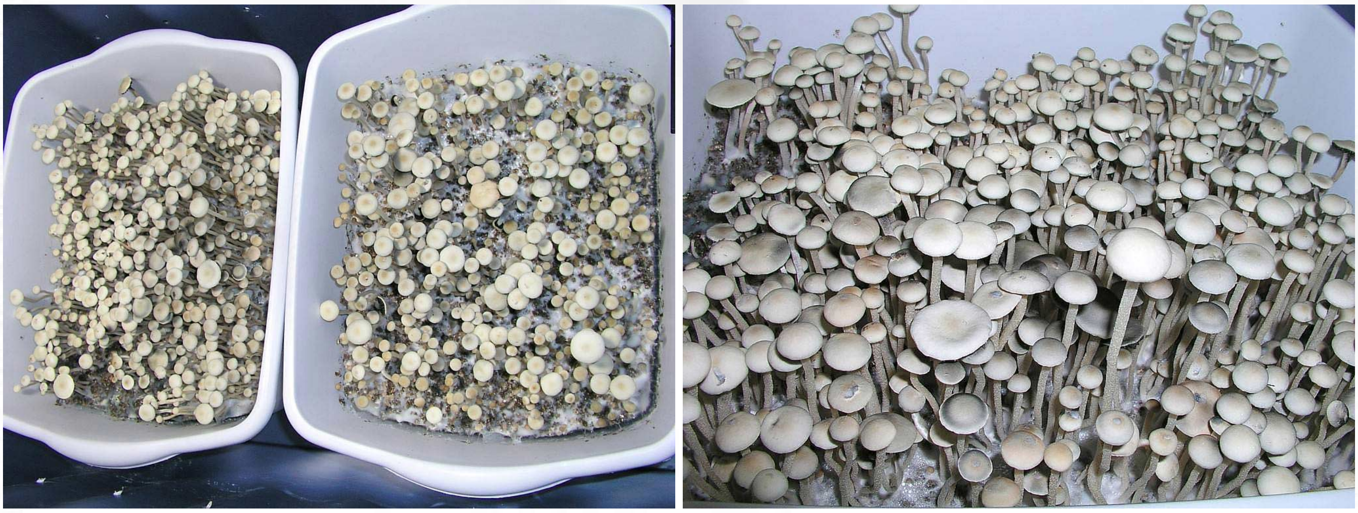


Note lower pin density
in overlaid areas

Day 9 in Fruiting Chamber. (arrows: Note lower pin density in overlaid areas.)



Day 10 in Fruiting Chamber.



Day 11 in Fruiting Chamber and the Harvest Day!

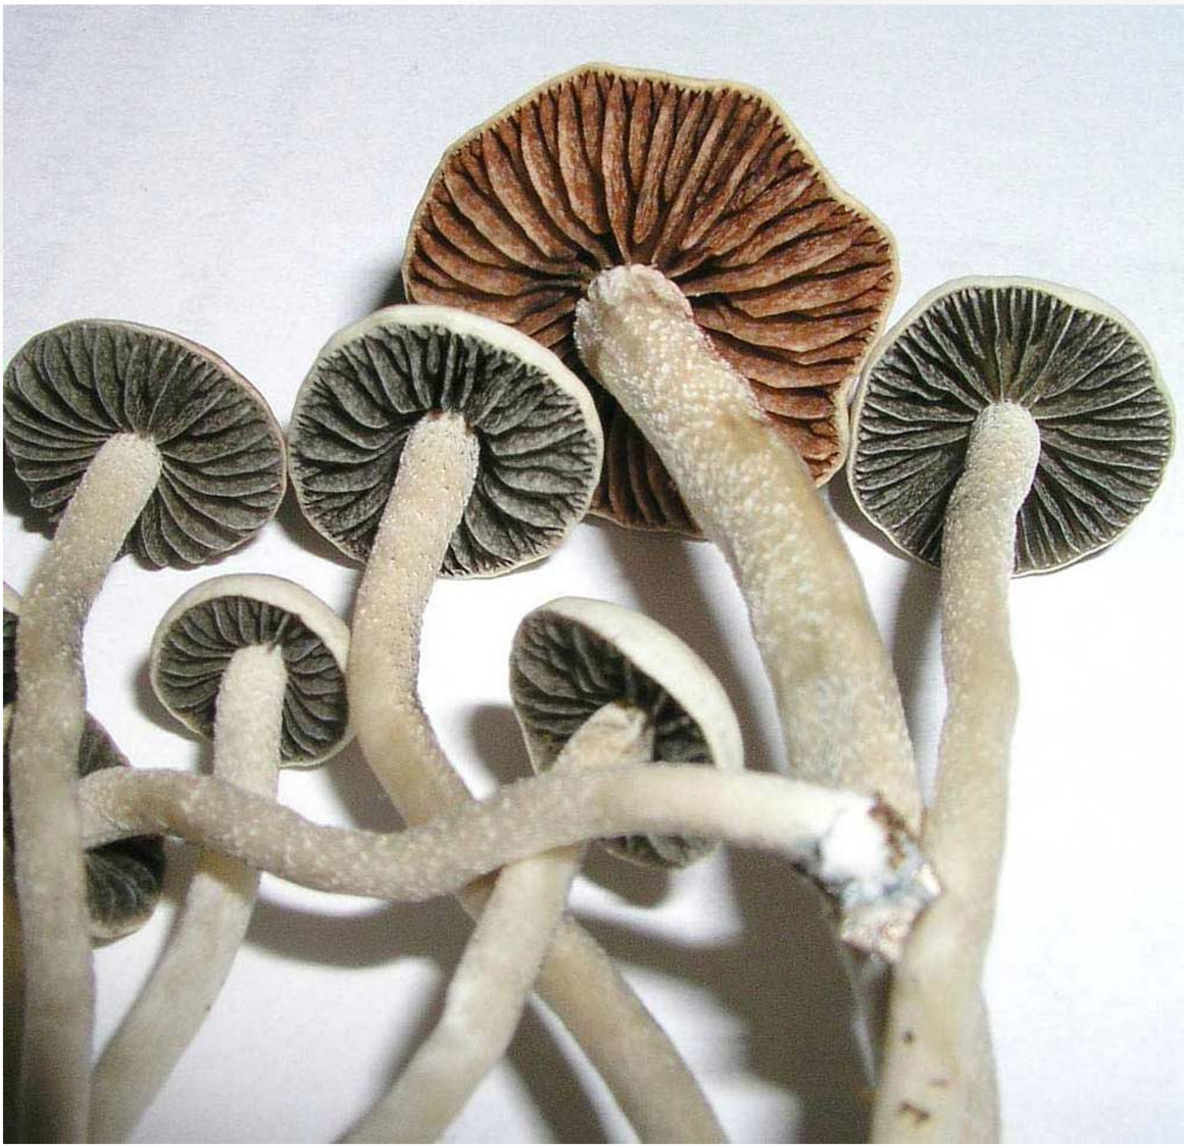
About the Harvest

I pulled that harvest on day 25 since the first spore was injected in the live culture. If I had used a few ml of a live culture to inoculate the live culture, I could have probably pulled the first flush off in 3 weeks! Now that is fast!

Although the pictures show the best trays, the trays did pretty well overall for a first timer. I estimate I harvested about 40% of a perfect first flush potential due to green mold which limited the yield. In fact I lost all of the trays after the first flush to green mold. It was all my fault too because I left town during the time the trays were in the fruiting chamber (that's why days 4 to 7 have no pictures) and the humidity and misting was way too high. The green mold formed on the soggy bottoms of the trays and extended up into the casing. Just don't over mist your trays! The fruits dried to exactly 10% their wet weight.

One thing that delighted me was the variation of this mushroom within the flush. Unlike cubensis, Pan Cyans show tremendous variation within a flush if one uses a multi-spore culture like I did. Some of the fruits were super tall, over 6 inches tall, and others were short (2 inches tall). Some had large caps (size of a quarter) and most had tiny caps (size of a nickel). The only thing that was consistent is that all the fruits were very small compared to cubensis. Indeed a single large third-flush cubensis can yield as much mass as half an entire tray of these!

One thing that really was a treat was the fact that about 1% or 2% of the caps had a light brown spore color while the others were grey. Here are some pictures of that fantastic phenomenon:



WOW! Isn't that beautiful?!?

So, that's all fine and dandy, but how strong are they?

Growing these over regular cubensis provides the grower a way to expand his or her cultivation skills to a new mushroom, but what about potency? Well, I have some firsthand experience to tell you, but first, let me preface this by saying that I am a seasoned cubensis tripper. I had my share of bad trips over the years. I know what it?s like to see both heaven and hell on shrooms, and hell always seems to come more often on stronger doses. I typically take about 3 grams on a cubensis trip, and I grow them strong on manure.

With these I decided to follow the dosage calculator here and take 10 fresh grams (would dry to 1 gram but is as strong as 1.35 grams dried). I was shooting for a level 3 experience. What I got was closer to a level 5 with total destruction of my ego.

I went from starting to see geometric patterns on the ground to tripping so hard that I couldn't even figure out how to put my Ipod's ear buds in my ears in less than 20 minutes! These shot off like a bomb in my brain way faster than anything I've taken, even cubensis tea doesn't hit that fast. I was so screwed up and it happened so fast that I had a massively terrible trip. I didn't know what the hell was going on. I won't go into details here, but let's just say I was heavily delusional in a negative sense and had trouble staying on my feet and not fainting. I am not a religious person, but basically I turned into a crazed religious schizophrenic for about 7 hours straight. The ordeal wore out my sitter--thank God I had one--big time. **I would equate those 10 wet grams to about 4 to 5 dried grams of extremely strong cubensis.**

I do not recommend taking over 1 dried gram until you know what you are dealing with. If you take them wet, you'd better start with no more than about 7 wet grams your first try. Now, I am serious here: these are not light weight mushrooms like cubensis! Like I said, **the batch I grew was at least 4 to 5 times as strong as any cubensis I have ever grown**, and I've grow lots of types on all sorts of stuff. Just be careful with them!

Spawn, Spawning and Spawn Growth

Measuring and Controlling Temperatures during Spawn Growth
Summary

The purpose of this fact sheet is to provide basic information on the process of seeding substrate and the management of the vegetative stage of growing the commercial mushroom, *Agaricus bisporus*. The process before this stage, substrate preparation and the processes after, casing and production, are discussed in other publications.

A mushroom is the fruiting structure of the fungus and consists of a cap and stem. The mycelium is the fine "root" system that grows in the composted substrate adsorbing nutrients and water. After fruiting is initiated and the mushroom matures, the cap opens and gills are exposed. These gills produce spores in huge quantities; for example, a three-inch mushroom produces 40 million spores per hour. In nature, spores germinate and grow very poorly; therefore, another method to seed the mushroom substrate is required. The mushroom mycelium (threadlike filaments that become interwoven) is propagated on a base of steam sterilized cereal grain (usually rye or millet). This cereal grain/mycelium mixture is called spawn. Most spawn is made with mycelium from a stored culture, rather than mycelium whose parent was a spore. This is because each spore is likely to yield a new strain and its performance would be unpredictable. Preparing spawn is highly technical task that is not practical for most mushroom growers to perform; therefore, it is mostly produced by specialized companies that supply growers with pure culture spawn. However, in some cases, it may be necessary for the growers to produce their own spawn. In such cases, access to cultures (cultivars) with proven productivity is a key component of a successful enterprise.

History

Spawn, spawning and spawn growth begin with a little fascinating history. Until the 20th century, mushroom growers used mill-track spawn to seed their substrate. Mill-track spawn was obtained from under the horses driven around a pole to provide power to the flour mills. Spawn from this source had uncertain varietal characteristics and was not free from pest and other competitors. Later "Flake Spawn" was developed. Flake spawn was the mushroom tissue or mycelium transferred to special substrate manure piles. When the spawn had thoroughly grown through this "Manure Spawn" was broken up and spread onto substrate in the house. England was the first to develop this "Manure Spawn" and when the Lambert brothers immigrated from Belgium to Minnesota, they brought the process to America. One brother, L. F. Lambert moved to Chester County Pennsylvania and began producing flat bricks of moist horse and cow manure that were stacked together with bits of mushroom mycelium.

Manure spawn was used worldwide until the 1930's, when a scientific breakthrough occurred in France and later in the United States. Researchers learned how to germinate spores on sterilized media. This procedure, which we all take for granted, allowed pure cultures to be maintained and then eventually used to make "Pure Culture" manure spawn. This spawn was usually made in a bottle that was stoppered with wool plug. The grower had to break the bottle to remove spawn for use. A practice that was probably fun for the kids, but messy and probably unsafe.

The next step in spawn history was "Tobacco Spawn", shredded dry stems of tobacco from Lancaster County, Pennsylvania. Tobacco spawn was more consistent than manure spawn, however the process of using reusable, screw top bottles was labor intensive and tedious. Tobacco spawn was used for about 10 years.

In 1930, Dr. James Sinden was assigned to the mushroom research project at Penn State. He needed a more consistent method of inoculating substrate for his research. He developed a method using sterilized grain inoculated with pure cultures of the mushroom mycelium. At first spawn, makers resisted its adoption, but by WWII grain spawn prevailed in the US. After 1950, it was introduced into Europe along with the process of thorough mixing of spawn into substrate, which was developed by Ms. Hauser and Dr. Sinden. Until 1926, cream-colored mushrooms were the only strains grown commercially. It was Chester County grower, named Downing that found a cluster of white mushrooms and realized its significance. He called L. F. Lambert from whom he had bought the spawn, who then made spawn from tissue cultures that grew only white mushrooms, hence the birth of the white strains.

Culture Maintenance

Maintenance of pure mycelial cultures is a necessity fo ultimate spawn preparation and spawn production. Once a culture is obtained, it is advisable to take note of the appearance of the mycelium, to observe the normal growth patterns of the specific lines. These observations are important to do, so that one will be aware of even the subtlest change that may lead to deleterious effects.

A desirable mycelial culture is one that is pure, free of contaminants and of sectoring of other abnormalities. Contaminants include other fungi, bacteria, or insects growing on or infesting the culture media along with the desired mycelial culture. When a culture is first obtained, by whatever means, it should be transferred several times to fresh media, to observe for any from of contamination.

Sectoring is any type of mycelial growth that differs in appearance, growth rate, color, or otherwise from the typical appearance of a given strain. Sectoring is often observed as a more rapidly growing area near the leading edge of growth, exhibiting a different growth habit from the rest of the culture. Other abnormalities that might appear in a culture are fluffy, aerial mycelium, thick or rubbery textures, of color changes such as browning or darkening of the mycelium. Sectors of other change in vegetative growth could affect the productivity of the culture. Therefore, it is very important to recognize and avoid propagation of abnormal mycelium to agar and further spawn production.

Cryogenic Storage

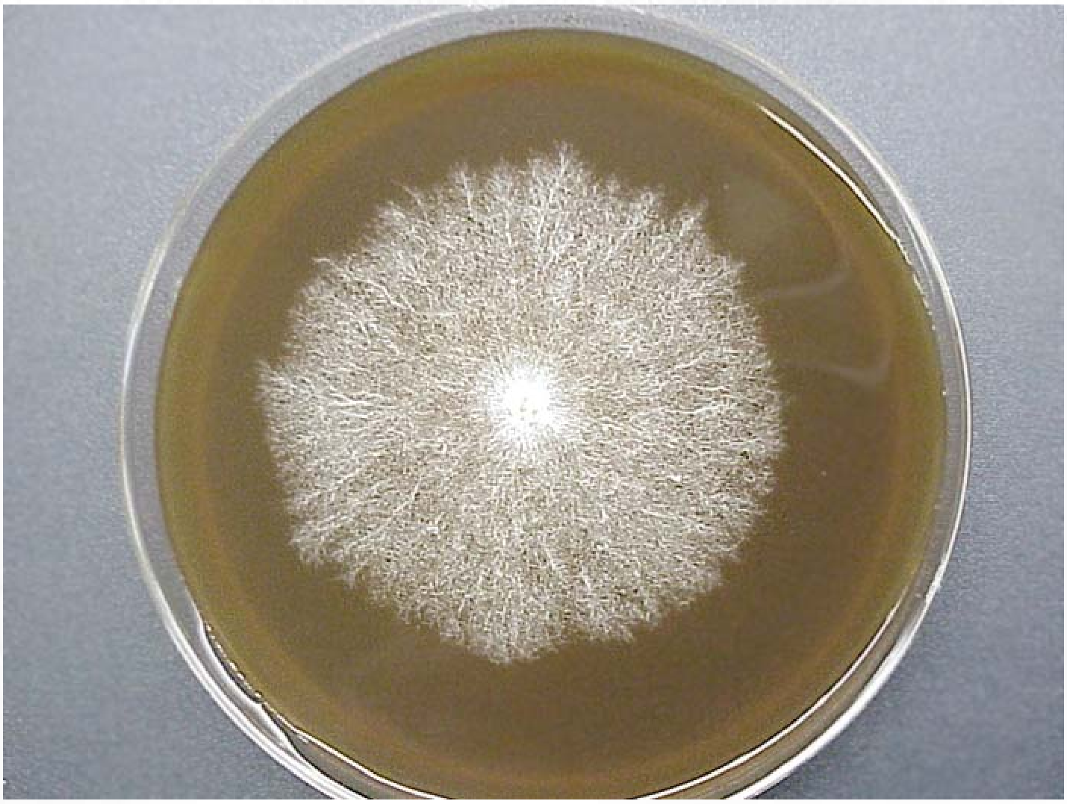
Storage of cultures in liquid nitrogen (LN2) is superior but expensive. It is the best long term culture storage method because mycelial growth is completely suspended at -196C. This method maintains a very stable mother culture for many years. Only the highest quality mycelial cultures are selected for long term storage - a culture's qualities will not improve with storage. Unfortunately it is also the most expensive. Initial equipment costs are high and liquid nitrogen is a continual monthly expense. The liquid nitrogen storage unit requires constant monitoring of the liquid nitrogen level in the chamber. The basic method is to fill a cryotube (special plastic tube designed for use in LN2) with a cryoprotectant and then to submerge a few mycelial plugs or spawn grains into the liquid. Then the filled cryotube is placed in a divided box or cane, then into rack and finally housed in the cryostorage unit. The purpose of the cryoprotectant it to protect the mushroom cells from damage during the freezing and thawing cycles.

Obtaining A Culture

Methods of obtaining a culture are: tissue culture, spore germination, or purchase of culture from a culture collection.

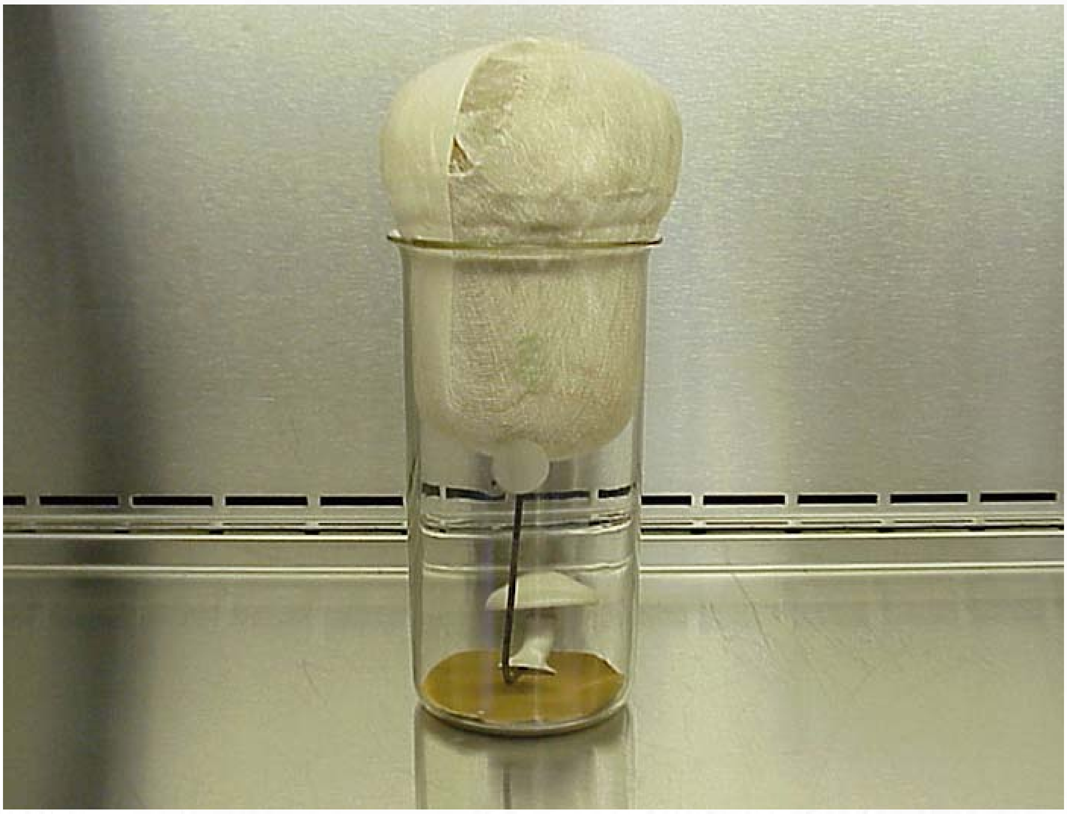
Tissue Cultures

Tissue cultures are the simplest way to obtain a mycelial culture. A tissue culture is essentially a clone of a mushroom. Clone is defined as an identical duplicate of an organism. The basic procedure is to sterilely remove a piece of the mushroom cap or stem, and place it on an agar plate. After a week to ten days, mycelium grows from the tissue and colonizes the agar. Great care should be taken to select a fruiting body of the highest quality, size, color, shape or any highly desired characteristic.



Spore Cultures

Mushroom spores are found on basidia lining the gills of the cap. To collect the spore, the cap is hung over sterile filter paper in a spore collecting chamber. Spore cultures differ genetically from tissue cultures. Cultures originating from spore germination are unpredictable. Spores germinate creating many different genetic combinations that are desirable when attempting to develop new strains, but undesirable when trying to maintain a specific strain. There is no way to predict if a culture's fruiting potential is similar to its parent other that to test many different lines obtained from spore germinations. Hundreds many be tested before obtaining a culture with good production potential.



Culture Validation Cropping Trials

There is no in-vitro test to determine a stock culture's validity. A series of cropping trials must be conducted on the mycelial stock culture to determine a culture line's value. Mushroom yield, size, color, cap shape and any other desired quality or growth factors are selected and then compared for each culture line.

Sub Culturing (agar to agar transfer)

Once a culture is obtained by whatever means, it needs to be maintained to preserve its viability. Agar to agar transfer (sub culturing) it the most popular culture maintenance method. Vegetative propagation of a mushroom culture is uncomplicated, but labor intensive. A small amount of mycelium from a mother culture is used to innoculate multiple fresh agar slants (these become the daughter cultures). The daughter cultures, after incubation at room temperature ~74F for 2 weeks. Are visibly screened for traits expressed in the mother culture. Then, one elected culture becomes the "new" mother culture. The new mother culture is stored in a refrigerator incubator at ~5C. After two months this culture is taken from refrigerator incubation and further transferred to freshly prepared agar slants repeating the cycle.

Spawn Production

The process of making spawn remains much the same as what Dr. Sinden first developed. The grain is mixed with a little calcium carbonate, then cooked, sterilized and the cooled. Small pieces of pure culture mycelium are placed in small batches of the grain. Once the small batch is fully colonized, it is used to further inoculate several larger batches of grain. This multiplying of the inoculated grain continues until the commercial size containers, usually a plastic bag with a breathable filter patch, are inoculated. During the colonization of each batch the containers are shaken every few days to further distribute the mycelium around. Temperatures are maintained where the mycelium is growing in a range of 75-76F . Uniformity of the air circulating around the bags is important to insure that all containers are keep at the desired temperature range. The mycelium is sensitive and its fruiting mechanism can be easily damaged at high temperatures.

Spawning

Before the spawning operation, attempts may be made to improve the substrate moisture. Sometimes water is applied or an pesticide application may be made. Farms with a historical problem of mummy disease may avoid water applications at spawning, because the free water improves conditions for the bacteria to reproduce and spread, thereby increasing the incidence of this disease. On bed farms spawn and supplement is broadcast over the surface of the substrate. Uniformity of the distribution is critical to achieve an even distribution and more even spawn growth and temperatures. On tray or bulk farms, spawn is usually metered into the substrate during the mixing operation. Some growers will bring the spawn brought to room temperature before mixing it into the substrate. Gypsum (1-2% of substrate dry wt.) can be added if substrate that is wet, little greasy and/or not completely conditioned.

Historically, three methods of spawning have been used. However, on most commercial farms the "Through Mixing" method prevails. "Broadcast" and "Ruffling In" spawning were the other two methods. Broadcast spawning consisted of covering the substrate surface with spawn. Whereas "Ruffling In" included the scratching the spawn into the top few inches of substrate.

"Through Mixing" spawning has many advantages over the other methods. Research has shown there are increases in yield. Because the mycelium does not have to grow far to colonize substrate, it reduces spawn-growing time, which is important because spawned substrate is exposed to various types of infection. Another advantage is that spawn grains act as supplemental nutrients for the mushroom mycelium. With through mixing spawning it is important that substrate must be cooled throughout the bed before spawning.

Spawning is the cleanest operation performed on a mushroom farm. All equipment, baskets, tools, etc. should be thoroughly cleaned and disinfected before spawning. Normally it is the first operation of the day when personnel have not been into any of the older houses. After spawning, the beds should be covered with plastic to protect the freshly spawned substrate from air borne contaminants and pest. Unfortunately, for any contaminants present before covering, the moist environment provides ideal conditions for germination and growth. Plastic sheeting is sometimes used to cover the substrate to help maintain substrate moisture.

How Much Spawn?

The amount of spawn used depends on the crop cycle and cost. The spawning rate can be expressed as a unit or quart per so many square feet of bed surface; 1 unit (~ 1 lb or 1 liter) per 6-8 ft. is considered a standard rate on a commercial farm. The rate is sometimes expressed based on spawn weight versus substrate weight; therefore, 2-3 percent spawning rate is equivalent rate. A low spawning rate is about 1 unit for every 12-15 sq. ft. (1-2% Dry Weight), whereas a high rate about 1 unit for every 4-5 sq. ft (>3% of Compost Dry Weight). The more spawn used the better, since it is a cheap supplement, increasing overall production; and the more initial growing points will provide a quicker and more efficient use of substrate nutrients. Both of these factors will improve the colonization of substrate, which also helps insure the mushroom will grow quicker than other fungal competitors. Furthermore, as the spawn rate is increased, more heat is generated and the heat surge occurs earlier during spawn growing period.

Spawn Growth

During the colonization of the substrate by the spawn (spawn run) is a good time to evaluate the crop and substrate. Spawn growth and the presence or absence of other molds helps to indicate how the substrate preparation process has been carried out. Problems with substrate formulation or process and Phase II composting or conditioning may first develop during the spawn-growing period. Weed and indicators molds may tell the grower how the composting process went and what nutrient was lacking or in excess. These molds may grow on compounds that have not been used by the microbes during the Phase II will often suggest a problem occurred.

Although the type of spawn growth depends on many factors, often it may user posted image indicate the nutritional and moisture level of the substrate. The spawn strain itself will vary in their inherent capacity for rapid or slow growth. This variation is a genetic characteristic; therefore, growers should be familiar with the characteristics of the different strains and the suppliers of spawn are a good source of this information. The other obvious important factor that determines the type of spawn growth is the substrate. Substrate element analysis is important but does not always correlate with growth or yield but should be monitored to determine trends in substrate preparation. The lab analysis should be used as guidelines and establishing trends from crop to crop. There is a direct correlation between substrate ammonia content and subsequent growth and yield of mushrooms. Substrate should have less that 0.05% ammonia, dry weight, at spawning time. By smelling, most growers can detect 0.1% ammonia levels, which will restrict spawn growth. Ammonia content above 0.2% will kill spawn. The substrate pH has little to no correlation to spawn growth or yield. Spawn can tolerate a pH in the range of 6.5 to 8.2 and normally it will decreases from 7.5 to 6.0 during cropping. When the substrate nitrogen content is analyzed at this time, it should be in a range of 2.0 - 2.5% on a dry weight basis. A positive correlation of substrate nitrogen and yield has been shown. The greater the nitrogen content, with no ammonia, the better the yield. Nitrogen content has no correlation with spawn growth, since rapid spawn growth has been observed in both high and low nitrogen composts. However, generally a high nitrogen substrate has a slower spawn growth, but fills out and becomes denser. The lipid (fats/oils) content of the substrate will influence both the rate and quantity of spawn growth. More nutritional substrate will support slower and finer texture spawn growth. It is suspected that the thinner strands of spawn are slowly adsorbing nutrients. In less nutritional substrate, spawn growth is more rapid and white with more rhizomorphs, suggesting the spawn is seeking nutrients.

Ideal substrate moisture at spawning varies according to the type of substrate. With horse manure substrate, moisture of 65-72% is normal. With synthetic composts a moisture range of 65-75% is normal. However, there are exceptions to these ranges where spawn growth and yield are better outside these ranges. Mushroom size and quality is affected directly by dry substrate, where dry substrate will produce smaller, off-color mushrooms.

Ventilation and environmental requirements for substrate are not well understood. It is assumed that little oxygen is required within the substrate. Carbon dioxide levels are kept high within the room or at least under the plastic that is used to cover the substrate after spawning. It is known that there is an increased spawn growth rate with increasing CO2 levels to 10,000 ppm. The desired relative humidity is 95% or more in order to preserve substrate moisture. Relative humidity within the room can be maintained by watering the walls and floors. Some high-pressure misting systems have been developed, but they are expensive to purchase and maintain. Steam can also be used to maintain humidity, however it is a source of heat and would increase energy cost and put more demands on the air conditioning system.

During the spawn-growing period, little outside ventilation is used, unless outside air is used as a supplemental source of cooling. During the warmer months outside air is not used, and the room air is re-circulated through the air conditioning units to be cooled. The higher humidity of the outside air requires more cooling capacity.

Substrate and Spawn Growth Management after Spawning

Substrate may lose about 5 F during spawning. During the summer, substrate may be warmer before spawn and therefore it is important to bring substrate temperature down to optimum temperature within 12-18 hrs after the spawning operation is completed. The mycelium within grain is slightly insulated; and this mycelium can survive in 90 F plus temperatures for a short time. However, with unfinished substrate it is usually better to be cooler than warmer when spawning, insuring the substrate temperature is brought down below the temperature range for mesophilic mold growth (> 85 F). The optimum spawn growth temperature is 75-76 F, however there is some indication that growth is faster at 73-75 F. Growers normally run substrate bed temperatures in the high 70's but most try not to exceed 80 F. At that temperature or higher the spawn growth becomes restricted and permanent damage to fruiting mechanism may occur. Spawn is killed at about 104 F.

Spawn growing temperatures should be maintained at a steady level. It is important to anticipate heat surges in substrate temperatures. Heat surges may occur early if the substrate is not conditioned properly. Spawn heat surges later in the growing period are a result of the spawn growth and dependent on the spawn and supplement type and rate. The initial first few days substrate activity should be minimal, unless substrate is unfinished and mesophilic microbes become active of the left over food. As tips of the spawn begin to contact each other and then fuse together (anastomose) more metabolic activity occurs. As the metabolic activity increases, more CO2, water vapor, other gases, and heat are produced. Gradually substrate temperature output will increase 6-9 days after spawning. Growers anticipate a heat surge at this time and will lower air temperatures before this heating occurs.

The removal of metabolic heat from the substrate involves conduction and other methods of heat transfer. Conduction is heat transfer by contact, like a touching a spoon in hot soup; eventually one feels the heat of the soup through the spoon. Metabolic heat is moves from one solid particle to another or water molecule to another. Therefore, tightly packed substrate with good moisture will help remove the heat from the substrate. Dense beds, less air spaces, its is easier for heat to be transfer to the surface and then removed. Loose, fluffy substrate is a harder to control more air spaces where heat transfer is slower. When the heat reaches the surface of the substrate heat it is removed by evaporative cooling and convection, heat transfer by circulation of currents from one region to another. Cooler air moving across the surface of the substrate removes the heat from the substrate. Evaporative cooling is the removal of heat when liquid phase turns to gas phase and occurs when dry air moves across the surface substrate moisture is lost and heat removed with it. Too much evaporative cooling is not good, since substrate will tend to dry out too much.

Measuring and Controlling Temperatures during Spawn Growth

The methods used to monitor and control temperatures vary at each farm. The quantity of thermometers used for a room may vary. One may use glass, dial thermometers, or use remote sensing thermocouples with computer control. At least two thermometers are usually placed into the substrate in most mushroom houses, and these are left in the same location throughout the entire spawn-running period.

Several factors should be considered when determining how to and how often one should monitor substrate temperatures. The cooling and volume capacity of the air handling units, substrate nutrition and dry weight are several factors that will determine how easily the spawn temperatures can be controlled during its most active period. At the beginning of spawn growth, when the substrate temperature is uniform, thermometers are usually left in the same location. One should monitor substrate temperature twice a day and during the accelerated spawn-growing period, more often is advisable.

These stationary thermometers are used to represent the range of temperatures encountered in all areas of a room. Probing of the substrate temperatures should be done to insure that the stationary thermometers represent that area of the substrate or room and provide another tool to monitor and control the crop temperatures. Most growers invest time every few days, if not daily, to probe all areas within each house, both upstairs and down, to monitor differences and changes in temperatures. Hand-held rapid response thermometers are inserted into as many spots of compost as possible to monitor temperatures. This probing determines the range of temperature within the substrate and areas of the room. However, it is important to have personnel available to spend the time probing the room. Probing can be done by any trained and culturally clean individual, not necessarily a grower. More uniformity in the substrate's moisture, nutrition and dry weight will reduce the need for extensive comprehensive probing. When the grower has enough experience about how the crop will react and can anticipate when and how much of a heat surge may occur, less probing may be required. After spawning, before the spawn heat surge, during heat surge and before casing are the most critical times to probe.

Probing and or stationary thermometer temperatures are usually averaged into a mean temperature for the room. This average substrate temperature is used to make decisions for raising or lowering the air temperature. Decisions on whether to lower the air temperature or to raise it should be based on both the average substrate temperature and the frequency or distribution of higher temperatures. If the majority of spots are a bit warm then air temperature should be lowered a degree or two. Conversely, if the majority of areas are a bit cool 68 - 72 F, either the air temperature or the volume of air should be decreased since both of these factors can affect the substrate temperature.

The varying air volume during spawn growing to control substrate temperature may be a new consideration for some mushroom growers. The use of air temperature to control substrate temperature is normally how substrate temperatures are controlled. By lowering the air temperature, the substrate temperature is decreased. It may also be obvious that the more air moved through a house, the greater the amount of heat removed from the air in the house and, indirectly, the substrate. If the air is dry, substrate moisture will evaporate and evaporation is a form of cooling. The greater air volume moving through a house and the drier that air, the greater the cooling effect on the substrate.

Substrate temperature control is also dependent of the cooling capacity of the air handling system. Most single-zone bed farms design their air conditioning systems on the requirements during spawn run. Tons of cooling that is required to maintain temperatures range from 2 to 5 tons per 1,000 sq. ft. of growing space. Cooling capacity is also dependent on the location of the farm and weather conditions. Cooling for spawn growth also depends on the air volume, movement and distribution within the room. Substrate density also determines to amount of cooling required, the more substrate dry weight the more cooling that is needed. The condition of the substrate will affect the amount of heating that occurs the first few days of spawn growth. When substrate is not conditioned well, other microbes have food to use and will tend to grow and produce a heat surge early is the spawn growing period. Substrate moisture also affects the temperature control during spawn run. The drier substrate the harder it is for the heat to be removed and substrate will tend to heat more rapidly and for longer time. While wetter substrate has less air in the pore spaces, and heat is conducted more easily, making substrate temperatures easier to control. When hot spots are found the plastic covering the bed should be removed. In addition, additional fans may be directed on the hot spots or one may dig a hole in the substrate and allow the heat to escape.

The spawn-growing period is normally 10-18 days. Longer spawn run times can reduce yield and substrate moisture, thus influencing fresh quality. A short growing time will create more heat production during the time after casing. This additional heat will require more cooling and increase the drying of the casing. The cooler air temperatures will slow the spawn growth into the casing, delaying the flush and first harvest. Spawn growing period is considered complete when the spawn has completely colonized the substrate and the metabolic heat surge is subsiding.

Summary

Important points to remember about spawning include the complete and thorough mixing of spawn into substrate. Spawn is a cheap nutrient supplement, therefore if economical; a high spawning rate is desirable. Spawning should be the cleanest operation the farm, often performed early in the workday. During the spawn run, it is a good time to evaluate the crop and substrate. Spawn growth and the presence or absence of other molds helps to indicate how the composting process has been performed. It is important to anticipate temperatures by monitoring temperatures often and by probing establishing crop variation and trends.

Spore printing pictorial

by

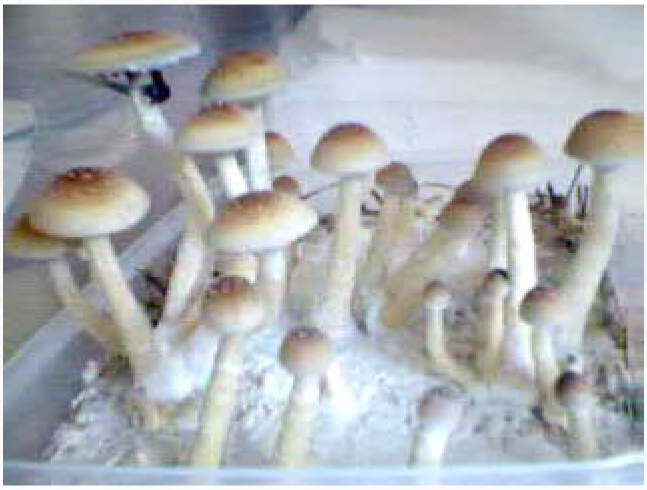
Shirley Knott

original source: http://www.shroomery.org/8404/Spore-printing-pictorial

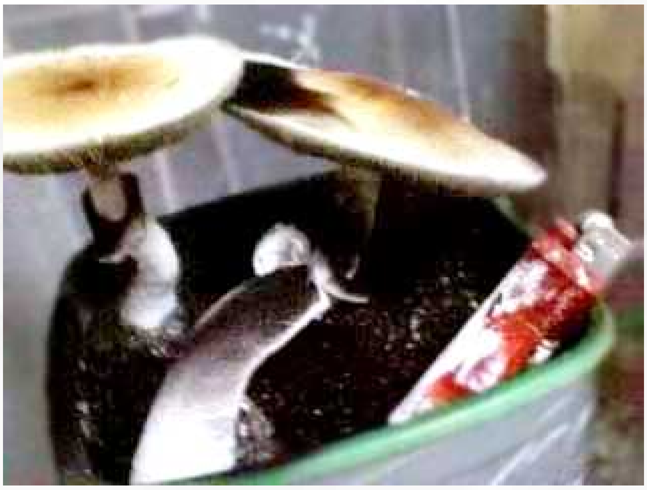
1. Get your stuff together:

- you'll need some foil,
- some rubbing alcohol (medical sterets work very well),
- a sterile blade,
- some thumbtacks with mini-handles,
- drinking glasses,
- a tray,
- two freshly laundered teatowels,
- and some ripe mushies, of course.

The mushrooms should have popped their veils, and formed a nice open cap that is nearly flat. it's best if you wait for the right time before printing, maybe another day or two past prime picking time.



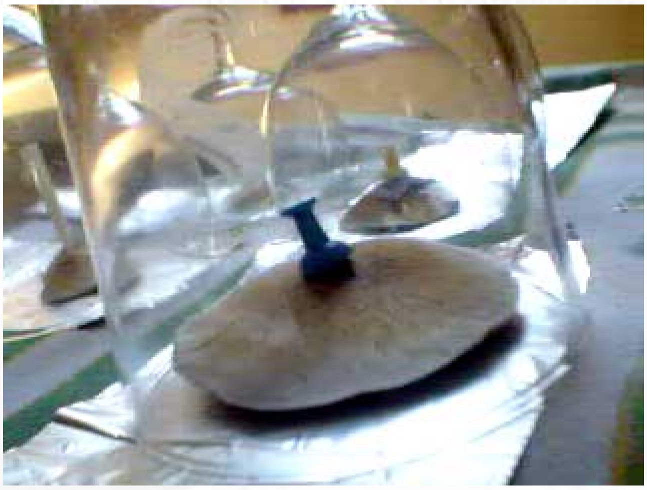
these are nearly ready



while these are probably a little late!
spores everywhere!

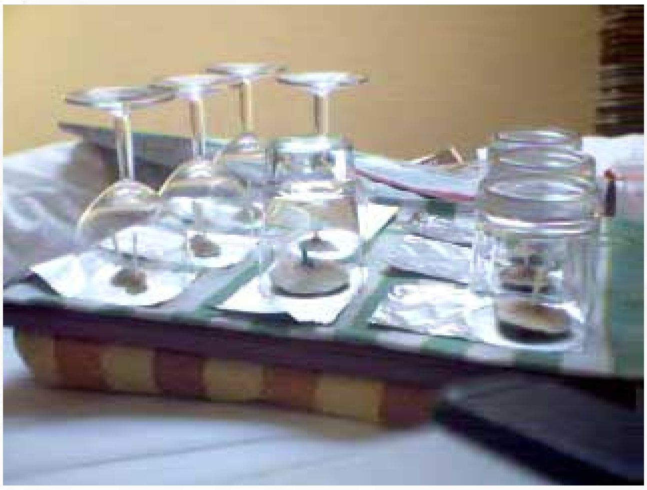
2. Clean your hands and wear a mask if you have one. lay one folded teatowel on the tray. Cut the foil into pieces maybe 15 x 8 cm. fold the foil pieces in half, then open then back up again (easier to fold later).
Swab them with alcohol. Swab the rims of some drinking glasses and put them on the foil. Don't put them on the fold, put them on one side of the fold only.

3. Now you're ready for action: clean your hands again, and open the terrarium lid. Choose your mushroom - one that has opened right up, and preferably has some purple spore dust on the stem, so you know it's already dropping. stick the pin in the middle of the cap. Holding the pin, cut off the cap as high up as you can with the sterile blade. Place cap gills-down on the foil, lifting glass briefly to do so. don't touch it with your fingers, they're filthy!



4. Position the glass carefully: make sure it does not completely seal the spore-dropping zone, so humidity can escape from a gap at the edge of the rim. either this, or make sure the foil is entirely enclosed within the glass: in at least one spot, the glass needs to rest on the teatowel, rather than creating an airtight seal (see on the right, in the pic above). The cap needs to be able to lose humidity slowly. As the cap dries, it sheds spores easier, like in nature. Otherwise the glass gets all sweaty and steamed up, and the spores just get stuck on the gills: Idoubt that many spores blow away on foggy days.

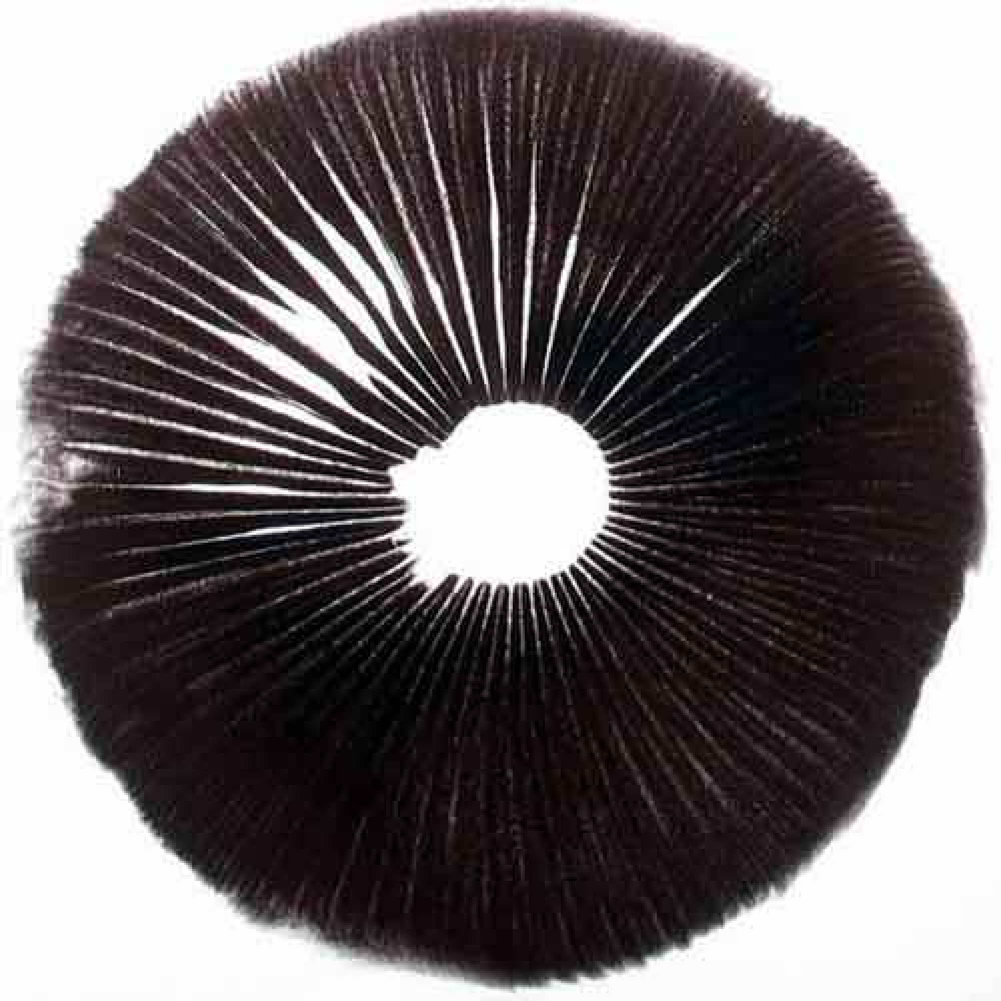
5. Repeat with the next mushroom, until the tray is full. Now cover the whole deal with the other clean teatowel, and put it out of harm's way in a dark cool drawer for a while, 12 - 24 hours.



6. When your chosen time is up (don't be mean, give them at least 12 hours), take out the tray and remove the top teatowel. If you look carefully through the glass, you should see a print laid down, where the edges of the cap have curled up as it dried.
Carefully remove glasses one by one, lifting out the cap and reswabbing the other foil-half and any sticking-out corners before folding over back along preformed fold. Now fold over two of the other three edges to form an envelope, with three closed sides and one open one. the caps can still be dried for consumption, or eaten on the spot if you're hungry!

Sorry, i haven't got a pic of the print - you want to get this covered asap, as any crap from the air that lands in the print (during photography, for example!) can spoil it. if these prints are for microscopy purposes, you want to keep them pristine. or if like me, you live somewhere that growing is legal, you'll be better off with a clean print as well. imagine if a contam spore landed in your print - you'd end up growing it!

Still, here is a picture of a print prepared on typing paper:



7. finally, give them a day in a sealed desiccant chamber for the print to dry before folding the fourth side and bagging the foil squares up individually. You wouldn't want the print to go mouldy after all that work! Here's an example of a desiccator chamber, without its lid:

FastFred's Media Cookbook

by

FastFred & ChesterKarma

(v0.97)

original source: http://www.shroomery.org/forums/showflat.php/Number/3077006

Table of Contents:

Section A. Classic Favorite Recipes
Potato Dextrose Agar (PDA)(FDA M127)
Potato Dextrose Yeast (PDY)
Malt Extract Agar (3%)(MEA)(General Microbiology)(FDA M93)
Malt Extract Agar with Yeast (2%)(MEAY)
Sabouraud's Dextrose Broth and Agar (SabDex)(FDA M133)

Section B. Special Blends
"Karo Water" (Corn Syrup Broth)
"Dextrose Tek" Liquid Media (Corn Sugar Broth)
Honey Water (Mycotopia Honey Tek)
Malt-Yeast-Peptone Agar (McKenna's MYP)
Malt Yeast Peptone Agar (Stamets MYP)
Grey Cardboard (instead of agar)
Oatmeal Flake Agar
Moonflower's Rice Malt-Alfalfa-Brewer's Yeast Agar
MycoPsycho's Liquid Mycelial Culture Broth
Ragadinks Liquid Medium
Amaranth Soy Agar
EntheoGenesis No.442

Section C: Food Based Recipes and Variations
Corn Meal Agar (CMA)
Cornmeal Dextrose Agar
Potato Flake Agar
Potato Starch Agar
Potato Flake Agar with Yeast
Potato-Carrot Agar
Barley Flour Malt Extract Agar
Barley Flour Modified Sabouraud's
Oatmeal Agar (OA)
Oatmeal Agar A
Oatmeal Agar B
V-8 Oatmeal Agar
V8 Medium
Bean Agar
Faba Bean Dextrose Agar (FDA)
Pea Agar
Cabbage Agar
Dr. Pollock's Modified [Dog Food] Agar

Section D. Other Media and Alternate Formulations
Potato-Glucose Agar 1

Section F. Sources

Section A. Classic Favorite Recipes

Potato Dextrose Agar (PDA)(FDA M127)

200 g Potato infusion [dilute to 1L total, ~4g solids]
20 g Dextrose
20 g Agar
1 L Distilled water (dH2O)

To prepare potato infusion, boil 200 g scrubbed, sliced(unpeeled) potatoes in 1 liter distilled water for 30 min. Filter through cheesecloth, saving effluent, which is potato infusion (or use commercial dehydrated form). Mix in other ingredients and boil to dissolve. [Dilute to obtain 1 L final volume] Autoclave 15 min at 121°C. Dispense 20-25 ml portions into sterile 15 x 100 mm Petri dishes. Final pH, 5.6 ± 0.2.

Medium should not be re-melted more than once. Medium powder is available commercially but may require supplementing with extra agar to a final concentration of 20 g/liter. To BBL or Difco dehydrated medium, add 5 g of agar.

The broth is clear to slightly opalescent and yellowish in color.[1, 2]

Potato Dextrose Yeast (PDY)

200 g Potato, infusion from [dilute to 1L total]
20 g Dextrose
2 g Yeast extract

20 g Agar
1 L Distilled water (dH2O)

Gently boil for ten minutes or until the solution is clear.
Autoclave 15 min at 121°C.[13]

Malt Extract Agar (3%)(MEA)(General Microbiology)(FDA M93)

30 g Malt extract
20 g Agar
1 L Distilled water

Boil to dissolve ingredients. Avoid overheating, which causes softening of agar and darkening of medium color. Autoclave 15 min at 121°C. Dispense 20-25 ml into sterile 15 x 100 mm Petri dishes. Final pH, 5.5 ± 0.2.

This medium is recommended as a general maintenance medium.[1]

Malt Extract Agar with Yeast (2%)(MEAY)

20 g extra light malt extract
2 g yeast
15-20 g agar
1 L water[10]

Sabouraud's Dextrose Broth and Agar (SabDex)(FDA M133)

40 g Dextrose
10 g Polypeptone or neopeptone
1 L Distilled water

Dissolve completely and dispense 40 ml portions into screw-cap bottles. Final pH, 5.8. Autoclave 15 min at 118-121°C. Do not exceed 121°C.

For Sabouraud's dextrose agar, prepare broth as above and add 15-20 g agar, depending on gel strength desired. Final pH, 5.6 ± 0.2. Dispense into tubes for slants and bottles or flasks for pouring plates. Autoclave 15 min at 118-121°C.[1]

Sabouraud Dextrose (SabDex) Agar is used for the isolation, cultivation, and maintenance of saprophytic and pathogenic yeasts and fungi.

SabDex Agar is an excellent substitute for Malt or Potato Dextrose Agar, when used by mushroom cultivators to propagate mushroom mycelium.

Sabouraud Dextrose Agar was described by Sabouraud in 1892 and was used for the identification of fungi based on their morphological characteristics. Sabouraud Dextrose Agar is a standard medium used to support the growth of yeasts and molds. It supplies peptone as the protein source and dextrose as the carbohydrate source for nourishment. Bacterial suppression occurs due to the low pH. This media is especially suited for the primary isolation of fungi from normally sterile sites such as cerebrospinal fluid (CSF).

Later, Emmons modified the medium by decreasing the dextrose content and adjusting the pH closer to the neutral range. This modification enhances sporulation and is particularly useful for the subculture of fungi that so not develop fruiting structures on other media, and so is useful in their identification. It also serves as a good holding medium for stock cultures.[3]

Section B. Special Blends

"Karo Water" (Corn Syrup Broth)

1 Teaspoon Light Corn Syrup (Karo Syrup or store brand Light Corn Syrup)
100 ml Purified Water

Mix well until dissolved, sterilize for 20-30 minutes at 15 psi.[17]

"Dextrose Tek" Liquid Media (Corn Sugar Broth)

1 Teaspoon Powdered Dextrose (corn sugar)
75 ml water[17]

Honey Water (Mycotopia Honey Tek)

40 g Honey (or roughly 1 tablespoon per pint of water)
1 L Water

The correct mixture for optimum results is 4% sugars (honey) by weight and 96% water.
Water weighs 1 gram per cc/ml so if you use 100 ml as total weight, then 96 grams/ml/cc of water is mixed with 4 grams of honey, etc.
Sterilize for 30 min at 121°C (15 psi).[14]

Malt-Yeast-Peptone Agar (McKenna's MYP)

7 g malt extract (powdered or syrup)
1 g peptone or soytone
0.5 g yeast extract
15 g agar[11]

Malt Yeast Peptone Agar (Stamets MYP)

20 g extra light malt extract
1 g yeast extract
1 g peptone
15-20 g agar
1 L water[10]

Grey Cardboard (instead of agar)

Here are the detailed steps for making cardboard plates. Note that you can also use small jars in place of Petri dishes.

1) Measure about 100 mls. of tap water into a small jar.
2) For nutrients, measure another 100 mls. of tap water into a second jar and add one drop of ordinary soy sauce to the water, and a quarter teaspoon (1.25 mls.) of molasses or light malt powder.
3) Find some gray cardboard, the thicker the better, preferably gray on both sides. Trace a Petri plate onto the cardboard with a pencil and cut out several disks to fit into your plates.
4) Weigh one of your disks and record the weight. Multiply this weight by a factor of 1.3 as a rough guide (you may need to experiment with the amounts here), and add the resulting weight of tap water or nutrient solution to each disk in its Petri plate. (Remember, 1 ounce of water equals 28.35 grams; one gram equals one milliliter.) Example: Suppose my disks weighed 0.17 ounces each. Multiplying 0.17 by 1.3, I get 0.22 ounces. There are 28.35 grams in an ounce, so 0.22 ounces x 28.35 equals 6.3 grams. That means I'll add 6.3 milliliters

of solution to each disk.
5) Close up the disks in the plates, and let the water or nutrient solution soak in.
6) Pressure-sterilize the jar of plain water, and the Petri plates with moistened newsprint disks inside, for 10 minutes at 15 psi (allowing the cooker to equilibrate steam for 10 minutes before putting on the pressure regulator).
7) Cool the cooker, and remove the plates and jar of plain water.
8) When the water has cooled, add 3.3 mls. 3% peroxide to the jar, using a pasteurized pipette, to give you a final concentration of about 0.1% peroxide in sterile water.
9) Add about one third of the initial weight of the cardboard as 0.1% peroxide to each disk. Let the solution soak completely into the disks. They are now ready to use.[23]

Oatmeal Flake Agar

75 g Oatmeal flakes
20-25 g Agar
1 L water

Stir for 5-10 minutes then filter out the larger particles by pouring it through some mesh, save the broth. [Then add the agar]

This is the best medium for Panaeolus cyanescens I've ever encountered. Beware, this medium will be less firm than the other recipes so extra agar has to be added to compensate.[22]

Moonflower's Rice Malt-Alfalfa-Brewer's Yeast Agar

1 cup alfalfa, infusion from
2 cups rice, infusion from
1 standard dolomite (oyster shell-crushed) tablet
1 pkg of regular brewer's yeast

Prepare infusion using approx. 1 1/2 quarts of clean water. Mix in the alfalfa and rice, then allow to soak for 2 hours at room temp with occasional stirring. Filter or strain before adding the infusion.
Prepare yeast by activating in water for around 30 minutes, then strain out solid yeast grains.
Sterilize in pressure cooker for 20 minutes at 15lbs.
This media is reported to produce more "banding" than other media. Will support luxuriant mycelial growth, it is also more than sufficient for starting spores.[19]

MycoPsycho's Liquid Mycelial Culture Broth

1/2 tsp malt (2.5 ml)
3/4 cup water

1. procure a half-pint jar with lid & ring and also a spore syringe.
2. drill/punch a hole in the center of the lid large enough for the syringe.
3. mix 3/4 cup of water with 1/2 tsp.(2.5 ml.) malt.
4. put lid & ring on and put aluminum foil over the top of that and then Pressure Cook (PC) for 20 min. @ 15 psi. , when finished let cool to below 90 degrees F.
5. once cool, setup your sterile environment (flow hood, glove box or even your oven will work) with an alcohol lamp, extra alcohol in a dish, paper towels/napkins, small round bandaid and lastly the spore syringe.
6. remove the foil from the jar, shake the needle and then sterilize the point with the alcohol lamp (get it red hot), cool the needle with a wipe & some alcohol and then inject 1-2 cc/mil spore solution into the jar.
7. once injected wipe the needle with alcohol and put the guard back on it.
8. cover injection site with round bandaid (thanks for that tip magash!).
9. put the jars in your incubator set at 82-84 degrees F. for 4-14 days, you should notice growth by then.
10. sterilize empty syringes in your PC for 15-20 @ 15 psi.
11. remove the bandaid from the jar, sterilize your needle again and then suck myc solution into empty

syringe(s) for use on PF style jars or substrate bags.[15]

Ragadinks Liquid Medium

16.5 g dextrose
1.5 g yeast
500 ml tap water[16]

Amaranth Soy Agar

20 g amaranth flour
20 g soy flour
9 g agar
500 ml potable or distilled water
Sterilize for 20-30 minutes at 15 psi.[20]

EntheoGenesis No.442

10 g amaranth flour
10 g brown rice flour
10 g potato flour
10 g soy flour
2 g malted barley
9 g agar
500 ml potable or distilled water

Sterilize for 20-30 minutes at 15 psi.[20]

Section C: Food Based Recipes and Variations

Corn Meal Agar (CMA)

2 g Corn Meal, Infusion from [filter]
15 g Agar
1 L dH2O [4]

Cornmeal Dextrose Agar

25 g yellow cornmeal
3 g dextrose
9 g agar
500 ml potable or distilled water[20]

Potato Flake Agar

20.0 g Potato Flakes
10.0 g Dextrose
15.0 g Agar
1.0 L Demineralized Water

Potato Dextrose Agar and Potato Flake Agar are formulations developed to promote sporulation of fungi. The potatoes contained in these media provide nutritious bases for luxuriant growth of fungi. Both media contain dextrose as a growth stimulant.
pH 5.6 +/- 0.2 @ 25°C[7]

Potato Starch Agar

30 g potato starch, soluble
20 g dextrose/glucose
15 g agar, pure (omit for liquid media)
1000 mL (d)H2O

The pH is adjusted following autoclaving to prevent agar hydrolysis by acid.[20]

Potato Flake Agar with Yeast

20 g potato flakes
10 g glucose
1-2 g dried yeast
20 g agar
1 L water[18]

Potato-Carrot Agar

grated potato 20.0 g
grated carrot 20.0 g
Agar 20.0 g
Tap water 1000.0 ml

Boil potato and carrot in 1000.0 ml of water for 1 h, filter, add water to the initial volume, adjust pH to 7.0 - 7.1 and add agar.
Sterilize at 121°C for 30 min.[6]

Barley Flour Malt Extract Agar

40 g barley flour
2 g malt extract
1 g yeast extract (optional)
9 g agar
500 ml potable or distilled water

Sterilize for 20-30 minutes at 15 psi.[21]

Barley Flour Modified Sabouraud's

25 g barley flour
5 g dextrose
2 g Polypeptone or neopeptone (optional)
1 g yeast extract
9 g agar
500 ml potable or distilled water

Sterilize for 20-30 minutes at 15 psi.[21]

Oatmeal Agar (OA)

60.0 g Oatmeal [filter]
12.5 g Agar [may require more]
1.0 L dH2O

Cook oatmeal 5-10 minutes then filter the liquid into another container using cheesecloth or a metal strainer with a tight mesh. Dilute liquid to 1L, add agar, and heat with swirling until solids dissolve.

This is reported to be a good media for cultivating Panaeolus cyanescens.[5]

Oatmeal Agar A

Oatmeal 20.0 g
Agar 20.0 g
Tap water 1000.0 ml

pH 7.2.[6]

Oatmeal Agar B

Oats 30.0 g
Agar 15.0 g
Tap water 1000.0 ml

Keep oats on a water bath at 58°C for 1 h, filter through 2 layers of gauze, dilute to 1000.0 ml and add 15.0 g agar.[6]

V-8 Oatmeal Agar

50 ml V-8 juice
25 g Cream of oats
20 g Agar
1 L Water

Be careful to use a container much larger then the volume of medium, i.e., prepare a 500 ml medium in 2 liter flasks or it will tend to boil over no matter how slowly it is cooled down.[20]

V8 Medium

50 ml V8 Juice
.2 g $CaCO_3$
20 g of agar
1 L Water

The commercial V8 juice is occasionally used for tissue cultures of edible mushrooms. It should be noted that most mushrooms prefer neutral to slightly acid range of medium, that is, a pH of about 5.5 to 6.5. However the straw mushroom, Volvariella volvacea, prefers a high pH medium, 6.8 to 7.8. Therefore, it is important to make sure the acidity or pH of the medium is correct for a particular mushroom. Here be careful to use a container much larger then the volume of medium, i.e., prepare a 500 ml medium in 2 liter flasks or it will tend to boil over no matter how slowly it is cooled down. [20]

Bean Agar

Beans (peas or pulse) 100.0 g [infusion from (filter)]
K_2HPO_2 0.5 g
Sucrose 10.0 g
Agar 20.0 g
Water 1000.0 ml

Prepare infusion from beans. Sterilize at 121°C for 30 min.[6]

Faba Bean Dextrose Agar (FDA)

200 g faba bean seeds or 400 g of faba bean leaves [infusion from]
[autoclave and filter to obtain faba infusion]
20 g of dextrose
18 g agar
1 L water

Method:
a. Weigh out 200 g of faba bean seeds or 400 g of faba bean leaves in a 1.5 L flask. Add 1L of water, and autoclave at 15 psi. for 30 minutes.
b. Pass the autoclaved beans through a sieve, add 18 g of agar, heat, and stir till dissolved.
c. Add 20 g of dextrose, stir till dissolved, and make up the volume to 1 L with tap water. d. Autoclave at 15 psi. for 20 minutes, cool to about 40°C, and pour into Petri dishes (normally 40 Petri dishes/L).

This medium is used for propagation of B. fabae, A. fabae, and A. tenuis.[12]

Pea Agar

100 g Yellow peas
0.5 g K_2HPO_2
10.0 g Sucrose
20.0 g Agar
1.0 L Tap water

Boil peas in 1000.0 ml of water, filter through gauze, add water to the initial volume; add phosphate, sucrose, and agar. Sterilize at 121°C for 30 min.[6]

Cabbage Agar

Cabbage 50.0 g
glucose 20.0 g
Peptone 10.0 g
Agar 20.0 g
Tap water 1000.0 ml

Boil 50.0 g of cabbage in 1000.0 ml of water, filter cabbage, adjust the volume of broth to the initial value.[6]

Dr. Pollock's Modified [Dog Food] Agar

10 g dried dog food (ground to flour)
10 g amaranth flour
2 g dextrose or malt extract
9 g agar
500 ml potable or distilled water

Sterilize for 20-30 minutes at 15 psi.[20]

Section D. Other Media and Alternate Formulations

Potato-Glucose Agar 1

grated potato 200.0 g
glucose 20.0 g
Agar 20.0 g
Tap water 1000.0 ml

Boil potatoes for 1 h in 1 L of water, filter through gauze. Add water to the initial volume, add glucose and agar.
Sterilize at 105°C for 30 min.[6]

Potato-Peptone Medium

Potato decoction 200 ml [infusion from 200 g potato]
Yeast extract 1.0 g
Peptone 5.0 g
Agar 30.0 g
Distilled water 800.0 ml.[6]

Potato-Peptone-Yeast Agar (PPYA)

Potato decoction 200 ml [infusion from 200 g potato]
Peptone 5.0 g
Yeast extract 1.0 g
Agar 25.0 g
Distilled water to 1000.0 ml

pH 8.0.[6]

Malt Agar (MA)(FDA M185)[aka 2% MEA]

20 g Malt extract, powdered
20 g Agar
1 L Distilled water

Mix ingredients, steam to dissolve agar and sterilize for 15 min at 121°C. Temper medium to 45°C and pour plates under aseptic conditions.

This medium is recommended as a general maintenance medium.[1]

Difco Malt Extract Broth (FDA M94)

6.0 g Malt extract base
1.8 g Maltose, technical
6.0 g Dextrose
1.2 g Yeast extract
1.0 L Water

Final pH, 4.7 ± 0.2.[1]

Malt Extract Agar for Yeasts and Molds (MEAYM)(FDA M182)

20.0 g Malt extract, powdered

20.0 g Glucose
1.0 g Peptone
20.0 g Agar
1.0 L Distilled water

Mix ingredients, heat to dissolve agar and sterilize at 121°C for 15 min. Temper media to 45°C and pour plates under aseptic conditions. Dehydrated MA is commercially available, but since several MA formulas exist, check for the correct composition.
Final pH 5.4.[1]

Malt Extract Peptone Agar

30 g Malt extract
3 g Soya peptone
15 g Agar
1 L Distilled water

Adjust pH to 5.6. Sterilize at 121°C for 10 min.[8]

Raper & Thom MEA (RTMEA)

To 2% MEA add:
Glucose 10 g
Soy Peptone 5g.[9]

ISP 2 Medium (Malt, Yeast, Glucose)

Malt extract 10.0 g
Yeast extract 4.0 g
Glucose 4.0 g
Agar 15.0 g
Distilled water 1000.0 ml

pH 7.2.[6]

Yeast Extract Agar (YEA)(FDA M181)

10.0 g Proteose peptone
3.0 g Yeast extract
5.0 g NaCl
15.0 g Agar
1.0 L Distilled water

Adjust pH to 7.2-7.4. Autoclave at 121°C for 15 min.[1]

Yeast Glucose Agar

Yeast extract 5.0 g
Glucose 10.0 g
Peptone 5.0 g
Agar 20.0 g
Distilled water 1000.0 ml

pH 7.2. Sterilize at 121°C for 15 min.[6]

Glucose and Yeast Extract Agar

Glucose 20.0 g
Yeast extract 10.0 g
CaCO2 20.0 g
Agar 17.0 g
Distilled water 1000.0 ml[6]

Glycerin Yeast Agar

Yeast extract 5.0 g
Glycerin 50.0 g (also called glycerine or glycerol)
CaCO2 1.0 g
Agar 20.0 g
Distilled water 1000.0 ml[6]

Manure Tincture

Cow manure (fresh) 1.0 kg
Distilled water 3000.0 ml

Boil, squeeze through gauze into a bottle and dilute 3 to 1.[6]

Manure Agar

Horse manure 100-125 g
Agar 25.0 g
Distilled water 1000.0 ml

Boil manure in 1000.0 ml of water for 10 min, then keep for 16-20 h, filter through 1-2 layers of filter paper, adjust to the initial volume, add agar.
Sterilize at 121°C for 15 min.[6]

Water Agar (aka Starved Agar)

Agar 20.0 g
Distilled water 1000.0 ml

Sterilize at 121°C for 15 min.[6]

Gelatin Agar (GA)(FDA M54)

4 g Peptone
1 g Yeast extract
15 g Gelatin
15 g Agar
1 L Distilled water

Suspend ingredients with constant stirring to prevent scorching gelatin, and boil to dissolve gelatin and agar. Adjust to pH 7.2 ± 0.2. Autoclave 15 min at 121°C. Cool to 45-50°C. Pour plates.[1]

Plate Count Agar (SMA)(aka Standard Methods Agar)(FDA M124)

5.0 g Tryptone
2.5 g Yeast extract

1.0 g Dextrose
15.0 g Agar
1.0 L Distilled water

Heat to dissolve ingredients. Dispense into suitable tubes or flasks. Autoclave 15 min at 121°C. Final pH, 7.0 ± 0.2.

For viable yeasts and molds, dispense 20-25 ml portions into sterile 15 x 100 mm Petri dishes.[1]

Nutrient Agar (FDA M112)

3 g Beef extract
5 g Peptone
15 g Agar
1 L Distilled water

Heat to boiling to dissolve ingredients. Dispense into tubes or flasks. Autoclave 15 min at 121°C. Final pH, 6.8 ± 0.2.[1]

Starch Agar (FDA M143)(Nutrient agar with starch)

23 g Nutrient agar (FDA M112)
10 g Potato starch
1 L Distilled water

Heat to dissolve agar in 500 ml water. Dissolve starch in 250 ml water. Combine and dilute to 1 liter. Autoclave 15 min at 121°C.

Note: add 3 g agar to Difco's dehydrated starch agar.[1]

Starch-Yeast Agar

Yeast extract 2.0 g
Starch (soluble) 10.0 g
Agar 20.0 g
Tap water 1000.0 ml

pH 7.3.[6]

1/5 Starch-Yeast Agar

Yeast extract 0.4 g
Soluble starch 2.0 g
Agar 20.0 g
Distilled water 1000.0 ml

pH 7.3.[6]

Long-term Preservation Medium (FDA M85)

3 g Yeast extract, 0.3%
10 g Peptone
30 g NaCl
3 g Agar
1 L Distilled water

Heat to dissolve ingredients. Dispense 4 ml portions to 13 x 100 mm screw-cap tubes. Autoclave 15 min at 121°C. Cool and tighten caps for storage. No pH adjustment is necessary.[1]

Peptone Meat Agar (Meat Water)

Peptone 10.0 g
NaCl 5.0 g [optional]
Agar 20.0 g
Meat water 1000.0 ml

Preparation of meat water: comminute 500 g of meat free of bones, fat and tendons, add 1000.0 ml of tap water and leave for 12 h at room temperature or in a thermostat at 30°C, or for 2 h at 37°C. Then squeeze the meat through gauze or cloth and boil the filtrate for 5 min. The proteins are denatured. Filter the cooled down mass through a cotton-wool filter and add water to the initial volume. pH 7.2 - 7.4.
Sterilize at 121°C for 30 min.[6]

Section E. Common Solutions

Gentamicin Sulfate Solution (FDA M57)

5.00 g Gentamicin sulfate
1.00 L Distilled water

Sterilize by filtration through 0.20 µm membrane. Store at -20°C.[1]

Chloramphenicol 0.2g/liter of media survives autoclaving.

Agar substitute

by

doc34

original report: http://www.shroomery.org/8514/Agar-substitute

Those of you who would like to study mycelium and can't find agar, can't afford it, or whatever your reason may be, can use this little technique.

This tek is very newbie friendly, cheap to prepare, and some seasoned cultivators may find it useful as well. Try it, you may enjoy it.

All of the ingredients combined = Total cost, $1.50 (current price of Rice). The Tyvek can be obtained at your local Post Office for freePriority Mail Envelopes.

Mahatma
BROWN RICE
PRIORITY MAIL

Ingredients:

- Brown Rice
- water
- 1/2 pint jars
- Tyvek
- foil
- coffee grinder

Preparation of media(for each jar):

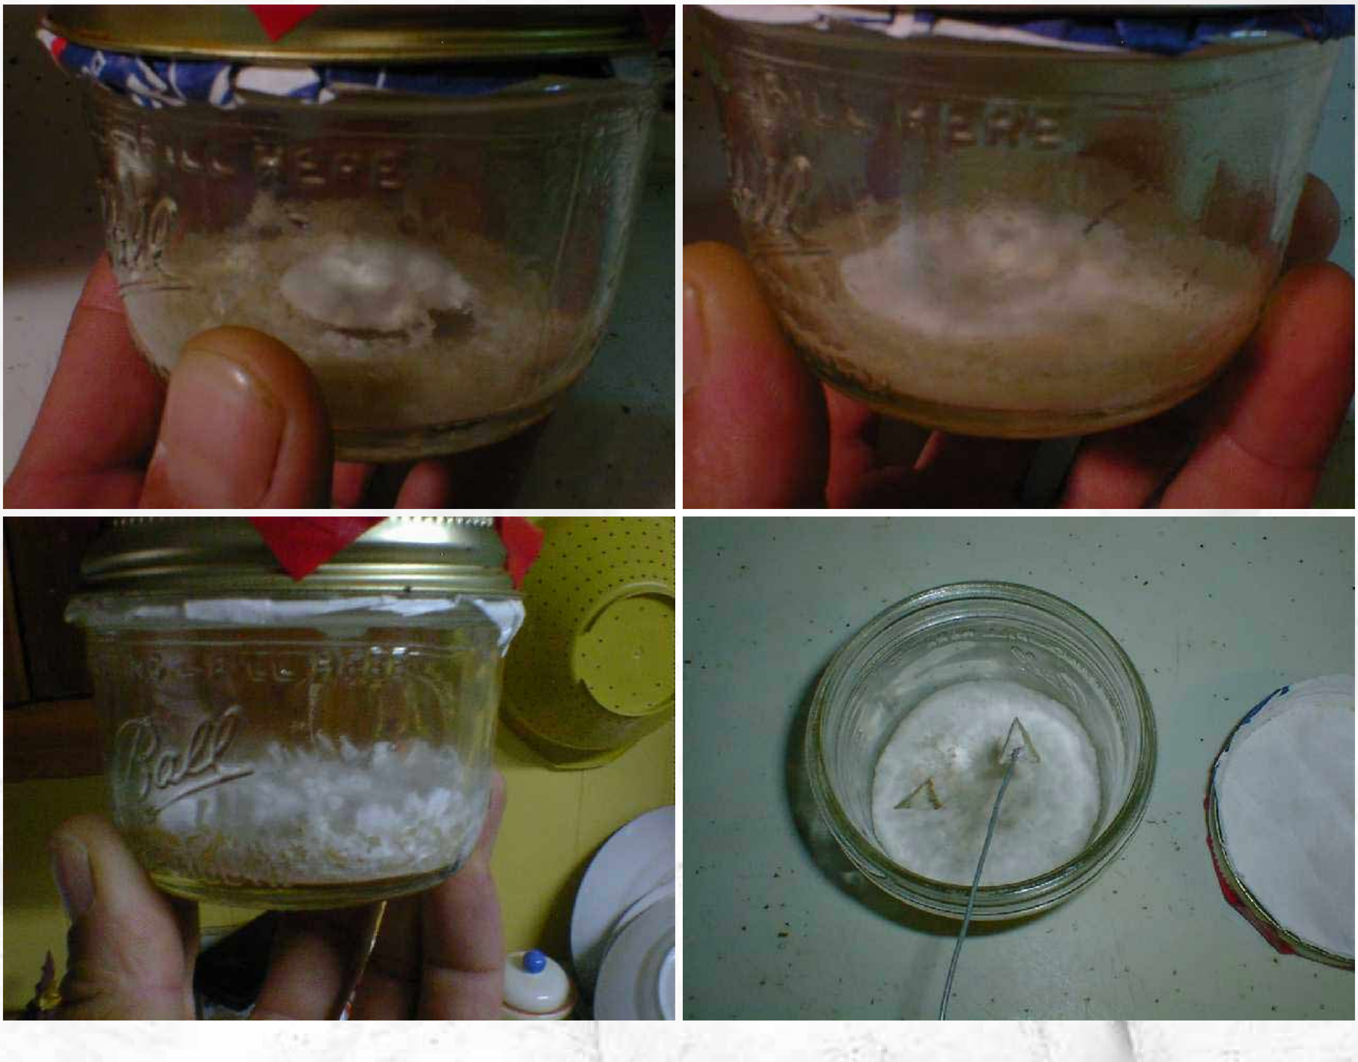
- 1->5 grams of Brown Rice ground into a fine powder.
- 2->16 ml (cc) of water.
- 3->place these ingredients in each jar you plan to use.
- 4->place Tyvek filter on jar, apply disc/polyfill filter and ring, cover with foil.
- 5->PC them for 15 minutes at 15 psi and allow to cool.

For a thinner layer:

- 2.5 grams of Brown Rice ground into a fine powder
- 8 ml (cc) of water

To inoculate with a spore syringe (multispore) simply flame needle, wipe with alcohol, and plunge syringe in through the polyfill, tyvek and inject 1 (one) drop of spore solution in the center of media.
Remove syringe, replace foil and incubate at 80°F - 85°F.

This colonizes 100% in about 2 weeks or less (less using the thin layer) .



Once you have the growth you are looking for you can transfer a wedge to the grain of your choice.

This is has worked well for me, and I hope you can find it useful.

Agar PDYA

Penn State Spawn Lab Procedure for Making PDYA

by

Vija L. Wilkinson

Research Support Technologist Department of Plant Pathology

original source: http://plantpath.psu.edu/facilities/mushroom/cultures-spawn/media-preparation

PDYA: POTATO DEXTROSE YEAST EXTRACT AGAR

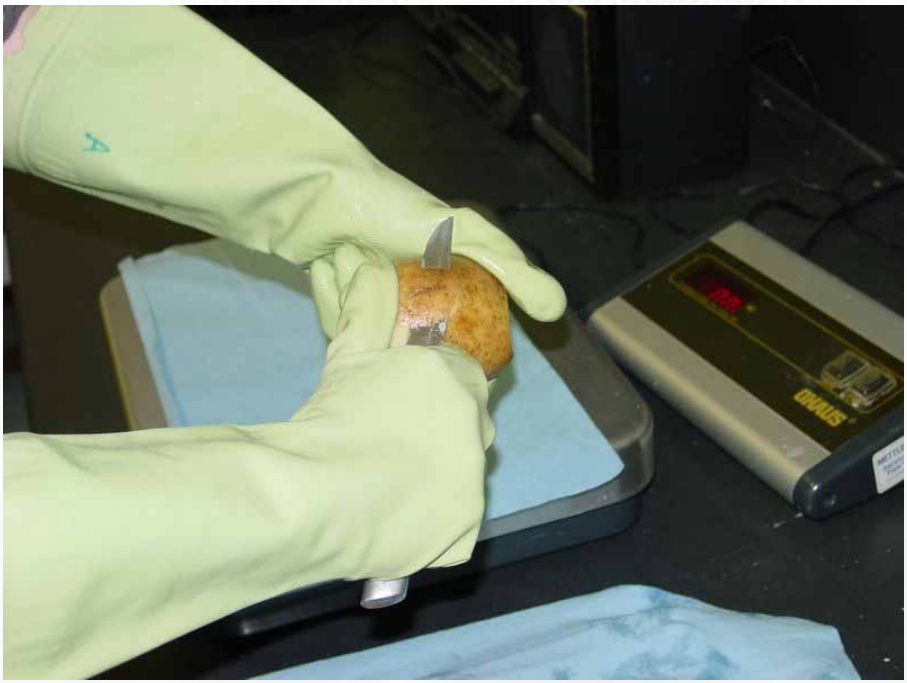
To Make 1 Liter:

- 250 grams potatoes; Do not peel. Scrub clean, cutting out eyes and bad spots.
- 20 grams Agar. Cut into 1/2" pieces.
- 10 grams Dextrose, Anhydrous.
- 1.5 grams Yeast Extract.

Rinse and drain cut potatoes twice with tap water and once with distilled water. Add 1 liter distilled water to the potatoes. Cook until potatoes are tender. Filter the potato broth through two layers of cheese cloth. Save the broth and discard potatoes. Add distilled water to broth bringing volume up to 1 liter. Heat the 1 liter of broth to a boil. While stirring slowly add agar, dextrose and yeast extract. Stir until dissolved, watch carefully or it will boil over.

Autoclave for 15 minutes at 121C.

Scrub potatoes clean.



Cut out eyes and bad spots.

Cut Potatoes into 1/2 inch Pieces.

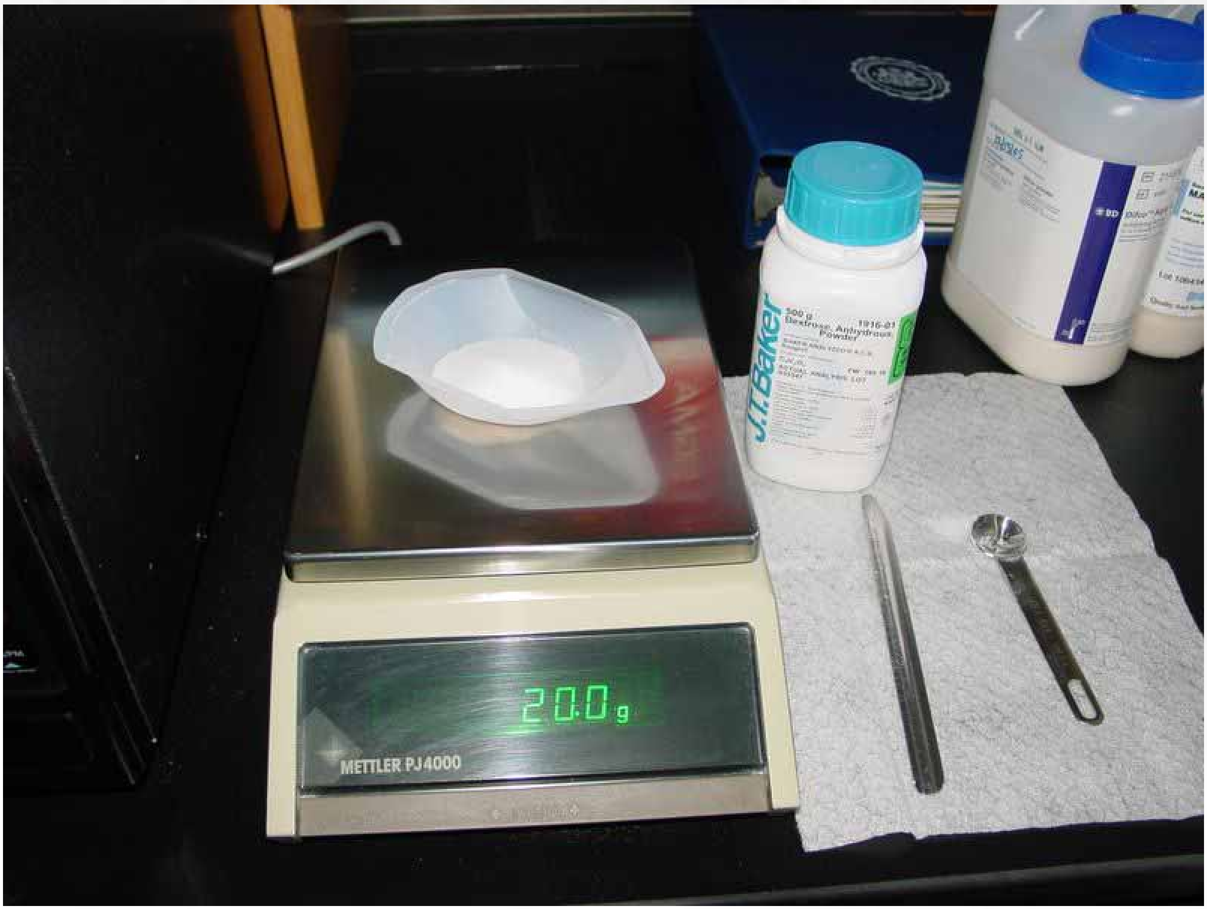
Potato Pieces.

Place Potatoes into large pyrex flask
Potatoes are rinsed twice with tap water, and a third time with distilled water.

Adding Distilled Water
Add one liter of distilled water to the potato flask.

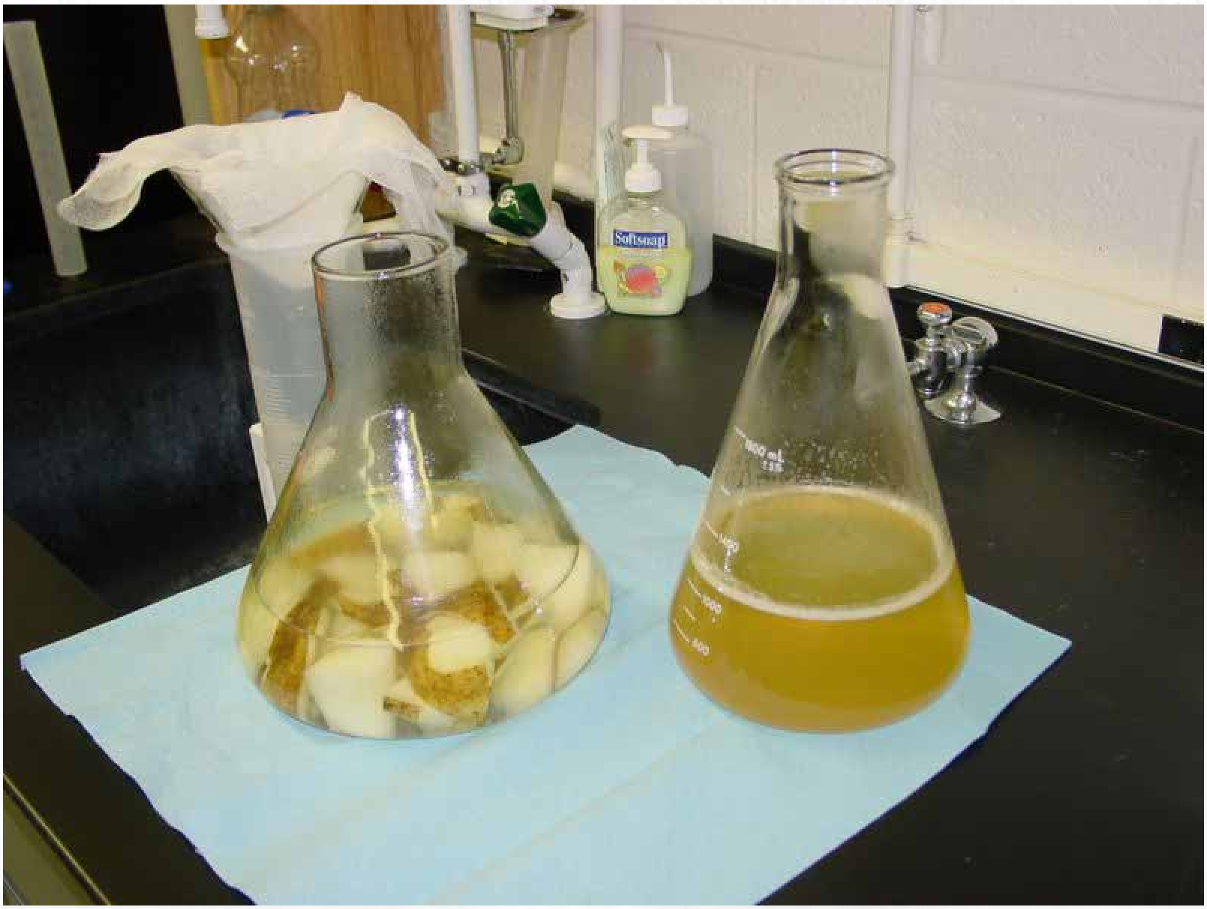
Prepare Agar
In a second flask, place 20 grams of Agar and one liter of distilled water. Place potato and Agar OPEN flasks in a metal pan.

Melt Agar and Cook Potatoes
Place the OPEN flasks (on a metal pan) in an autoclave. Autoclave on 'steam bypass' for 45 minutes. (Steam bypass - 100 C at 8 pounds pressure).



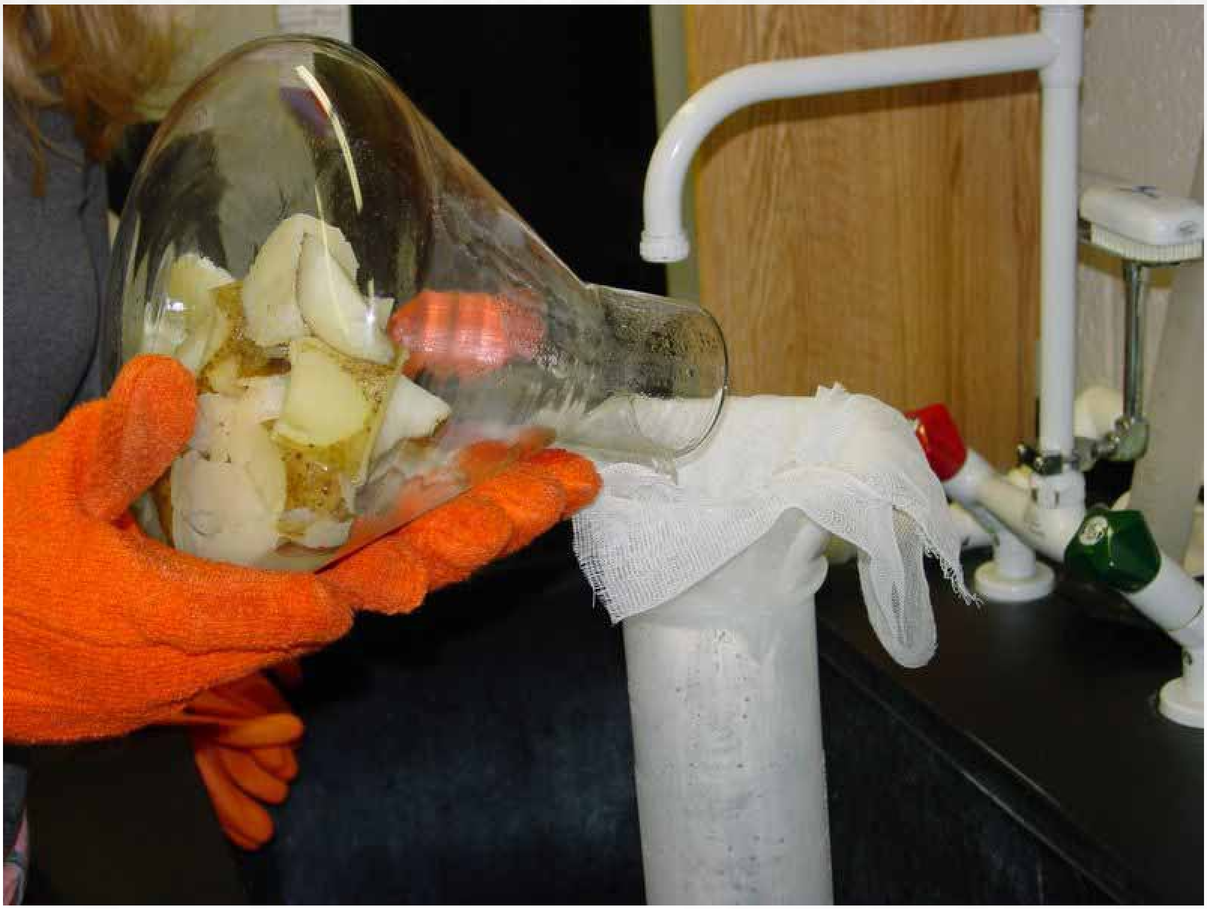
20.0 g
METTLER PJ4000
J.T.Baker
500 g
Dextrose, Anhydrous Powder

Measure ingredients
While potatoes and Agar are cooking, weigh out 10 grams of Dextrose and 1.5 grams of Yeast Extract.



Cool Potatoes and Agar

Set up a 1 liter plastic cylinder with glass funnel lined with 2 layers of cheesecloth while potato broth is cooling.



Filter the potato broth by pouring through the cheesecloth into the cylinder. Add distilled water if needed, to bring the volume in the cylinder to 1 liter. Add Dextrose and Yeast Extract to the melted Agar and swirl to mix. Mix filtered potato broth and Agar by pouring back and forth between the flask and the cylinder four times.

Autoclave test tubes and/or flask of PDYA for 15 minutes at 121 C. Slow exhaust.

Cooling Agar
Test tubes should be slanted on a slant board until set, about 3 hours. Plates can be poured once the PDYA flask is cool to the touch. For PDY Broth: made the same way but omitting agar. For Acide PDYA: add 1 ml Lactic Acid to liquid media just before pouring plates.

Honey Tek

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/honeytek.htm

This tek is a method for multiplying spore syringes by growing in liquid, specifically water mixed with honey. Honey is used because it is common and cheap, but substitution can be made of honey by malt extract/dextrose/corn sugar if available. The tek is flexible in that it can easily be done in different size jars as long as the proper ratio is maintained between the sugars and the water. The correct mixture for optimum results is 4% sugars {honey, malt} by weight and 96% water. Water weighs 1 gram per cc/ml so if you use 100 ml as total weight, then 96 grams/ml/cc of water is mixed with ~4 grams of honey, etc. (you must use dry sugar to be exact). See: Karo Tek

For those who figure that close is good enough, roughly 1 tablespoon of honey per pint will work.
The basic idea then is to get a jar with a good lid, canning jars like commonly used in pf tek work great.
The lid can be drilled and the hole covered with a filter disk or stuffed with polyfil to allow spores to be injected after the mix has been sterilized. Alternatively, one can use a glovebox and simply crack the lid a little to inoculate.

After the lid has been prepared, add the water and honey and stir until the honey dissolves. It's easier if warm water is used. Then tighten the lid and pressure cook or steam for 20 minutes. Don't overdo it because too much heat too long will ruin the mix by carmelizing the sugars.

After it cools to room temperature it is ready to be inoculated. Inject 1 or 2 cc's of spore solution into each jar. Alternatively, instead of spores, mycelial tissue from any part of any living shroom can be substituted.

Keep the inoculated jar warm in a clean environment. 86°F is ideal. Within several days, strands of mycelial tissue will appears and begin to grow. Allow it to grow at least several days then it is ready to use. You can draw up syringfuls through the polyfil/filter or open it inside a glovebox, etc. Try to get as much tissues as possible in the syringes, a nice thick mix will grow out very fast when used to inoculate jars, etc.
Store excess in clean refrigerator or discard within a few more days as the mix is best used fresh.
In the fridge, it can last until the sugar runs out, about a month or so, usually.

Notes

Liquid (tissue) cultures are used to expand mycelium into a liquid solution to inoculate your chosen substrate. Like a multi-spore syringe, except the spores have germinated into a network. Since the spores are already germinated; colonization times are substantially faster and inoculated substrates have an edge over contamination with speed.

In addition to the significant speed boost over MS (multi spore) inoculation, mycelium is not harmed by hydrogen peroxide (H_2O_2), so this can be added to your substrate to help reduce contamination. Normally you can not do this until the mycelium has started growing, because H_2O_2 kills the spores.

One spore syringe can be made into gallons of liquid culture. One spore print, agar culture and mushroom tissue can also make gallons.
Liquid cultures are economical, as 1cc from a spore syringe can supply you with a large volume of liquid inoculant which can be used on many jars/bags. Also if the liquid inoculant is a clone (generated from sectored agar or mushroom tissue), then each jar should show similar growth speeds and maturity.

Liquid cultures are normally at a 4% dilute solution of various sugars and other nutrients in water.This would be 4 grams of sugars per 96 ml/cc water. (Water weighs 1 gram per ml/cc.)

Medium

Some nutrient sources are:

- Karo (You want the clear one that has the red label; "Light with Vanilla". DO NOT get the dark Karo, such as the one containing brown sugar)
- Honey (Non-organic has been known to work, but organic honey is highly recommended.)
- Corn sugar
- Light malt extract (or extra light. The lighter the better, because it will make it easier to observe growth in the jar.)
- Dextrose (glucose)
- While only the above are recommended, because they have been tried and tested, other sources have been successfully used, such as organic maple syrup.

Household sugar (sucrose) shouldn't be used.

Dextrose alone is usually not recommended, but will work, due to the lack of additional nutrients its growth may be slower but due to its clarity it may be easier to spot contamination. Light malt extract and honey can be used alone. Additional nutrients can be added such as peptone, various flours could be used but it is much harder to determine the stage of mycelium growth due to cloudiness.

1 tablespoon of light malt extract and 1 tablespoon dextrose were weighed out. These are the weights;

1 tablespoon light malt extract = 10.3g
1 tablespoon dextrose = 10.1g
Give or take a point of a gram.

Malt and Dextrose

One member uses -
1 tablespoon dry malt extract or dextrose to 250ml (1 cup) water.

Another -
2% dextrose and 2% light malt extract.
This would equal close to 1/2 tablespoon dextrose and 1/2 tablespoon light malt extract per 250ml (1 cup) water.

Nanook from Nan's Nook uses -
1 level teaspoon dextrose (or light malt extract) to 75ml water.
-OR-
1 1/4 teaspoon dextrose (or light malt extract) to 100ml water.

Honey

4 cc/ml is the exact 4% ratio wanted. A syringe without the needle inserted is good to use as a measuring device. 1 teaspoon organic yellow honey to 100ml water is fairly close.

Note on ratio of solution

If your solution is a little off (3%-5%), don't worry. It'll still put out viable mycelium in most situations. It is better to be too weak a solution than too strong, too strong a sugar solution (around 10%) is toxic for the mycelium, and will not let anything grow in it (why jam is called preserve!)

Mixing

Once you have picked your method (which ever suits you best or is easiest to get) then its time to do some mixing.

Optionally, water can be hot or warm before adding sugars to allow for quicker dissolving.

Wrap top with aluminum foil and place jar in pressure cooker and slowly bring it up to 15 psi. for 15-20 min. Longer with Karo/Honey can cause carmelization.

Allow pressure cooker to cool before removing.

Vacu-tainers

You can bore a small hole big enough for a syringe needle in the top of a jar. (Half pints work best for this) Now put a blob of silicone sealant on it (preferable transparent) on both sides. Swirl it around to make sure it is a centimeter thick around the hole on each side. This is a self healing inoculation point so you can add spores and suck up inoculant without having to open the jar after sterilization. If you band the jar tight before pressure cooking, it will form a vacuum and suck in spores, so you must only prick the injection spot quickly. If you leave the band loose, you should tighten it right after the pressure cooker has cooled down, as it will not have a vacuum seal. You should always wipe your silicone injection spot and needle (flame sterilize before) with alcohol before inoculation.

Agitation

Some people add a piece of broken glass, a glass marble or a pebble to the jar before sterilization. Agitating allows you to cut up the mycellium which can form into an unsuckable clump in the jar. This is why wide (18 gauge or lower) needles are preferable.

A slightly more advanced method is adding a stir rod (or just a 1" piece of non-insulated wire) to the jar and using a magnetic stirring plate to agitate the mycelium. This is the preferred method of agitation because it doesn't have the potential to get your lid filter (polyfil for example) wet when you shake the jar, which can lead to contamination. Do it yourself (DIY) magnetic stirrers are pretty easy to make and there are a ton of guides available both on the Shroomery.org forums, and the Internet.

(TODO) Add links

Microwave sterilization

It is possible to sterilize honey/Karo in the microwave. Be sure to add more water to the mixture as it will boil off during heating leaving you with a more concentrated sugar solution (this does not occur in a pressure cooker). Do not use metal bands in the microwave. Plastic lids are sold next to the metal ones. Never put thin metal like tinfoil or syringe needles in the microwave. Bring the liquid to a boil, then turn to low/defrost for about 15 minutes. KEEP THE CAP LOOSE! Allow it to cool completely in the microwave for a few hours.

Sediments

Once removed, some sediments may be present.
To fix this, open up the jar and filter liquid through 2 coffee filters, stick liquid back in jar, cap with filter lid, and pressure cook again. If you have a lot of liquid you can decant it carefully into another jar leaving the sediment behind. (The sediments are not harmful but can be mistaken for mycelium growth, it is nicer to see clear growth) This should not be done with Karo/honey. After a few days with honey proteins may sink to the bottom or float around. After shaking these will re-mix.

Aeration

During sterilization/heating most of the oxygen will be driven out of the liquid. Shaking will help the network grow faster, but things like hooking up air flow to jars are not necessary. Be careful not to wet the filter patch (if using one) as this can cause contaminants to grow from the outside inwards through the filter.

Growth

Once inoculated by whatever means (spores, clone, agar), stick in a DARK place with a temp of 82-86F optimally, and room temperature if there is no incubator available. Signs of growth after one week max, and fully done at week 3 max. Some see growth in under a day and fully done in 3. Once growth has slowed down (done), either use immediately or store in a fridge.

Storage

Liquid cultures can be stored in a fridge for 6-8 months (or longer). Some add a little H_2O_2 (approx 1-3cc) at this point since the mycelium is able to handle it, this can help prevent contamination.

Sugar carmelization

With Karo and Honey, if you PC for too long your solution may turn yellowed. This is called caramelization and is over-baking of the sugars which may result in little or no growth at all. If this happens you can still try and grow a culture in the caramelized sugar jar, but if you are pressed for spores it is best to just start over. This is something you want to avoid. Liquids don't take very long to sterilize so you don't get any benefit from PCing for longer than 15-20 minutes max.

Boil sterilization

If you do not own a pressure cooker, boiling can also be used. Bring to a high rolling boil and boil your containers with water at least halfway up the jars for 20 minutes.

Notes

1 ml water weighs 1 gram.
1 tablespoon dextrose weighs ~10 grams. (may vary slightly)
1 tablespoon light malt extract weighs ~10 grams. (may vary slightly)
10 ml honey weighs 14 grams.
1 tsp (5 ml) honey = 7 g
1 tbsp (15 ml) honey = 21 g

The Effect of Light upon Basidiocarp Initiation in Psilocybe cubensis

Summary

Formation of basidiocarp initials in *Psilocybe cubensis* occurred only when cultures were illuminated. Short durations of light (0.0025 sec of xenon-arc flash) were sufficient for initiation. Light-induced initiation was saturated at a dose of 0.345 x 10^4 ergs/cm^2 at 460 nm. UV and blue wavelengths of 370, 440, and 460 nm were the most effective. Green and red wavelengths greater than 510 nm were ineffective.

The requirement of light for basidiocarp initiation or development is well documented: Alasoadura, 1963; Lu, 1965; Manachière, 1970, 1978; Miller, 1967; Miller and Palmer, 1977; Plunkett, 1956, 1961. Chapman and Fergus (1973) found that the blue end of the spectrum at intensities above 1.5 x 10^4 ergs/cm^2/sec induced mature basidiocarp formation in *Coprinus domesticus* Fries, whereas green, red, and far red failed to induce initials. Kitamoto *et al*. (1970) studied initiation in *Favolus arcularis* (Fries) Ames and found that a half-maximal response is reached at 1.8 x 10^8 ergs/cm^2 (at 398 nm). Photoinduction was observed in the region between 350 and 560 nm and six peaks were described. Later Kitamoto *et al*. (1973) studied light-dependent pileus development in *Coprinus domesticus* and found the action spectra to be similar. Perkins and Gordon (1969) determined the action spectrum for basidiocarp initiation in *Schizophyllum commune* Fries. They showed that the dose response was linear up to a dose of approximately 1.1 x 10^5 ergs/cm^2 (at 440 nm). Spectral sensitivity peaked in the blue and UV. No light of wavelengths greater than 525 nm was photoinductive. Heim and Wasson (1958) reported that initials of *Psilocybe cubensis* (Earle) Sing. may be formed in darkness at elevated temperatures (27 C). Jackson and Alexopoulos (1976) stated that this species requires light for basidiocarp initiation (at 22-25 C).

The purpose of this study was to determine an action spectrum for basidiocarp initiation in *Psilocybe cubensis*.

Materials and Methods

Culture isolate

The isolate of *P. cubensis* used in this study was obtained during 1975 by allowing a basidiocarp to deposit basidiospores onto agar. A subculture was deposited with ATCC (#36359). The original basidiocarp is deposited in the University of Tennessee Herbarium (TENN 40476).

Preparation of cultures

An agar medium (Brodie, 1975) containing relatively low levels of sugars (maltose, dextrose, sucrose), asparagine, peptone, yeast extract, in addition to salts was used. Six ml of medium were poured and slanted in plastic test tubes (16 x 125 mm) giving a surface area of $3cm^2$. Inoculation of these tubes was made from stock cultures which were grown in the dark for 1 mo in plastic Petri plates (15 x 100 mm) with taped lids. One 3 x 3-mm cube was taken from these and placed in each slant tube. The slant tube caps were not tightly closed. These transfers were made under "safe" light (15-watt incandescent light filtered by a red filter, Carolina Biological Supply red, 650). The cultures were grown for 3 wk in well-ventilated but light-tight boxes. Both cultures and light sources were kept in a controlled temperature room at 21 C &plsmn; 2 and under relative humidity of 85% &plsmn; 15%. In most cases light treatments were given once per da for 5 da; the cultures were examined on da 6. Exposures were given at the same time each da. If manipulations were necessary they were accomplished under the same safe light described above.

Light sources and filters

Two preliminary experiments were conducted to determine: 1) the general wavelengths of importance for fruitbody initiation, and 2) the duration of light necessary for initiation. In the first of these, dark-grown cultures were illuminated for 12 h per da by Cool-white fluorescent lamps at 100 ft-c. filtered with broad-band filters: UV (Kodak 18-A) peak at 350 nm, blue (Carolina Biological Supply) peak at 450 nm, green (CBS) peak at 550 nm, and red (CBS) peak at 650 nm. In the second preliminary experiment the white light of a xenon-arc lamp (Honeywell photoflash) at 0.0005 sec per da was used to initiate fruitbodies.

Based on preliminary observations further experiments were conducted to determine: 1) the relative effectiveness of different doses of light, and 2) the relative effectiveness of different wavelengths of light. Both of these experiments used a 300-watt General Electric quartz-iodine projector lamp in conjunction with a 0.25-m Jarrell-Ash monochromater with 2-mm slits. The ½ band width was 15 nm. The lamp was placed 2.5 cm from the entrance slit and the cultures were placed at the exit slit. Using a spectroradiometer (International Light #783), equal light energies at different wavelengths were obtained by adjusting the voltage to the bulb. The light energy was adjusted to 23 ergs/sec/cm^2 at all wavelengths. Second-order spectra were eliminated for this calibration but were not eliminated when light was used to initiate cultures.

For dose-response experiments monochromatic light (460 nm) was used at eight different dosages to initiate fruitbodies. All cultures were illuminated once per da for 5 da and scored on da 6. For treatments providing doses greater than 0.345 x 10 ergs/cm^2 (23 ergs/sec/cm^2 per da for 5 da) an increase in the time of illumination was used to increase the dose. For treatments less than this amount neutral-density filters (Kodak) were used to decrease the dose. Ten cultures per treatment were used.

For spectral-sensitivity experiments approximately 30 cultures per light treatment were illuminated each da at 23 ergs/sec/cm^2 for 30 sec with monochromatic light of wavelengths from 370 to 510 nm and scored on da 5, 6, 7, or 8. Most replicates were scored on da 6 and those scored on other da were normalized to 6-da data for the interpretation of the results.

Scoring

For preliminary experiments cultures were scored for the presence of basidiocarp initials (here defined as the first "knots" of hyphae which are visible to the unaided eye and which can, under appropriate conditions, become basidiocarps). For further experiments an attempt was made to use a more precise method of scoring which involved: 1) the size and degree of development and 2) the number of initials per total area of the slanted tube. Numerical values for these categories were assigned as follows: size and degree of development - 0, rhizomorphs only, 1, flat aggregations of hyphae, 2, spherical initials 600 µm diam, 3, spherical initials 1,000 µm diam, 4, initials pyramidal in shape; for density of initials in the tubes - 1, 1-3 initials, 2, 4-8 initials, 3, 9-30 initials, 4, 31+ initials. A combination of these factors (the sum of the scores) was here termed the "degree of initiation" and was a useful quantitative index to the experimental induction of basidiocarp initiation.

Results

Preliminary experiments

When cultures were illuminated with light from Cool-white lamps filtered by broad-band filters only blue and UV-illuminated cultures formed fruitbody initials. When other cultures were illuminated with one 0.0005-sec flash/da for 5 da initials were present on the 6th da.

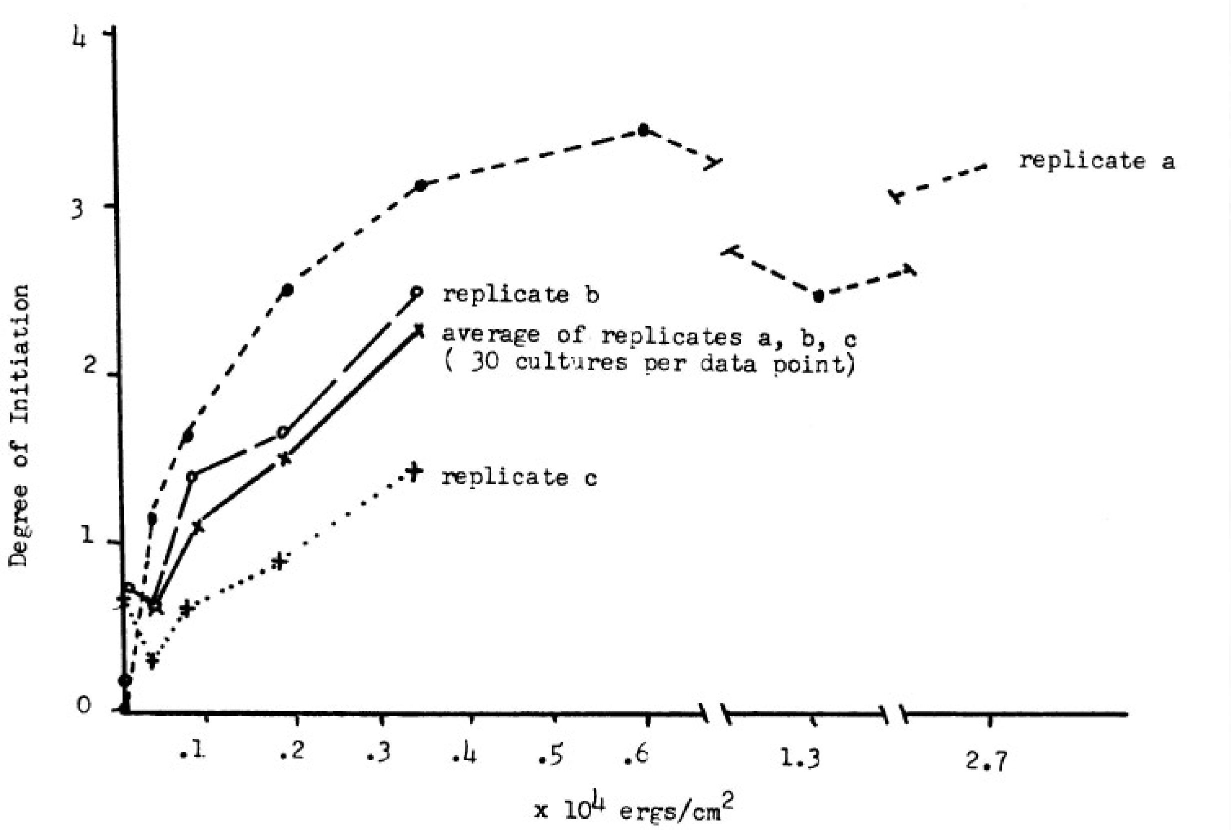

FIG. 1. Dose-response of *Psilocybe cubensis* to light. Eight different doses of monochromatic light (460 nm) used to initiate fruitbodies in dark-grown cultures. Average response approximately linear between 0.086 x 10^4 and 0.345 x 10^4 ergs/cm^2.

Dose-response experiments

This experiment was conducted to determine in what range of light doses a direct proportion exists between the light dose and the degree of initiation. Such a relationship, if it is linear, is called the Bunsen-Roscoe law of reciprocity. Proof of this relationship is essential to determination of action spectra because if, for example, a spectral-sensitivity study was conducted at doses above saturation all wavelengths would be equally active. As seen in FIG. 1 the average response is nearly linear in the range of 0.086 and 0.34 x 10^4 ergs/cm^2 at 460 nm. Also based on replicate "a," response is saturated at doses greater than 0.345 x 10^4 ergs/cm^2. Further studies concerning spectral sensitivity were conducted in the range of doses described above.

Spectral-sensitivity experiments

These experiments were used to determine the effect of different wavelengths of light on fruitbody initiation (action spectrum). The average degree of initiation at the various wavelengths is shown in FIG. 2.

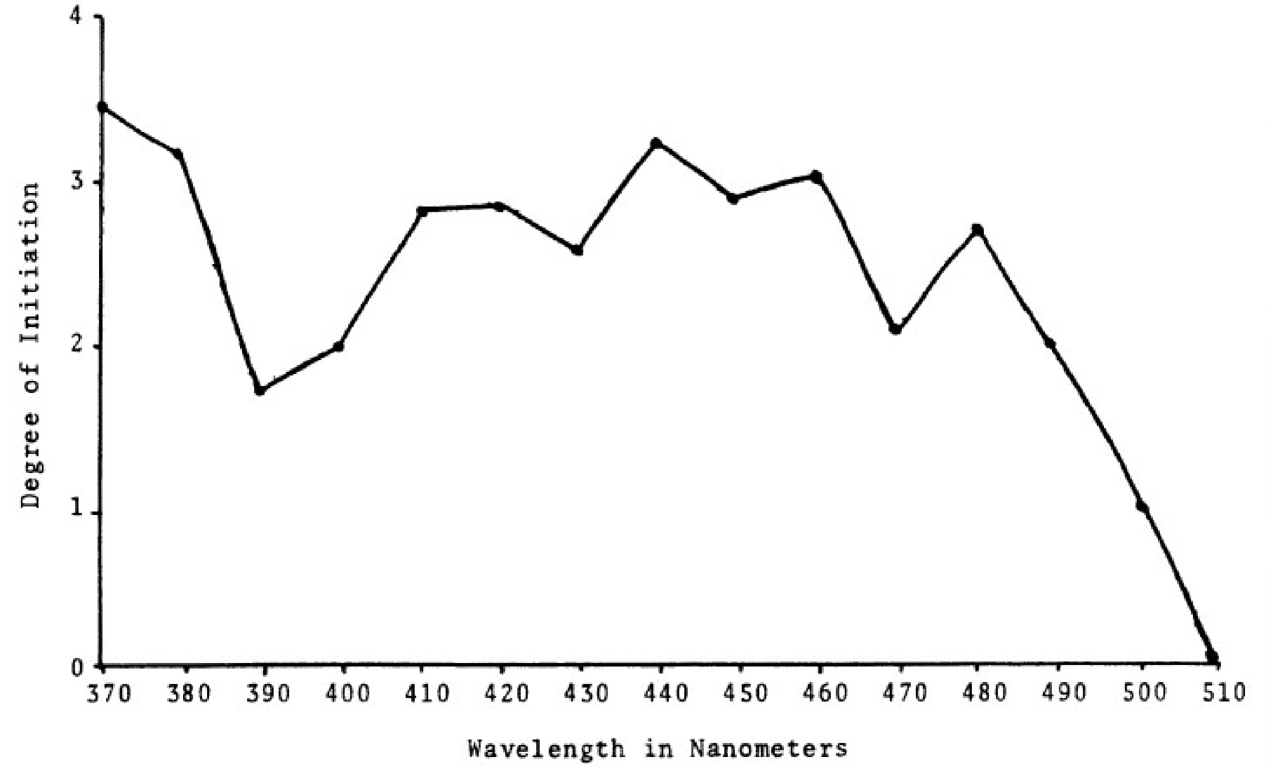

FIG. 2. Spectral sensitivity of photoinduction of basidiocarp initiation in *Psilocybe cubensis*.

Observations of cultures

Initiation did not occur in cultures that were not ventilated. Gases present in the atmosphere or those produced by metabolism may be responsible for this effect. Light has no effect on initiation before vegetative maturity is completed, i.e., the agar surface is covered by mycelium. In one case atypical initials were formed which increased in size as chestnut-colored spheres up to 5 mm diam. These structures contained spores and were grown at 10 C. In some sealed cultures one-celled conidia borne on clamped hyphae were noted (probably "ramifications acremoniformes," Heim and Wasson, 1958). Abnormalities in basidiocarp development were also noted, i.e., morchelloid forms (McKnight, 1971; Watling, 1971). Sometimes when primordia were developed under low levels of light a blue zone subtended the pileus. This zone is in the exact location of the phototrophic zone described by Plunkett (1961). The blue pigment has been related to the presence of hallucinogenic indoles (Singer, 1958) and its location might provide a clue to the role of these substances.

Discussion

This study provides another addition to the growing list of Basidiomycetes that require light for initiation or development. The low level of light necessary for initiation of basidiocarps in *Psilocybe cubensis* is in agreement with the requirements of other Basidiomycetes that have been studied and emphasizes the need for prudence in suggesting that certain mushrooms do not require light for fruitbody initiation (Heim and Wasson, 1958). Spectral-sensitivity studies show that at least two areas of the spectrum stimulate fruitbody initiation, the blue and the UV. This is characteristic for many photoresponses of fungi (Tan, 1978). Both action spectra determined for fruitbody initiation by Kitamoto *et al.* (1972) and Perkins and Gordon (1969) show relatively strong activity at 370 nm. Similarly strong activity at 440 and 480 nm (Kitamoto, 1972) and 420 and 480 nm (Perkins and Gordon, 1969) are in agreement with the present study. However, the peaks at 400 and 520 nm and the lack of activity at 460 nm (Kitamoto, 1972) are very unlike the results obtained in this study.

The observation that a lack of ventilation can inhibit basidiocarp initiation is well documented in the literature (Plunkett, 1956; Tschierpe, 1974). Additionally, the effect of maturity upon the ability of cultures to respond to photoinitiation has been previously reported (Lu, 1965).

Briggs (1976) suggested that the blue-light reactions in green plants and fungi are similar. If this is so then many of the known blue-lightmediated effects in green plants need to be reviewed for fungi. Of particular concern to this study is the connection between blue-light reactions and red-light reactions (phytochrome system) demonstrated by Chon and Briggs (1966). Since red light did not initiate fruitbodies it was considered appropriate as a "safe" light. This may be an incorrect assumption. Finally, although development after initiation seems to require light, it is not known if the action spectrum required is similar to that needed for initiation of basidiocarps.

Acknowledgments

I would like to thank Dr. Ronald Petersen, Dr. Larry Jones, and and Dr. Raymond Holton for guidance throughout this project. Also appreciation is extended to John Berg of the Ecology Department at the University of Tennessee for the use of the spectroradiometer. Dr. Abraham Held is acknowledged for his help in revision of the manuscript. This paper is part of a Master of Science Thesis submitted to the Botany Department at the University of Tennessee at Knoxville in March, 1978.

Mushroom Composter Construction

How to generate superior compost for mushroom growing on a small scale

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/composter.html

Table of Contents:

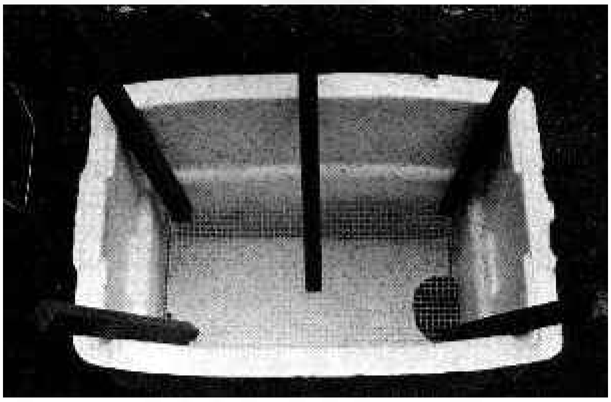
Materials needed to construct composter
Things to check for
To begin a compost run
Notes

This method uses a styrofoam picnic cooler with a steam humidifier and a common light dimmer (or variable transformer) to control the steam and compost temperature. The final product is about 3 gallons of pure pasteurized compost in just 6 to 7 days. Total cost for the bits and pieces to construct this composter should be no more than $30.

Materials needed to construct composter

- Styrofoam cooler
- Steam humidifier or vaporizer (VICKS Warm Mist or similar)
- Bottle, one gallon or larger
- Hose (2 feet) that will fit mouth/cap of the bottle
- Wooden sticks (5), each being 2 feet in length
- Single pole, solid-state dimmer switch
- Metal mesh screen (4 square feet with a 1/4" or 1/8" mesh size)
- Long stem thermometer, 120°C, scientific or kitchen (meat therm.)

The construction of the composter utilizes a styrofoam cooler, preferably one close to 14 inches by 22 inches by 15 inches deep in size. Six 3/4" holes, evenly spaced across the surface of the lid, are melted with a soldering iron or cut with a knife. Six more holes of the same size are melted or cut into the body of the cooler, three along each side, two inches up from the bottom edge. On the short sides of the cooler body, one hole is cut or melted on each side at the bottom edge. One of these holes is sized 1/2", and will serve for drainage. The other end has a hole cut just the right size to accommodate the steam output head or nozzle of the steam humidifier.



The bottom of the cooler is lined with aluminum foil, being careful to not obstruct the drain or steam inlet. A screen support is made from the 1/4" or 1/8"-mesh screen (sometimes called hardware cloth). The screen is cut 8 inches larger than the dimensions of the bottom of the cooler. 4 inches of screen are folded 90° at each edge to form supports, which hold the surface of the screen 4 inches above the bottom. The compost sits on the top surface of the screen so that the steam can flow evenly underneath the compost. This screen support should fit the bottom of the cooler without large gaps around the edges.

A single-pole solid-state dimmer is used to control the humidifier power. Good wiring and insulating procedures need to be followed. If you aren't knowledgeable about wiring, find someone who can help. It is important for safety that the wiring be correctly installed. The best method is to wire the dimmer switch (in a plastic electrical switch box) to both the power-cord of the humidifier (cut off the plug end[male]). Then take an extension cord (cut off the plug end[female]) and wire it to the dimmer switch.

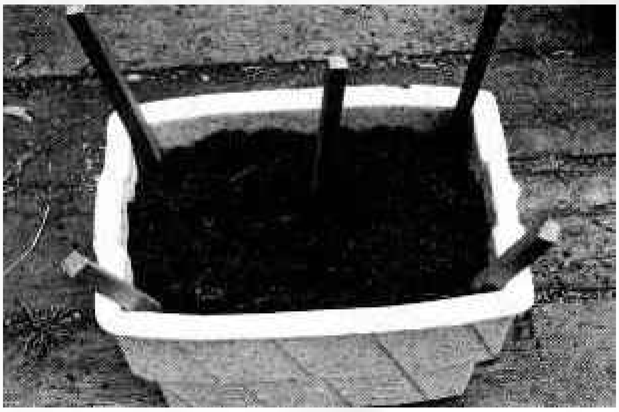
Things to check for

1. The maximum capacity of the dimmer switch (in Watts) should be greater than the load imposed by the humidifier. (almost all dimmers have the necessary rating)

2. The wiring methods should be well insulated and suitable for the damp environment it will be used in.

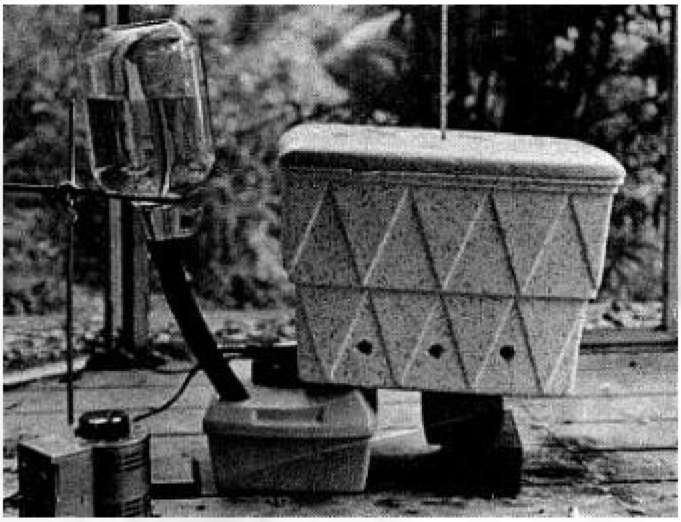
Finally, a water reservoir is constructed. Arrangements are made to secure a one-gallon or larger water bottle above the humidifier. A 1 and 1/2-inch hole is cut in the top surface of the humidifier body to accommodate the hose. The humidifier is filled with water to the "fill" line, and the hose is inserted so that the open end of the hose hangs 1/2-inch below the fill line. In this way a constant level of water is maintained in the humidifier, which makes the steam output constant for a given dimmer setting. It is important to maintain accurate steam/temperature settings during a composting run. During a run, the humidifier electrodes must be cleaned at least every other day, or output will be seriously effected. Using distilled water is a slightly expensive option to regular cleaning.

Before the first time a composter is used, it is best to set it up where in the final location, tape all the holes closed except the drain hole and the humidifier nozzle hole on the bottom, fill up the humidifier and reservoir jug with water and turn on the humidifier at full power dimmer setting allowing the cooler to steam for 4 hours or so to eliminate any plastic or chemical odors and to test your composter's operation.



To begin a compost run

Mix in a bucket, approximately 2 and 1/2-gallons of shredded straw with 1 gallon shredded dry fresh manure (cow or horse). Mix in 3 to 4 ounces cottonseed meal or 1 to 2 ounces blood meal (nitrogen sources, available at most plant nurseries). Add 3 and 1/2-quarts of hot water, preferably with a sprayer, and mix thoroughly. This warm mixture is loaded into the cooler without delay, loosely filling the cooler to within 1 to 2 inches of the top. Five sticks are placed in the cooler before adding the compost mixture, so that after the compost is loaded, 2-inch square ventilation shafts can be created by wiggling each of the sticks around. The sticks are withdrawn, and the lid put in place, all the vent holes are taped shut except the one on the lid furthest from the steam nozzle, and the dimmer set on maximum. The thermometer is placed through the untaped hole so that it is measuring the middle of the compost.



During the first phase of the run pasteurization occurs, killing all insect life. Note that this is opposite of how it is done at a commercial mushroom farm or in outdoor nature composting, where pasteurization is done at the end of a composting run. After about 2 hours of full power steaming, the temperature should rise to approximately 65°C (60° to 70°). Quoted temperatures are only a rough guide, try to maintain the temperatures within the given ranges. For this first phase it is necessary to reach a minimum of 60°C. Once the temperature reaches 60°C check the time and let the compost remain above 60°C. for 3 to 4 hours.

At the end of this time remove all the tape from the ventilation holes and leave the dimmer setting on full. Within a day ammonia will be noticeable in the exhaust steam and the temperature should be 55 to 65°C. Hold this temperature for 2 to 3 days. After the first day the ammonia odor should disappear. After this happens, white fire fang, or *actinomycete* fungi, will be apparent in the compost. It is best to allow the compost run to proceed undisturbed, but if you wish to check it is okay to briefly lift the lid and move the compost surface. Don't allow the compost to cool during any brief investigations. At the end of the 3 days *actinomycete* should be prominent and there should be no ammonia smell. If not, extend the high temperature phase for up to an additional day.

The dimmer setting is now lowered slowly so that the compost temperature drops 2° to 3° every 2 to 3 hours, until a temperature around 50°C is reached (45° to 55°). The compost is then held at this lower temperature for 3 to 4 days. At the end of this time the power is turned off and the compost is allowed to cool slowly inside the closed cooler. It is ready to lay out and spawn when the temperature cools to 24° to 28°C. It is best to spawn the compost immediately after it has cooled, although it can be stored for a few weeks if necessary.

The compost made in this way is usually excellent, comparable to the best commercial mushroom farm compost. An added benefit is that new compost recipes can be experimented with in small quantities and in short time frames. One extra is that the drain water makes an exceptional organic fertilizer for houseplants.

Notes

1. The formula for compost here is very basic. With trial and error many materials can be formulated into usable compost. In particular, it is important to mix for the correct carbon / nitrogen ratio (saccharides / protein). Any properly balanced mixture suitable for large scale composting is suitable for use in this composter. Very useful tables of compost ingredients are included in *The Mushroom Cultivator* and *Growing Gourmet and Medicinal Mushrooms*, both by Paul Stamets.

2. Some species of mushrooms culture well on ordinary pasteurized straw with no additions. This composter is ideal to pasteurize straw. It is much simpler and more accurate than immersion in hot water or other methods. Just load with shredded dried straw and pasteurize at greater than 60° for 4 to 6 hours. Allow to cool slowly covered, and spawn when the temperature is less than 28°C. Typically the straw will be at proper moisture content when unloaded.

Compost Tek

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/composttek.htm

Table of Contents:

Phase I: Making Mushroom Compost
Phase II: Finishing the Compost

This tek is for large scale composting but could be modified for a smaller scale operation.
Mushroom farming consists of six steps, and although the divisions are somewhat arbitrary, these steps identify what is needed to form a production system.

The six steps are Phase I composting, Phase II composting, spawning, casing, pinning, and cropping.
These steps are described in their naturally occurring sequence, emphasizing the salient features within each step.

Compost provides nutrients needed for mushrooms to grow. Two types of material are generally used for mushroom compost, the most used and least expensive being wheat straw-bedded horse manure.
Synthetic compost is usually made from hay and crushed corncobs, although the term often refers to any mushroom compost where the prime ingredient is not horse manure. Both types of compost require the addition of nitrogen supplements and a conditioning agent, gypsum.

The preparation of compost occurs in two steps referred to as Phase I and Phase II composting. The discussion of compost preparation and mushroom production begins with Phase I composting.

Phase I: Making Mushroom Compost

This phase of compost preparation usually occurs outdoors although an enclosed building or a structure with a roof over it may be used. A concrete slab, referred to as a wharf, is required for composting. In addition, a compost turner to aerate and water the ingredients, and a tractor-loader to move the ingredients to the turner is needed. In earlier days piles were turned by hand using pitchforks, which is still an alternative to mechanized equipment, but it is labor intensive and physically demanding.

Phase I composting is initiated by mixing and wetting the ingredients as they are stacked in a rectangular pile with tight sides and a loose center. Normally, the bulk ingredients are put through a compost turner. Water is sprayed onto the horse manure or synthetic compost as these materials move through the turner. Nitrogen supplements and gypsum are spread over the top of the bulk ingredients and are thoroughly mixed by the turner. Once the pile is wetted and formed, aerobic fermentation (composting) commences as a result of the growth and reproduction of microorganisms, which occur naturally in the bulk ingredients. Heat, ammonia, and carbon dioxide are released as by-products during this process. Compost activators, other than those mentioned, are not needed, although some organic farming books stress the need for an "activator."

Mushroom compost develops as the chemical nature of the raw ingredients is converted by the activity of microorganisms, heat, and some heat-releasing chemical reactions. These events result in a food source most suited for the growth of the mushroom to the exclusion of other fungi and bacteria. There must be adequate moisture, oxygen, nitrogen, and carbohydrates present throughout the process, or else the process will stop. This is why water and supplements are added periodically, and the compost pile is aerated as it moves through the turner.

Gypsum is added to minimize the greasiness compost normally tends to have. Gypsum increases the flocculation of certain chemicals in the compost, and they adhere to straw or hay rather than filling the pores (holes) between the straws. A side benefit of this phenomenon is that air can permeate the pile more readily, and air is essential to the composting process. The exclusion of air results in an airless (anaerobic) environment in which deleterious chemical compounds are formed which detract from the selectivity of mushroom compost for growing mushrooms. Gypsum is added at the outset of composting at 40 lbs. per ton of dry ingredients.

Nitrogen supplements in general use today include brewer's grain, seed meals of soybeans, peanuts, or cotton, and chicken manure, among others. The purpose of these supplements is to increase the nitrogen content to 1.5 percent for horse manure or 1.7 percent for synthetic, both computed on a dry weight basis. Synthetic compost requires the addition of ammonium nitrate or urea at the outset of composting to provide the compost microflora with a readily available form of nitrogen for their growth and reproduction.

Corn cobs are sometimes unavailable or available at a price considered to be excessive. Substitutes for or complements to corn cobs include shredded hardwood bark, cottonseed hulls, neutralized grape pomace, and cocoa bean hulls. Management of a compost pile containing any one of these materials is unique in the requirements for watering and the interval between turning.

The initial compost pile should be 5 to 6 feet wide, 5 to 6 feet high, and as long as necessary. A two-sided box can be used to form the pile (rick), although some turners are equipped with a "ricker" so a box isn't needed. The sides of the pile should be firm and dense, yet the center must remain loose throughout Phase I composting. As the straw or hay softens during composting, the materials become less rigid and compactions can easily occur. If the materials become too compact, air cannot move through the pile and an anaerobic environment will develop.

Turning and watering are done at approximately 2-day intervals, but not unless the pile is hot (145° to 170°F). Turning provides the opportunity to water, aerate, and mix the ingredients, as well as to relocate the straw or hay from a cooler to a warmer area in the pile, outside versus inside. Supplements are also added when the ricks are turned, but they should be added early in the composting process. The number of turnings and the time between turnings depends on the condition of the starting material and the time necessary for the compost to heat to temperatures above 145°F.

Water addition is critical since too much will exclude oxygen by occupying the pore space, and too little can limit the growth of bacteria and fungi. As a general rule, water is added up to the point of leaching when the pile is formed and at the time of first turning, and thereafter either none or only a little is added for the duration of composting. On the last turning before Phase II composting, water can be applied generously so that when the compost is tightly squeezed, water drips from it. There is a link between water, nutritive value, microbial activity, and temperature, and because it is a chain, when one condition is limiting for one factor, the whole chain will cease to function. Biologists see this phenomenon repeatedly and have termed it the Law of Limiting Factors.

Phase I composting lasts from 7 to 14 days, depending on the nature of the material at the start and its characteristics at each turn. There is a strong ammonia odor associated with composting, which is usually complemented by a sweet, moldy smell. When compost temperatures are 155°F and higher, and ammonia is present, chemical changes occur which result in a food rather exclusively used by the mushrooms. As a by-product of the chemical changes, heat is released and the compost temperatures increase. Temperatures in the compost can reach 170° to 180°F during the second and third turnings when a desirable level of biological and chemical activity is occurring. At the end of Phase I the compost should: a) have a chocolate brown color; b) have soft, pliable straws, c) have a moisture content of from 68 to 74 percent; and d) have a strong smell of ammonia. When the moisture, temperature, color, and odor described have been reached, Phase I composting is completed.

Phase II: Finishing the Compost

There are two major purposes to Phase II composting. Pasteurization is necessary to kill any insects, nematodes, pest fungi, or other pests that may be present in the compost. And second, it is necessary to remove the ammonia which formed during Phase I composting. Ammonia at the end of Phase II in a concentration higher than 0.07 percent is often lethal to mushroom spawn growth, thus it must be removed; generally, a person can smell ammonia when the concentration is above 0.10 percent.

Phase II takes place in one of three places, depending on the type of production system used. For the zoned system of growing, compost is packed into wooden trays, the trays are stacked six to eight high, and are moved into an environmentally controlled Phase II room. Thereafter, the trays are moved to special rooms, each designed to provide the optimum environment for each step of the mushroom growing process. With a bed or shelf system, the compost is placed directly in the beds, which are in the room used for all steps of the crop culture. The most recently introduced system, the bulk system, is one in which the compost is placed in a cement-block bin with a perforated floor and no cover on top of the compost; this is a room specifically designed for Phase II composting.

The compost, whether placed in beds, trays, or bulk, should be filled uniformly in depth and density or compression. Compost density should allow for gas exchange, since ammonia and carbon dioxide will be replaced by outside air.

Phase II composting can be viewed as a controlled, temperature-dependent, ecological process using air to maintain the compost in a temperature range best suited for the de-ammonifying organisms to grow and reproduce. The growth of these thermophilic (heat-loving) organisms depends on the availability of usable carbohydrates and nitrogen, some of the nitrogen in the form of ammonia.

Optimum management for Phase II is difficult to define and most commercial growers tend toward one of the two systems in general use today: high temperature or low temperature.

A high temperature Phase II system involves an initial pasteurization period during which the compost and the air temperature are raised to at least 145°F for 6 hours. This can be accomplished by heat generated during the growth of naturally occurring microorganisms or by injecting steam into the room where the compost has been placed, or both. After pasteurization, the compost is re-conditioned by immediately lowering the temperature to 140°F by flushing the room with fresh air. Thereafter, the compost is allowed to cool gradually at a rate of approximately 2° to 3°F each day until all the ammonia is dissipated. This Phase II system requires approximately 10 to 14 days to complete.

In the low temperature Phase II system the compost temperature is initially increased to about 126°F with steam or by the heat released via microbial growth, after which the air temperature is lowered so the compost is in a temperature range of 125° to 130°F range. During the 4 to 5 days after pasteurization, the compost temperature may be lowered by about 2°F a day until the ammonia is dissipated.

It is important to remember the purposes of Phase II when trying to determine the proper procedure and sequence to follow. One purpose is to remove unwanted ammonia. To this end the temperature range from 125° to 130°F is most efficient since de-ammonifying organisms grow well in this temperature range. A second purpose of Phase II is to remove any pests present in the compost by use of a pasteurization sequence.

At the end of Phase II the compost temperature must be lowered to approximately 75° to 80°F before spawning (planting) can begin. The nitrogen content of the compost should be 2.0 to 2.4 percent, and the moisture content between 68 and 72 percent. Also, at the end of Phase II it is desirable to have 5 to 7 lbs. of dry compost per square foot of bed or tray surface to obtain profitable mushroom yields. It is important to have both the compost and the compost temperatures uniform during the Phase II process since it is desirable to have as homogenous a material as possible.

Worm Composting

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/Worm_Compost.html

Table of Contents:

General information
How You Do It
What You Need
Harvesting Your Compost
Common Problems

General information

Worms can compost rubbish faster than any other type of composting method. Worms also are very efficient in digesting kitchen food wastes. Each day a worm eats half its weight in food. The care and feeding of worms take far less effort than maintaining an outdoor compost pile. Some of the benefits of keeping a worm bin include: recycling kitchen food waste, reducing waste disposal costs, producing soil amendments or fertiliser for house and garden plants, and having a ready supply of fishing worms.

worms

A worm bin is a self-contained system. As with any system, several components are involved.

Red worms are the most satisfactory worms to use in a home vermicomposting (composting with worms) system. The species of red worm best suited for a worm bin is Eisenia foetida pronounced "I see nee a fet id a." Eisenia Foetida is known by several common names: red worm, brandling worm, red wriggler, manure worm, and fish worm among others. Starter worms of this species for a worm bin may be found in old compost piles (ones that no longer generate any heat) or from local bait suppliers.

Once the worm bin is constructed, make bedding for the worms with shredded and moistened newspaper or cardboard. Maintain the system by burying food wastes throughout the bin on a rotational basis. Every three to six months move the compost to one side of the bin and add new bedding to the empty half. The worms will soon move to the new bedding. Harvest the compost and add new bedding to the rest of the bin.

How You Do It

This system is composed of a box to contain the worms (see back for a description of how to build a worm bin); the worms themselves; a controlled environment; and regular maintenance procedures. Worm compost is made in a container filled with moistened bedding and red worms. Add food waste and with assistance from micro-organisms, the worms will convert bedding and food waste into compost. Worm composting can be done year-round, indoors in schools, offices and homes. It is a natural method for recycling nutrients in food waste without odour. The resulting compost is a good soil conditioner for houseplants, gardens and patio containers.

What You Need

1. A container (made of wood or plastic)
2. Worms (500-2,000 red worms)
3. Bedding (shredded newspaper, corrugated cardboard and/or leaves)
4. Kitchen waste (fruit and vegetable waste)

1. The Container

Buy or build a container (see How to Make a Wormbin) or use an old dresser drawer, box or barrel. Wood containers are absorbent and good insulators for worms. Plastic containers do work but compost tends to get quite wet and may need more drainage. Raise the bin on bricks or wooden blocks for air circulation. Place a tray underneath to capture excess liquid, which can be used as liquid plant fertiliser. Some newer containers replace drainage holes in the bottom with a venting system higher in the container.

Worms like a moist, dark environment. Their bodies are 75 to 90 per cent water and worms' body surfaces must be moist for them to breathe. Cover the bin to conserve moisture and provide darkness. Indoors, place a sheet of dark plastic or burlap sacking on top of the bedding. Outdoors, use a solid lid to keep out unwanted scavengers and rain.

Worm bins can be located in a cellar, shed, garage or balcony. They need to be kept out of the hot sun, heavy rain and cold. When temperatures drop below 4 degrees C, bins should be kept in a frost-free place, heated or well insulated. The container can be heated with an electric heating cable placed in the bottom third of the container. To insulate, surround the container with (5 - 7.5cm.) rigid polystyrene, which can be bought from a builder's merchant.

2. The Worms

Red worms are best suited to worm composting. They are often found in aged manure, compost heaps, and piles of leaves. They are also known as red wriggler, brandling and manure worms. Their official names are Eisenia foetida and Lumbricus rubellus. Red worms are best suited for composting because they thrive on organic material, such as food waste. Earthworms, on the other hand, are better suited to life in the soil and shouldn't be used in a worm bin.
You can get your worms from an existing compost bin, purchase them or find a horse stable or farmer with an aged manure pile.

Red worms mature sexually in 60-90 days and can then produce cocoons, which take 21 days to hatch baby worms. Once they start breeding they can deposit two to three cocoons per week with two baby worms in each cocoon. The limits on their reproduction include availability of food and room to move and breed. So worm populations don't usually exceed the size of the container.

Lumbricus terrestris

3. The Bedding

Provide damp bedding. Suitable bedding material includes shredded newspaper and cardboard, shredded fall leaves, chopped-up straw and other dead plants, seaweed, sawdust, dried grass clippings, aged manure and peat moss. Peat moss is quite acidic and should be well soaked and combined with other bedding material. Vary the bedding in the bin to provide more nutrients for the worms and to create richer compost. Two handfuls of sand or soil will provide the necessary grit for worms' digestion of food.

Fill the bin with a mixture of damp bedding so the overall moisture level is like a "wrung-out sponge." Lift the bedding gently to create air spaces. This maintains aerobic activity, helps control odours and gives the worms freer movement.

4. The Food Waste

Your worms will eat any soft organic food scraps such as vegetable waste generated during food preparation, potato peelings, vegetable peelings, grapefruit and orange rinds, cantaloupe and watermelon rinds, outer leaves of cabbage and lettuce. Plate scrapings, spoiled food from the refrigerator, coffee grounds, tealeaves or eggshells are wastes that you may want to feed your worms.

To avoid potential rodent problems do not add cooked meats; decaying meat can produce offensive odours, dairy products, oily foods or grains.
Needless to say such things as glass, plastic, tin foil, wire ties, bottle caps, rubber bands and heavy shiny type paper should not be put in the wormbin.

For the first couple of weeks, collect food wastes in a container and weigh it. Do this for two weeks to get an estimate of average food waste. Your bin should provide one square foot of surface area for every pound of food waste per week. And you will need two pounds of worms for every pound of food waste per day. Once the worm colony has settled down and established itself, the waste can be put directly in the wormery.

Harvesting Your Compost

After six weeks, the bedding will be noticeably darker with worm castings. After two and a half months have passed, there will still be some of the original bedding visible in the bin plus brown and earthy-looking worm castings. Although food waste is being added regularly, the bedding volume will gradually decrease. As more bedding is converted into castings the worms will begin to suffer. It is time to decide whether you want to do "some fuss" or "more fuss" worm composting.

"Some Fuss" Harvesting
Some fuss worm composting involves moving the finished compost over to one side of the bin, placing new bedding in the space created, and placing food waste in the new bedding. The worms will gradually move over to the fresh bedding and food waste, and the finished compost can be harvested. Fill the space created with new damp bedding.

"More Fuss" Maintenance
If you want to use all of the compost at once, dump the bin's entire contents onto a large plastic sheet and make piles of material. Use sunshine or a hundred watt light bulb to drive the worms to the bottom of the piles. Worms don't like bright light because the single cells on the epidermis (skin) react to light. Scoop off the tops of each pile until all you have left is the worms. Most children love to help! Watch out for the tiny, lemon-shaped worm cocoons that contain the baby worms. Mix a little of the finished compost in with the new bedding of the next bin.

Show a Little Respect
We must act responsibly if we take worms out of their natural environment and place them in containers. They are living creatures with their own unique needs, so it is important to create and maintain a healthy habitat for them to do their work. If you supply the right ingredients and care, your worms will thrive and make compost for you.

Common Problems

Unpleasant Odours
Unpleasant odours may waft from your bin when it is overloaded with food waste. If this occurs, gently stir up the contents to allow more air in. Stop adding food waste until the worms and micro-organisms have broken down what food is already in the bin. Check the drainage holes to make sure they are not blocked and drill more holes if needed. If the moisture level seems right, the bedding may be too acidic from citrus peels and

other acidic foods. Adjust by cutting down on acidic wastes.

Fruit Flies

Fruit flies aren't harmful, but they are a nuisance, and a very common problem with worm bins. Discourage fruit flies by always burying the food wastes and not overloading the bin. Keep a plastic sheet; piece of old carpet or a lid on the compost's surface in the bin. Unfortunately there is no easy answer to the fruit fly problem but adding a spider or two helps reduce fruit flies. If flies persist, move the bin to a location where flies will not be bothersome.

Culture source and cloning

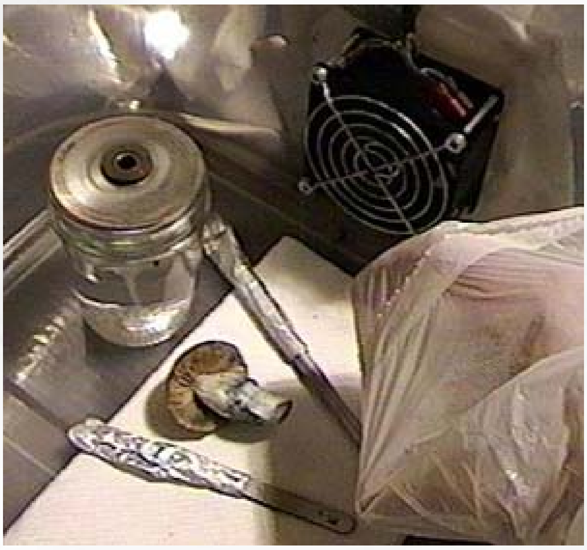
by

9er

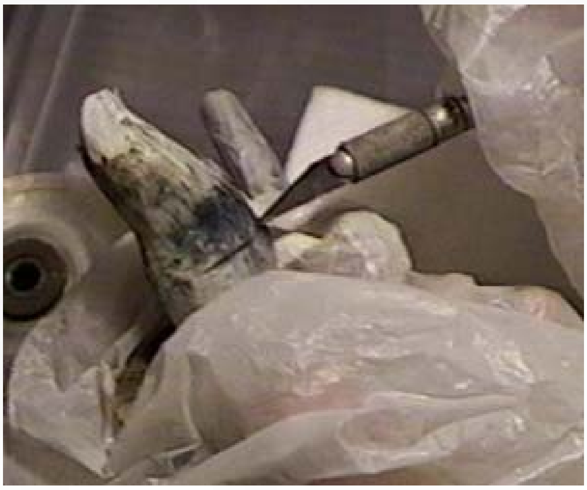
original source: http://mycotopia.net/archives/discus/messages/5/3384.html

Culture source:
Either acquire a spore syringe or get started from a fresh fruit body.
Spores can be injected into the whole grain recipe or the MMGG recipe.
It /seems/ that spores work better in the MMGG recipe, but more tests need to be made. After getting a strain started, you can farm it for a long time with the procedure below.

Cloning procedure:
Take a healthy mushroom for cloning around the time that the veil breaks. You want one that is still growing vigorously, not an abhort. Place it in the transfer chamber. Avoid fruit with brown streaks on the stem. Use a sterilized Xacto knife and tweezers to extract a clean chunk of stem to add to sterile water in a mason jar.

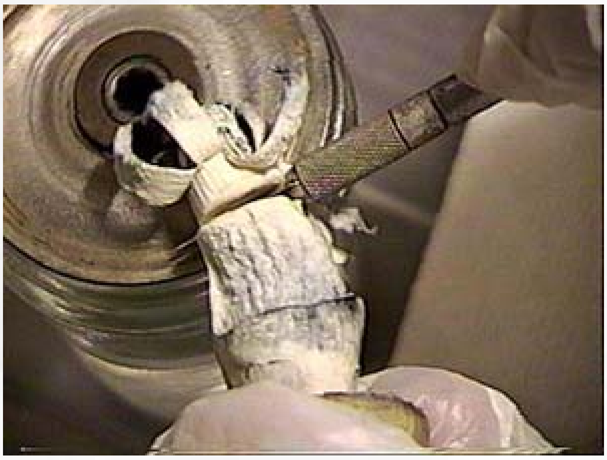


This is done by holding the freshly picked shroom near the cap, and using the sterile knife to cut a ring around the stem about 2" from the bottom. Only cut a little way into the stem.

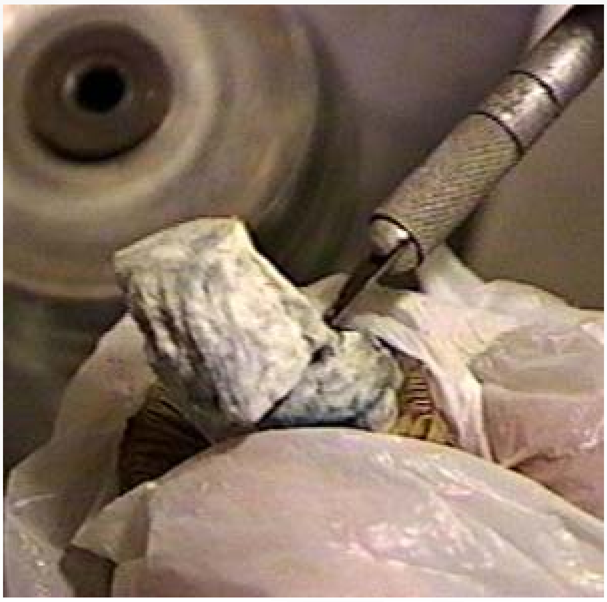


Use sterile tweezers to **grab and peel the surface layer back toward the base of the stem until it resembles a peeled banana.**

Then cut the stem just above the peels. Once you've removed the Al foil from the sterilized blade assembly and mason jar, You have a sterile table to work on for cutting off the stub.



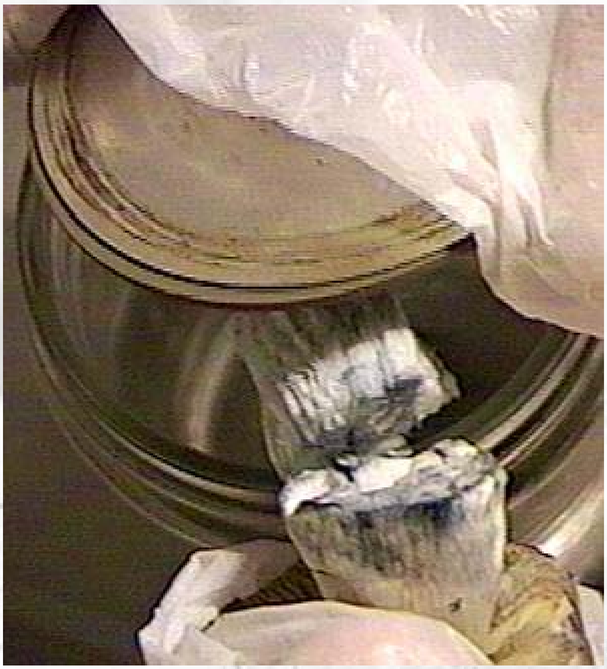
Then slice off the clean chunk and let it fall into a mason jar (8 oz regular mouth) 2/3 full of sterilized water. The jar is prepared by covering with the metal blade assembly and seal from the blender and that is covered with Al foil and sterilized. The transfer is done in the glove box. For more details see the "Blender Usage" page.



It turns out that a regular mouth mason jar has the same size and thread as the plastic blender container part from an Osterizer blender (probably other brands as well), so after dropping in the piece of stem, remove the jar from the chamber, then screw on the base of the blender and proceed to blend for about 3 or 4 seconds at the fastest speed. Allow to stop, then repeat. Be sure to hold the jar while blending. When done, remove the blender base, put the jar (w/seal and blades) in the chamber, remove the blades and seal, then immediately cover with a new baggie (in the transfer chamber). Then draw syringes of the inoculant water by piercing the plastic bag. This procedure has proved to be very effective. For pictures of the details of the blender parts and mason jar assembly go to the Blender Usage page.

Additional info/tips:
1) It is best to use a rubber band around the shroom water jar/baggie to keep out contaminants.

2) If one cuts the peeled chunk of stem almost all the way thru, then one can lift the blender parts just enough to stick the stem thru and finish severing the sterile chunk from the rest of the stem with the edge of the jar and the blender blade assy.



3) The shroom water has been stored for 1 week with no harm and it's gone bad in 2 days. I have no idea how long it can remain viable. It is MUCH better to make up the shroom water and use it immediately. The growth rates are incredible when the shroom water is fresh. One pint cakes (rice only) have been birthed 10 days after inoculation. 14 to 21 days is more common.

4) The knife and tweezers are sterilized in Al foil sheaths in the pressure cooker.

5) Eventually the cloned strain will lose stamina and stop producing and growing vigorously. It is a good idea to take a spore print and start a new culture every year or so (at least.) See the spore print procedure.

LC Cloning - Newbie friendly pictorial tek

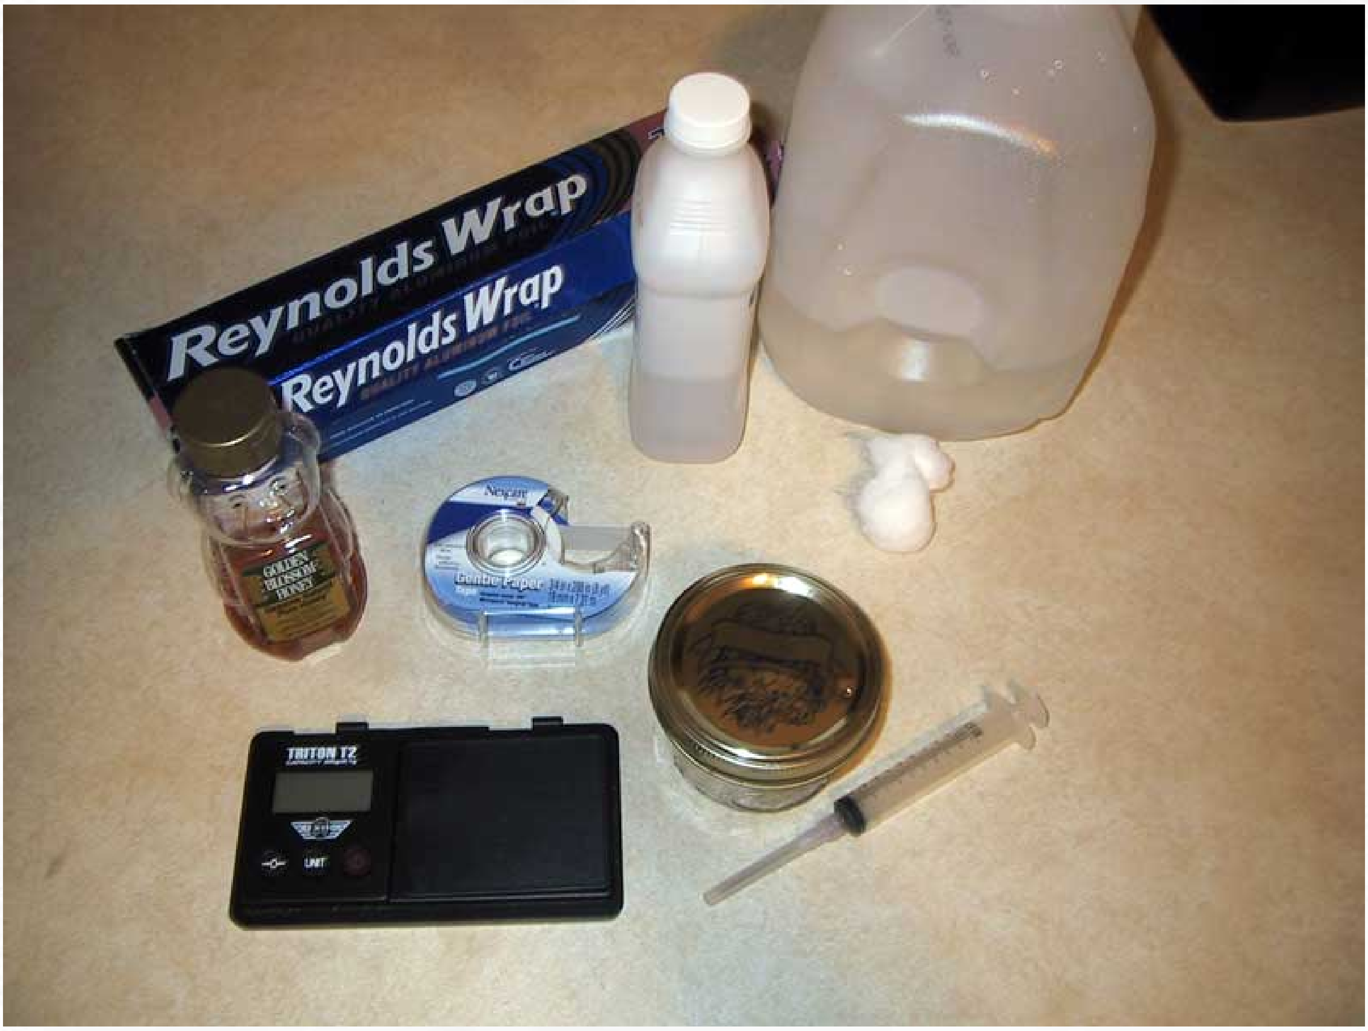
Cloning with liquid culture, the easy way

by

creamcorn

original source: http://www.shroomery.org/forums/showflat.php/Number/5874305

This is a tek on how to clone without the need for advanced methods, agar, gloveboxes, flowhoods, or even a pressure cooker. Its simple enough for a beginning pf-tek'er to complete. You'll probably also find some good LC tips here if you've been struggling with those. As always, comments, questions, suggestions, and kudos appreciated! I apologize if this is a little wordy, but I wanted to cover all the bases. I've been answering newbie questions long enough to anticipate them before they've even been asked, so hopefully I got everything covered.



Materials needed.

Step 1. Prepare a small liquid culture

For this, I am of the thinking that SIMPLE IS BEST. My liquid culture containers are simple jars, with a regular old metal lid and ring, with a single hole punched at the top. The hole should be big enough to accomodate your needle, with a little room to spare so that a vaccum is not created later when aspirating solution. The hole is covered with a piece of micropore tape, and then covered again either with a coffee filter and rubber band, or a piece of aluminum foil loosely crumpled, to act as a dust cover.

Jar with just a hole.

Recipe: Recipe is the same as any liquid culture; 4% media by weight. You may use any of the standard LC media, honey, caro, dex/malt will all work. Water quality is important to LC. I find that distilled works best, and gives the clearest solution. You may also use bottled spring water, or tap water filtered with a Brita pitcher or the like. (Your mileage may vary depending on the quality of your locality's tap water. In my area, I avoid it.) Honey quality also varies widely - I've found this particular variety works fantastic for me, and doesn't make any sediment in my LC's even without filtering. You may need to experiment with brands and types of honey to find one that works. For a sure thing, you can definitely use karo, and if you're industrious and willing to hunt down dextrose/malt, by all means use that. The honey I've got seems to outperform karo, so it works for me.

TRITON T2
CAPACITY 300gx0.1g
4.0
→0←
UNIT

Measure 4 grams of media per 100 ml of water.

When cloning, I generally start with a small half pint container. You'll see I've measured exactly 4 grams of honey. Water weighs 1 gram per 1 ml, so I'll fill it to the 100 ml point. I nuke this in the microwave for about 30 seconds, just to warm the water, allowing the honey to dissolve easier, and I stir it up. Obviously, when making larger LC's, just do the math to stay at that 4% mark.

This will be my "master" culture. From this culture, small samples are taken to start larger liquid cultures in quart jars that are my "working" culture that I use for inoculation. The remainder of the master culture can be refrigerated, where it will keep for several months. When I run out of working culture, it only takes a few drops of the master to start a whole quart of working culture all over again. Its important to take from the master each time, rather than go from working culture to working culture, so that each of your working cultures are "second generation."

Step 2. Sterilization

In my opinion there's only two acceptable ways to sterilize LC for consistent results: steaming, and pressure cooking. This gives those an option who don't own a PC. Microwaving works for some, but I don't trust it. If it works for you, fantastic, go with it.

In both cases, wrap the top of your jar in tinfoil as usual, and take a syringe about half full of water, and also wrap it in tinfoil. We'll sterilize them both at the same time.

Syringe with some water;

wrapped in foil and ready to sterilize.

Steam sterilization:
Place a cloth at the bottom of a pot with a tight fitting lid. Use an inch or two of water. Place your jar and syringe inside. Bring to a slow rolling boil. Once a boil has been achieved, start your timer for 30 minutes. At the end of 30 minutes, turn off the heat, walk away and don't even think about it for a few hours. Let it cool.

PC sterilization:
Use your PC as per its instructions with something to keep the items off the bottom of the pot (like a cloth, or a rack if you got one.) Slowly bring up to pressure. 10psi is plenty if that's all you got. 15psi is fine too. Do not exceed 15psi. Once at desired pressure, set your timer for 15 minutes. DO NOT exceed 15 minutes. When the time is up, cut your heat and walk away until its cooled.

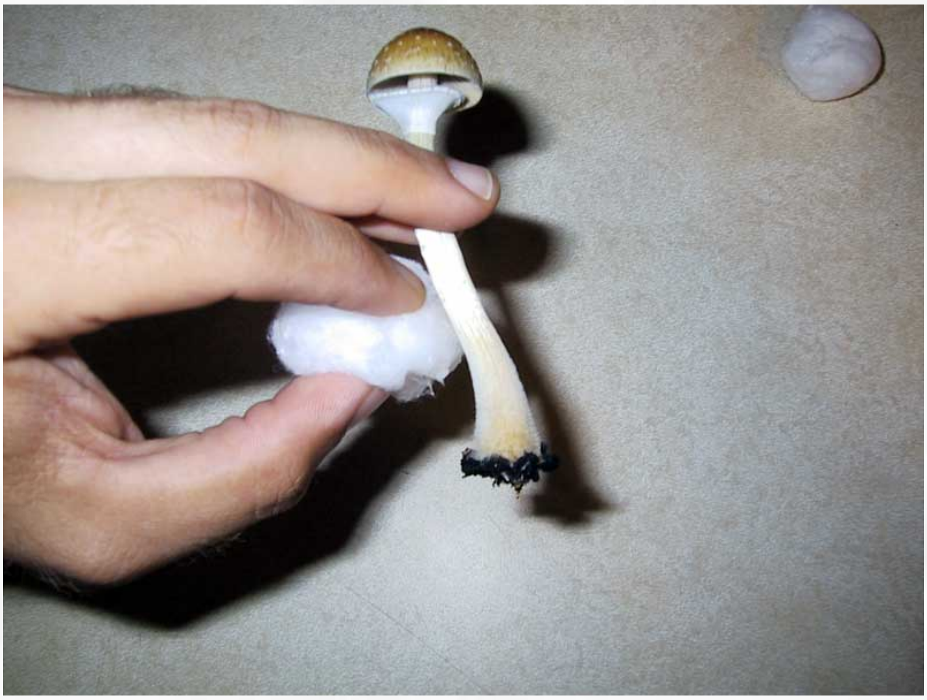
Step 3. Select specimen

Find a nice looking fruit! We want to clone desirable qualities. Many have different ideas as to which fruit to clone; ie. choosing the first one up might give you a speedy isolate to work with later, choosing a big one might give you a genetic predisposition towards large fruits; and so on. I believe that there's just so much variation in growing methods, even though we are taking a clone, we have no idea how closely its going to resemble its "parent" when grown out later - so I take a nice looking fruit and hope for the best. You'll find out in time if it was a good choice or not when you get your first crop of clones in, and can assess how long they took to grow, the yields you got, and of course, the potency after sampling some. If it didn't turn out as good as you were hoping, don't fret, you can try again from a different specimen from a different multispore grow. If it did turn out for you, treat that master culture like gold!

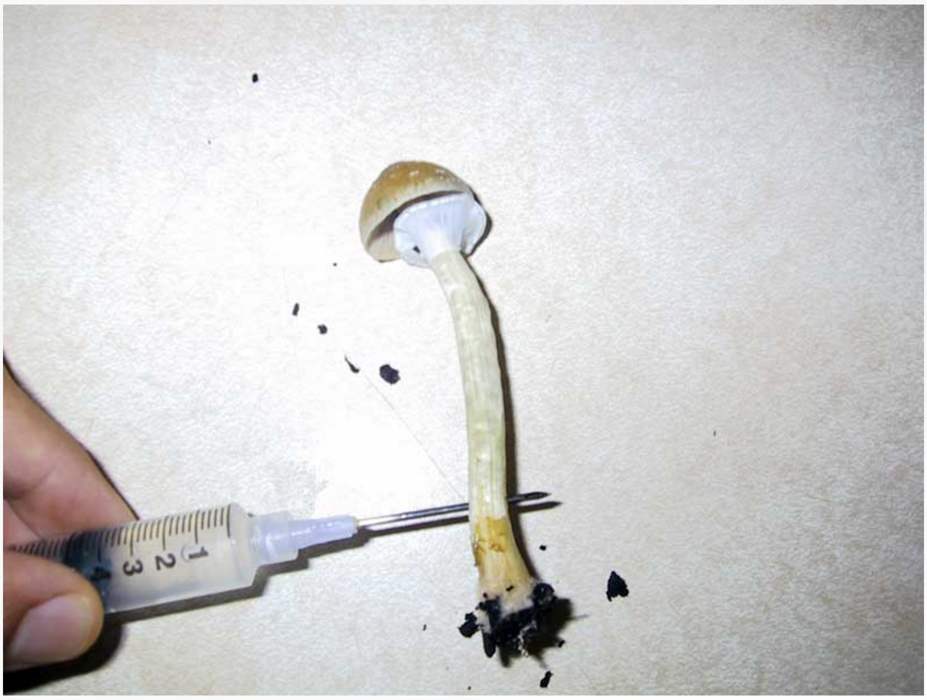
Step 4. The biopsy

Here's where you'll want to practice your sterile procedures. No need to go overboard, all I do is ensure there's no drafts, clean my work surface, wash my hands with antibacterial soap, and hit them a second time with some hand sanitizer. If spraying Oust into the air and washing everything with bleach or whatever makes you happy, knock yourself out.

Take your fruit, and clean the stem thoroughly with an isopropyl soaked cotton swab. Clean it all the way around. Do not touch any areas with your hand near the site of the biopsy. Quickly wipe your needle with iso (flame if desired, I don't bother - we did just sterilize it after all!) and stab it straight through the stem to the other side.

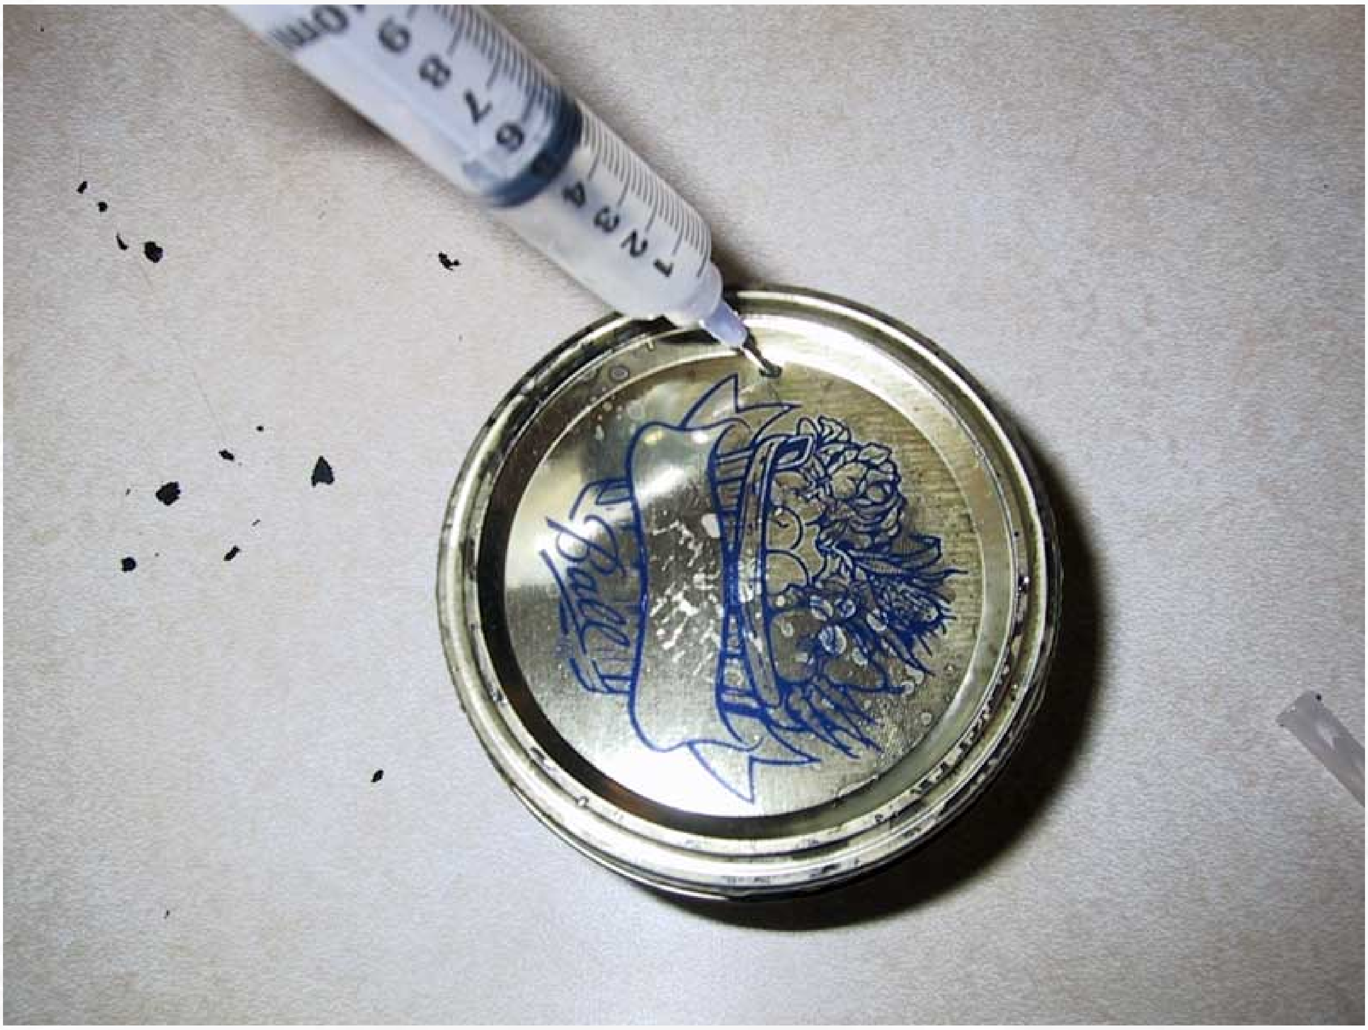


Swabbing the stem;



taking the biopsy. (This is where 3 hands would come in handy, somebody had to work the camera! You'll obviously want to hold the mushroom near the top and swab the bottom, and when taking a biopsy not allowing the mushroom to touch any surfaces.)

Remove the foil from your prepared LC jar. Using a dry cotton swab, clean up any condensation/moisture on the lid. Then using an alcohol soaked one, clean the lid again. Give the needle another wipe, insert into hole, and push the plunger. The water in the syringe will force the cross section of the stem out into your LC. Quickly cover the hole with a piece of micropore tape (if your lid is still wet with alcohol, that's fine, the tape will stick just fine once it dries) and cover with a dust cover of your choice.



Knock 'er up! You might need to push a little hard, but the liquid will force the piece of stem out.

You can sort of make out the piece of stem in there.
My solution really was clear I promise, this was without a flash to reduce glare
and hopefully get a picture of the piece inside.

Don't
forget
to
label!

Foil loosely back on as a dust cover, don't forget to label!

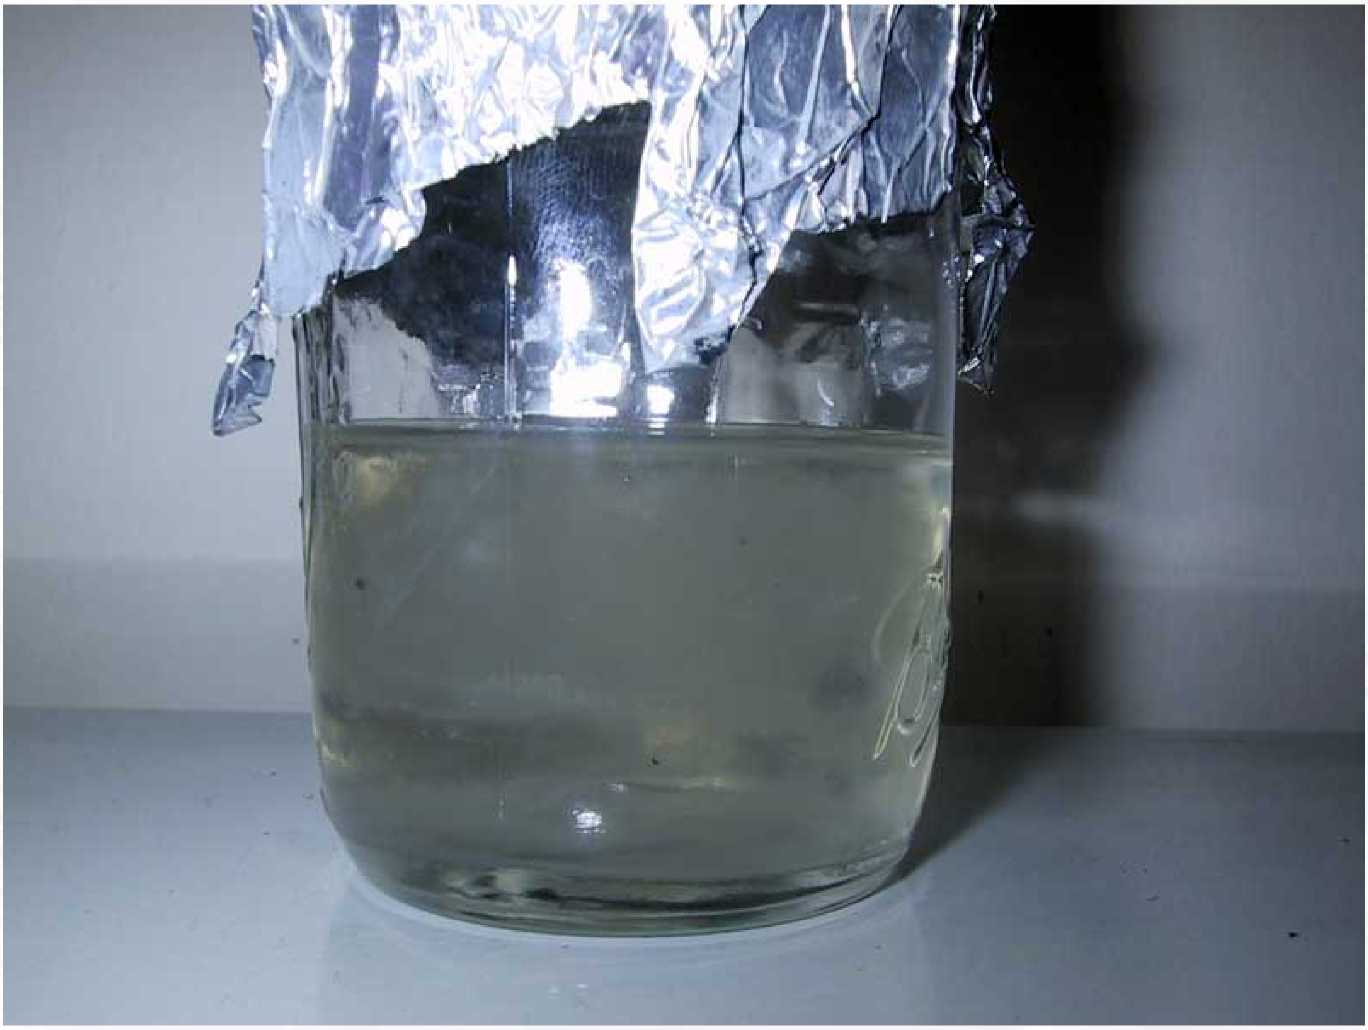
She's looking a little beat up after being stabbed!

Incubate, and wait.

7-10 days later you should have a nice looking cloud of mycelium.

As they do on the cooking show.... "here's one we've prepared earlier!" When doing all the above steps, you'll want to work quickly to avoid contamination. I obviously stopped to photograph everything so who knows if we got a clean sample here.

Here's a "master" culture, about 10 days colonizing. You'll notice some is already missing, as I've used some of the solution to inoculate larger LCs.



The master culture. Notice its very thick! Obviously my little micropore'd hole provides all the gas exchange you need.
You'll also note a few dark specs, that's leftover pieces of the stem. It kind of dissolves and breaks up to an extent.
It turns dark blue/grey, because you bruised it for sure when poking it with a needle!

Here's a working culture, this is 5 days old. It was started with about 4cc of solution from a master, and then constantly agitated on a magnetic stir plate. Use it (or make it) if you got it, but its not necessary. They'll colonize great without, it just takes a little longer. LC to LC is FAST no matter what.

Thermolyne
SYBRON
Type 17400 Stirrer
2
4
6
8
.15 Amps
120 Volts
50/60 Hz

Enough LC to kill a small army, from a few CC's of the master.

Some additional LC tips:
-Follow the measurements carefully. You'll get no growth or poor growth if you use too much media. When in doubt, use a little less than 4%.
-If your myc cloud is thick and can't be sucked up easily, suck up what you can, and squirt it back down into the cloud. It will break right up.
-To aspirate from my single-hole jars, I just tilt them on their sides, being very careful not to spill any out the hole. The needle reaches in just fine. I gently swirl it around and capture as much mycelium in the syringe as possible. The thicker the better!
-People often ask, "when is my LC done?" Well, its done when you want to use it! If there's enough mycelium floating around that you can capture a bunch in your syringe, go for it. The rest will continue to grow until the

nutrients have run out. When it doesn't seem to be growing any more, you can refrigerate it, and it lasts many months. (6 or more.)
-When I aspirate, I take an alcohol soaked cotton swab, and swab right over the piece of micropore tape. I then stick the needle right through the tape, and fill up my syringe. I quickly cap the syringe, and quickly replace the soggy piece of micropore tape with a fresh piece. You can certainly use any number of the fancy LC container teks out there, but it doesn't get much simpler than a hole with a piece of tape on it kids.
-LABEL EVERYTHING. Keep track of dates, strains, generation number, anything you feel relevant.
-A perfectly prepared karo or honey LC should be nearly crystal clear. Dex/malt will produce a yellowish solution. If your karo or honey solution turns yellow, you may have overcooked. Did you follow my sterilization directions to the T? Either way, a little overcooked will still work, its not the end of the world. Likewise, sediment from honey, or from malt/dex will not harm a thing - it just makes spotting possible contamination a little more difficult. Some take some pretty extreme measures to filter their solutions before sterilizing to get the sediments out, I'll leave it up to you.
-Unless you want cracked jars, heed my advice and allow them to cool gradually and naturally.

Quick Cloning FAQ:

Q: Why clone?
A: Cloning ensures the most efficient use of your substrate, the best possible yields, and once you've found a clone that has a desired potency, the most consistent potency! See, with a multispore inoculation, you end up with many many strains (each dikaryotic spore mating is technically its own strain). These strains sometimes grow side by side, and sometimes mate a second time by a process known as anastomosis. So in the end, you've got a cournicopia of genetic materials and strains. Not all of these are capable of fruiting! I think of these strains as "guy on the couch" strains - they'll gladly eat your food and drink your water, but never produce any fruits for you. By cloning an actual mushroom, we're dealing with one single isolated strain that's already proven itself as being able to fruit. Another benefit to cloning is nice even pinsets. When you're dealing with all the mixed strains of an MS inoculation, some parts of your substrate are going to be ready to pin before others. With clones, they're all going to be ready at nearly the same time, resulting in even, consistent pinsets, and more defined flushes.

Q: If I clone a large fruit, will the resulting fruits grown from it be large?
A: Maybe! If you have identical twin humans and one eats nothing but cheeseburgers and plays Nintendo all day, while the other eats a balanced diet and exercises regularly, are they going to be the same shape and size? Of course not. There's genetic predisposition of course, a large fruit obviously has the genetics needed to be capable of producing more large fruits - but conditions have to be right. Its nature AND nurture. Nurture is very, very important, so take care of your babies.

Q: If I clone a mutant, will the resulting fruits be mutants?
A: Again, maybe! It depends on why the mutation occurred. If there was a genetic problem that caused the mutation, then sure, it will carry over. You might not end up with the same exact mutations later, but you'll end up with some funky fruits. If the mutation occurred because the fruit came in contact with a harmful chemical while growing, that's not going to carry over - the result may very well be a healthy clone. Nature versus nurture again. Using the human analogy, if I cloned a person with 6 toes (yeah it happens), the resulting clone will be born with 6 toes. If I clone a human who broke their leg, of course the baby isn't going to be born with a broken leg! Got it?

Q: Where should I take my biopsy?
A: I've found that near the base of the stem works best. I can't tell you why, I don't know, just my experience.

Q: How mature should the mushroom be before cloning?
A: As the viel breaks, or just before. If it starts to sporulate, it will drop spores on the stem. You're likely to get spores mixed in with your biopsy, and guess what - its no longer going to be a clone! You want to avoid spores.

That's all for now, if anybody has any ideas for the little mini clone FAQ above, ask away, and I'll answer to the best of my knowledge (or maybe others can chime in and help out.) The only way I can make this any simpler is if I were to come to your house and do it for you - and unless you got boobies, and plan to pay travel expenses, it ain't happening. Thanks for reading, and good luck.

The Outdoor Cultivation of Psilocybe cubensis

by

Gerald Peppard

original source: http://mycotopia.net/archives/discus/messages/5/118001.html

We have seen a plethora of information on indoor cultivation. But what I find amazing is there is little or no information on outdoor cultivation of Psilocybe cubensis. Let me ask you a couple of questions: Are you tired of small mushrooms? Would you like a mushroom the size of a small dinner plate? Are frustrated by the number of steps involved? Are you always worrie about the posibility of contamination?

This species (P. cubensis) can be grown outdoors with a high rate of success and all with a limted amount of money and time. Eventhough P. cubensis is a warm sub-tropical mushroom, I believe it can be grown outdoors as far north as Canada. In order for a mushroom to grow it must have the right enviroment. As long as you meet the requirements, anybody can be succesfull.

Let's talk about a location for these wonderous creatures. Clumps of grass, yes that's right clumps of grass. You can look at a clump of grass as if it was a terrium. The grass will act like a barrier and keep humidity at a high level for well over 6 days. If the humidity level ever drops to low, take a hand mister and spray until the desired level of humidity is reached. The grass will then help with a couple of things by filtering the sun and absorbing CO2 during the day.

What substrate is suitable? Aged cow dung is best: but I would say horse dung might be a good subsitute. A good way to determine whether or not the dung is aged enough, is observing other fungi growing from the dung. Some of the species you might encounter are Psilocybe, Panaeolus, Coprinus, etc... Another way of determining whether dung is aged enough is checking it out. I like to take my walking stick and flip the pies upside down and then break it in half with my stick to check the moisture content. It should be the same consistency throughout the whole piece of dung, dry. After awhile you will be able to judge what is suitable and what is not. Once it is determined to be suitable, pick it up and place it in a collection bag. A good bag for collecting cow pies is an old pillow case. For those of you who are a little squeamish about handling cow dung, go buy a pair of RubberMaid kitchen gloves. Pick up all sizes of dung for your future endeavor.

Personally I don't pretreat my cow dung before use. The problem I see with pretreating the dung, is there is a chance you might kill some of the beneficial microbes. Besides that P. cubensis mycelium is known for its rapid and highly aggressive behavior. There are maybe a few other fungi whose mycelium can compete with P. cubensis in the wild. Here are a few suggestions for those of you who want to pretreat their dung. First take the dung and place it on a cookie sheet. Then place the dung in the oven at 150 degrees for 30 minutes. Second you can microwave 4 cups dung with a 1 cup of water for about 5 minutes.
Watering your homemade cow pie is not difficult, just water the pie every 3 to 5 days. How much water to apply depends on how big of a pie you made. Personally I like to collect rainwater for my pies; but tap water will do if you let it stand for 24 hours before use. Water the pies directly from the top with a watering can. Apply the water all over the pie while allowing at least 60% of the water to flow through the medium and loose substate. This will allow the water to transfer itself throughout the whole pie. Overwatering is not hard to do, so when the water comes rushing from out the pie you have overwatered. If you do overwater just add 1 to 2 days to your normal watering schedule before you water next.

Look around your yard and find a healthy clump of grass. An ideal clump of grass would be over 2 feet high with a diameter 2 to 3 feet. Clean out the middle of the clump to a diameter of 1 to 1 and a half feet. There should be nothing in the middle of the grass clump except bare ground. (fig 1)

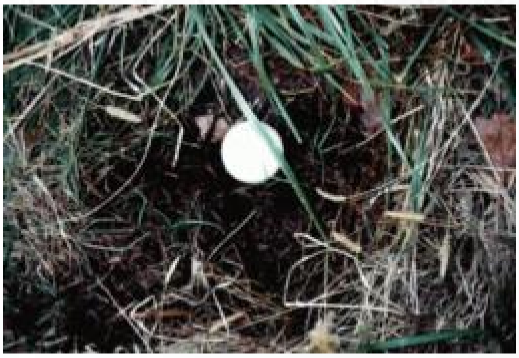


Figure 1

Now is a good time to separate the dung into three piles; large, medium, and small crumbled up pieces. (fig 2) If you don't have enough medium pieces break up some of your large pieces. The same goes with the small pieces just crumble up some medium or large pieces. Soak your dung at least 2 to 4 hours in a large container. When done soaking wring out the crumbled up dung to the point where it is moist; but not soaking wet.

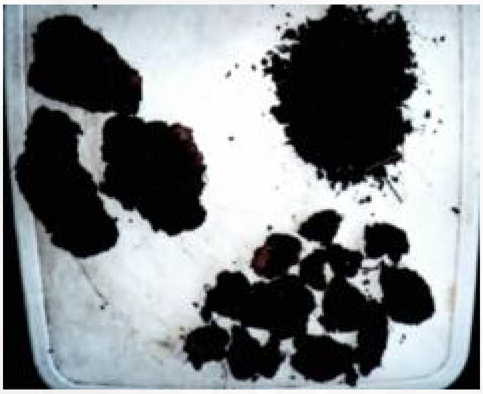

Figure 2

Fill in the area you had previously cleaned out with a 2 inch layer of the small substrate. (fig 3)

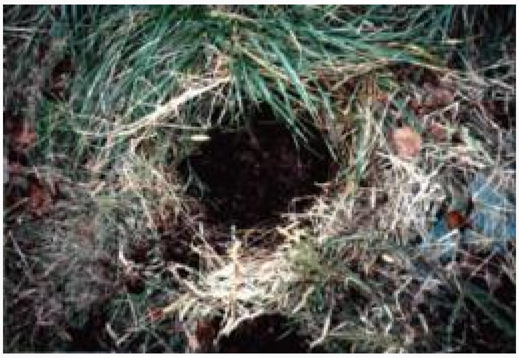

Figure 3

Take a print or a syringe and apply half of your spores on the exposed substrate. Place the larger pieces of substrate along the edge of the small substrate. (fig 4)

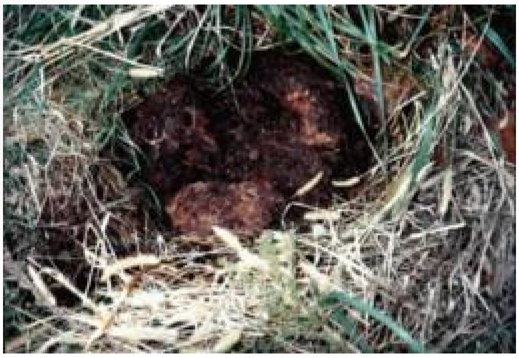

Figure 4

Fill in the inside with the medium substrate, and fill in the cracks and crevices with the small loose substrate. (fig 5) Use the rest of your spores and apply them to the top of your homade cow pie. Take the the grass that surrounds your homemade pie and fold it over. The idea is to make a dome, and not to have the grass lay flat on top of your substrate. Wait until your pie slightly dries up before you water the pie for the first time.

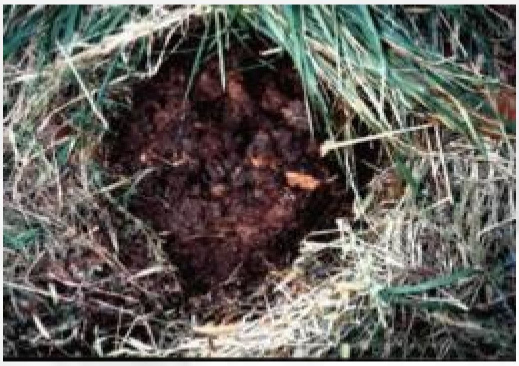

Figure 5

In Spring it would be best to wait until the night temps average in the mid 50's and the day temps were at least in the high 60's. The more you water the substrate the faster the mycelium will grow once it is established. Don't overwater because your mycelium can drown. When you are ready, let your substrate dry up somewhat and those cubes will begin to pop up. If you have the urge to water more when the caps start sprouting or the humidity level is to low use a hand mister. After a flush you may water the pie heavily again. Then just repeat the process through out the growing season. It is that simple and there is no worry of contamination or the use of sterile techniques.

A Comprehensive Sclerotia Cultivation Guide

  Fruiting BRF Cakes
  Alternative Fruiting Method
Harvesting & Spore Printing

Intro

I've decided to put this guide together because there are numerous old threads and outdated information floating around regarding the cultivation of the sclerotia producing *Psilocybes*.
There are however some really great threads too, like the Easier than Cubes! or the Sclerotia FAQ
I'll try to cover the most popular and readily available species:

- *Psilocybe galindoi*/ATL#7
- *Psilocybe mexicana*/A
- *Psilocybe tampanensis*/Pollock
- *Psilocybe mexicana*/Jalisco

I have worked mainly with these four stone producers for the last year.
Section *Mexicanae* is my absolute favorite from the *Psilocybe* genus.
As you probably already know these species have the ability to produce sclerotia (stones) invitro and fruit bodies as well.
Most people cultivate them for stones only but hopefully after reading this thread they'll change their mind and give it a go at fruiting 'em too.
They aren't much harder to fruit than *Psilocybe cubensis* just require a thin casing layer and some extra TLC.
Let's get started!

Grain/BRF Substrate Preparation (From Best to Least Optimal)

- Rye Berries
- Rye Grass Seed (RGS)
- Wild Bird Seed (WBS)
- Brown Rice Flour (BRF)

I will not go into details with the BRF, WBS and RGS preparation, because these three methods are truly inferior to a perfectly prepped rye berries substrate.
Here's a short version of those three.

BRF Preparation

BRF cakes preparation is the regular formula (1/1/2 - BRF/water/verm)
but instead of 100% water use a 50% coffee/50% water solution.
Steam sterilize for 90 minutes or PC for 60 minutes @15psi.

Psilocybe tampanensis sclerotia forming on BRF substrate

RGS Preparation (quart jar)

300ml RGS
150ml coffee/water mix (50/50)
Pinch of gypsum.
Put RGS and gypsum in your jar, pour coffee/water on it.
Shake to distribute the liquid evenly and let sit for two hours. Then PC it for 60 minutes @15psi.

Psilocybe galindoi sclerotia on Rye Grass Seed

WBS Preparation

I hate WBS because it's messy and pretty difficult to clean the millet away from the sclerotia.
Use it however if for some reason rye or RGS is not available.
You can also prepare it at the same way like the rye berries below.

Psilocybe tampanensis colonizing on Wild Bird Seed

Rye Berries Preparation

As for the rye berries here's a detailed and pictured preparation method.

This is basically identical to RR's Rye Grain Preparation with the addition of coffee to the soak water.

I start it by brewing a full pot (2 quarts) of strong coffee.
In a large pot/kettle heat up 2-2.5 gallon of water and add the coffee.
Add a couple of teaspoons of gypsum and stir.

Prepping the coffee/water soak

On/Off
12:19
Program
Cuisinart
AUTOMATIC GRIND & BREW THERMAL™

While the water/coffee is heating measure out your rye.
Use a cup of rye for each quart jar.
Rinse the grains a few times to clean them from all the dirt/debris.
When the water runs clear drain it. Whenever the coffee/water is around 160F go ahead and shut off the stove and dump in the grains.
Stir it around, cover and let it sit for 4-24 hours.
I usually do this overnight, with a soaking time of 8-10 hours.

Rinsing the rye and adding it to the coffee/water

Your rye is soaked, now it's time to boil.
Bring it up to a full boil and let it go for 10-15 minutes.
Turn off the stove and strain the grains in to large colanders/strainers.
I like to put a fan on them and move them around a few times while drying.
Make sure that the surface of the kernels are completely dry!

Boiling, straining and drying the Rye Berries

Now they're ready to load into jars.
Use your favorite lids with your favorite filter (mine is synthetic filter disc).
Tyvek or polyfill will work too, but nothing beats the SFDs.
Screw on lids and put a layer of aluminum foil on them.

Filling the jars and fit them with lid & foil

Now you can load the jars in the pressure cooker.
PC them for at least 90 minutes (I like to go with 120...) @15psi.
As always let the PC completely cool before removing the jars.
Jars are room temperature and the foil is removed.
The grains are a little bit compacted so I like to shake them gently a bit now.
Ready to be inoculated!

Jars before & after sterilization

STONESUN
LATEX GLOVE

Inoculation Methods

So you have a spore print or syringe.
If you don't want to complicate things or just simply don't have the supplies/resources go ahead and inoculate the substrate with your spore syringe. If you have a print, well you know, just make a spore syringe...

Spore print and spore syringe of Psilocybe mexicana

ological S
es suspended
r microscop
silocybe mexic
r. M-4 04/10

If you are a bit advanced and make LCs for you cubensis, these species will do great in a DME (Dried Malt Extract) and DEX (Dextrose) LC.
Use your favorite recipe.
My preferred one is 1 tsp Malt Extract and 1/8 cup of Dextrose per quart.
The best and most advanced method however is to start your spores on agar.

Psilocybe galindoi mycelium on LME/DEX LC

ATL-#7
STIR
Cimarec® 2
Thermolyne

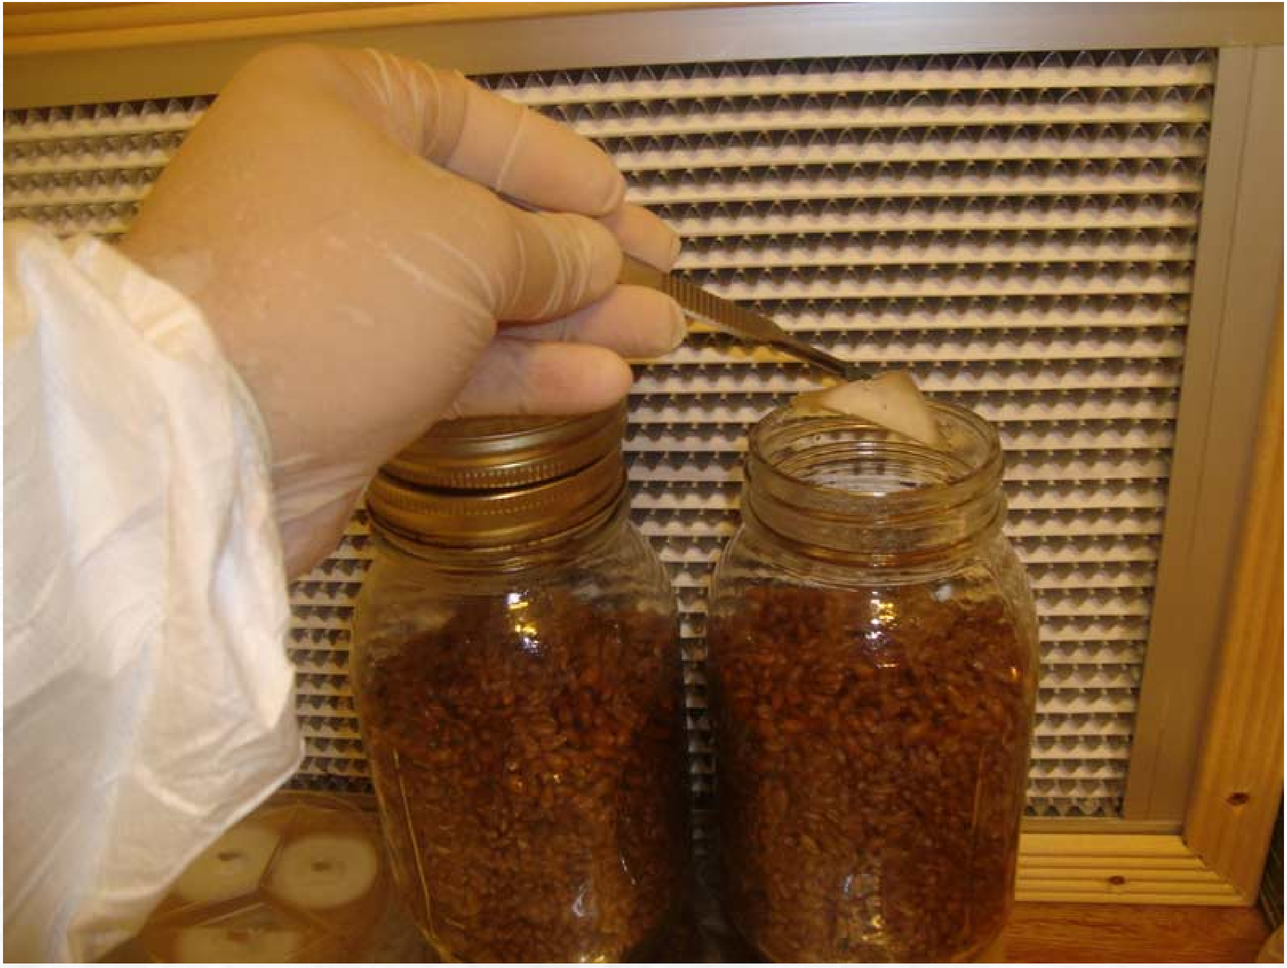
Cimarec® 2
Thermolyne

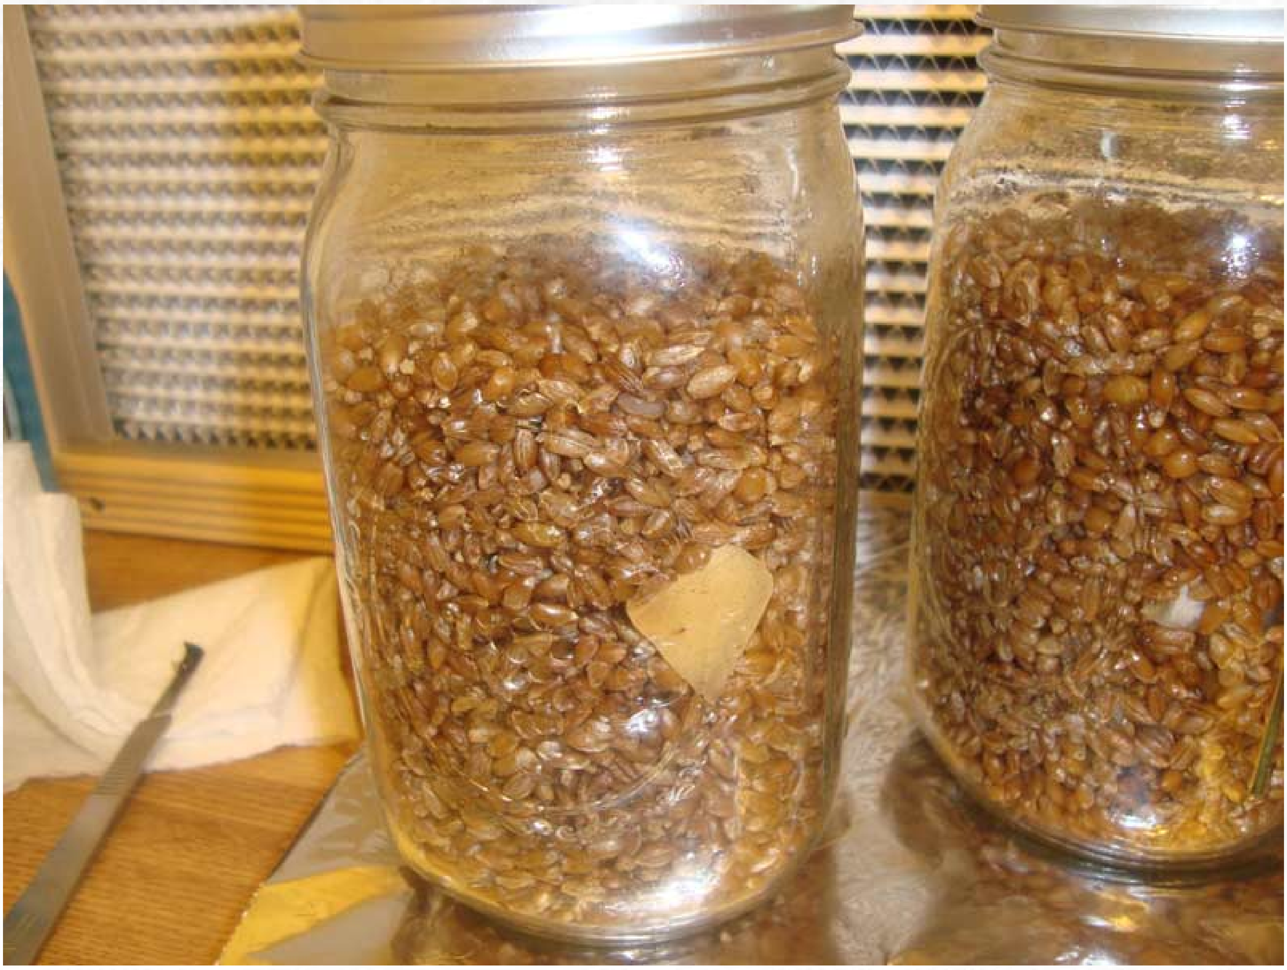
I use premixed MEA media and have never had germination issue.
When you have a nice healthy grow on your plate (not going into isolation…), you can inoculate your grain substrate or LC with a wedge.

Psilocybe galindoi and Psilocybe mexicana on agar

ATL #7
1/17/09
MEX -A
8/1/10

Rye inoculated with agar wedge

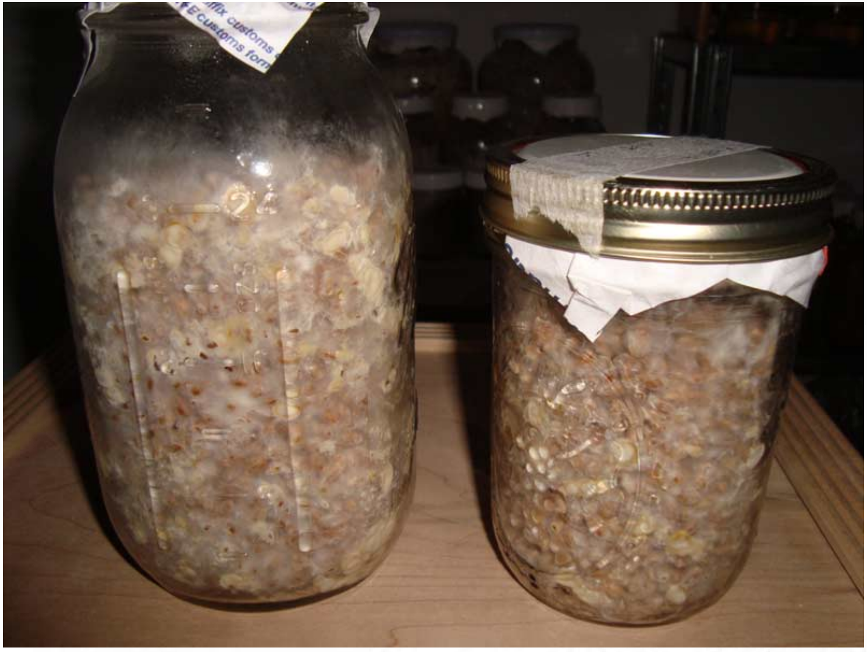




Now just set it and forget it!
Are you ready for some stones?!

Very often (especially with spore and agar wedge inoculation) sclerotia will form before full colonization of the substrate. This is perfectly normal.
If you inoculate with LC, the mycelium usually just rips through the substrate and stones will form after 100% colonization.
Either way you should see stones soon.

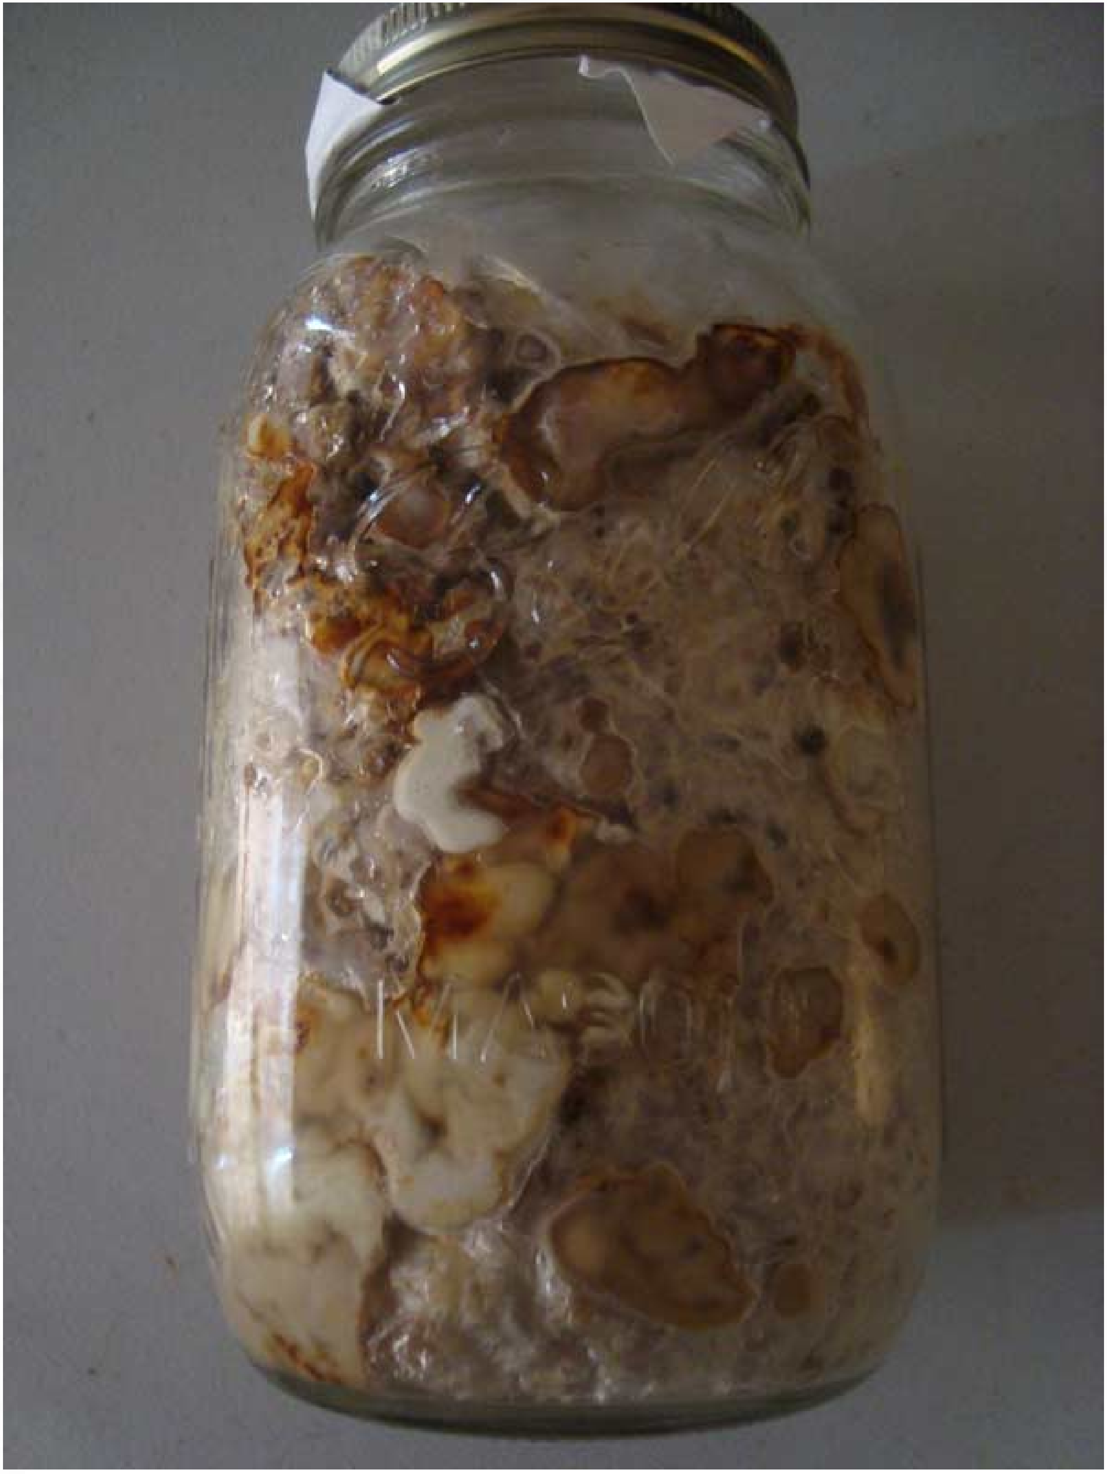
Some "young" jars (less than 30 days)



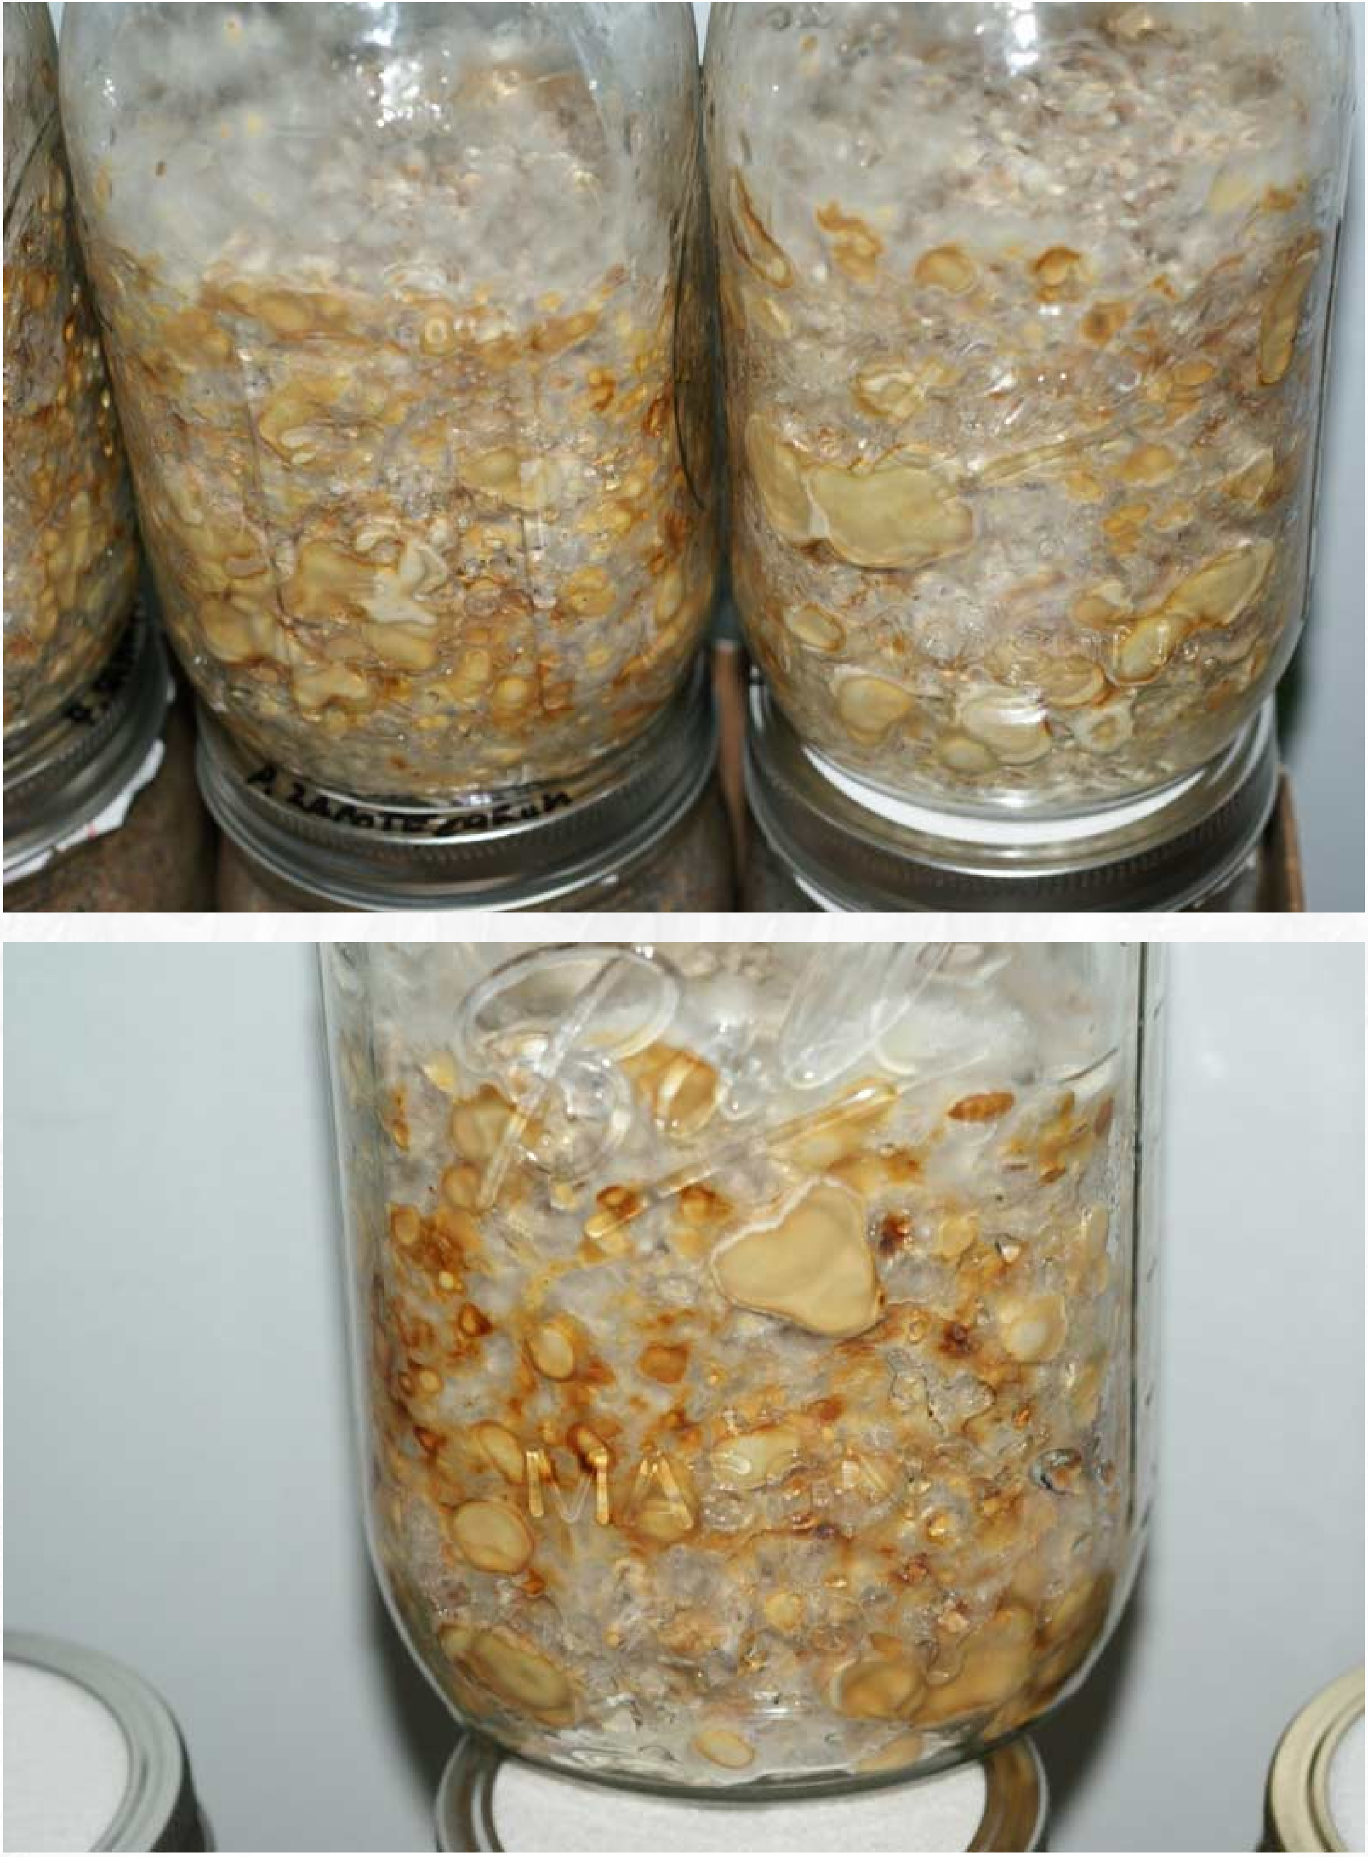
There's a controversy on shaking or not at the 20-30% stage of colonization.
Some say it's OK some say don't do it.
I've done it with success, but failed a few times too.
Therefore I don't shake anymore.

When I want to expand and plan on doing G2G transfers, the best method IME is to start with LC.
I use 3-4cc per jar and it's always done within a week.
Stones are not forming yet or if so, they are very tiny.
Just as usual, break up your colonized grain by shaking your jar, and transfer a small amount into new sterilized substrate jars.
However if you have a fair amount of LC, I'd rather go that way instead of G2G.

Psilocybe mexicana/A rye jars around 60 days



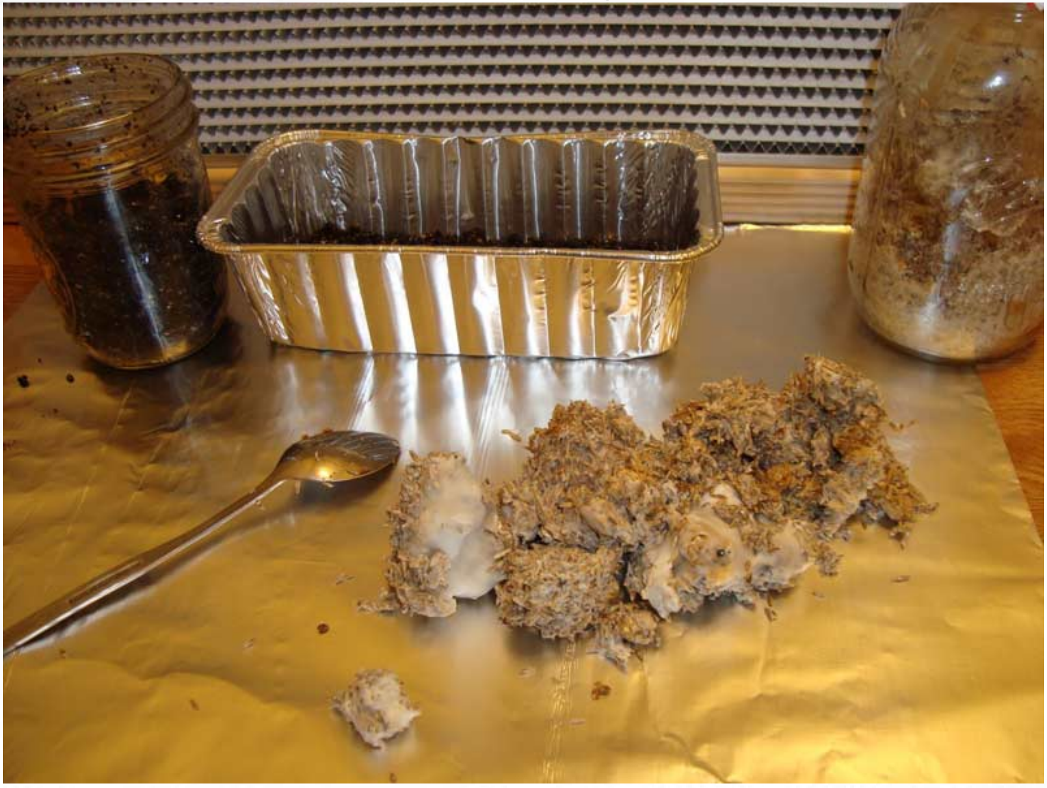
Psilocybe galindoi rye jars around 60 days



Harvesting the Stones

Well it is time to enjoy the first "fruits" of your labor.
When you're at this stage, your jars should be at least 2 months or older.
There's no point to harvest before 2 months and my latest harvest was 6 months.
Some leave it longer, but I always in need of jars/space.
Anyhow...
Get a spoon and sanitize it with alcohol.
Scrape out and separate the substrate and sclerotia on aluminum foil.
I have done this before in laminar air flow and totally open air.
Never ever get a contam with either method.

Stones harvested from RGS and rye berries substrate



Clean your stones with a brush and store them fresh in paper bags in the fridge for weeks or dehydrate and store them for months.

Psilocybe mexicana/A sclerotia harvested from rye

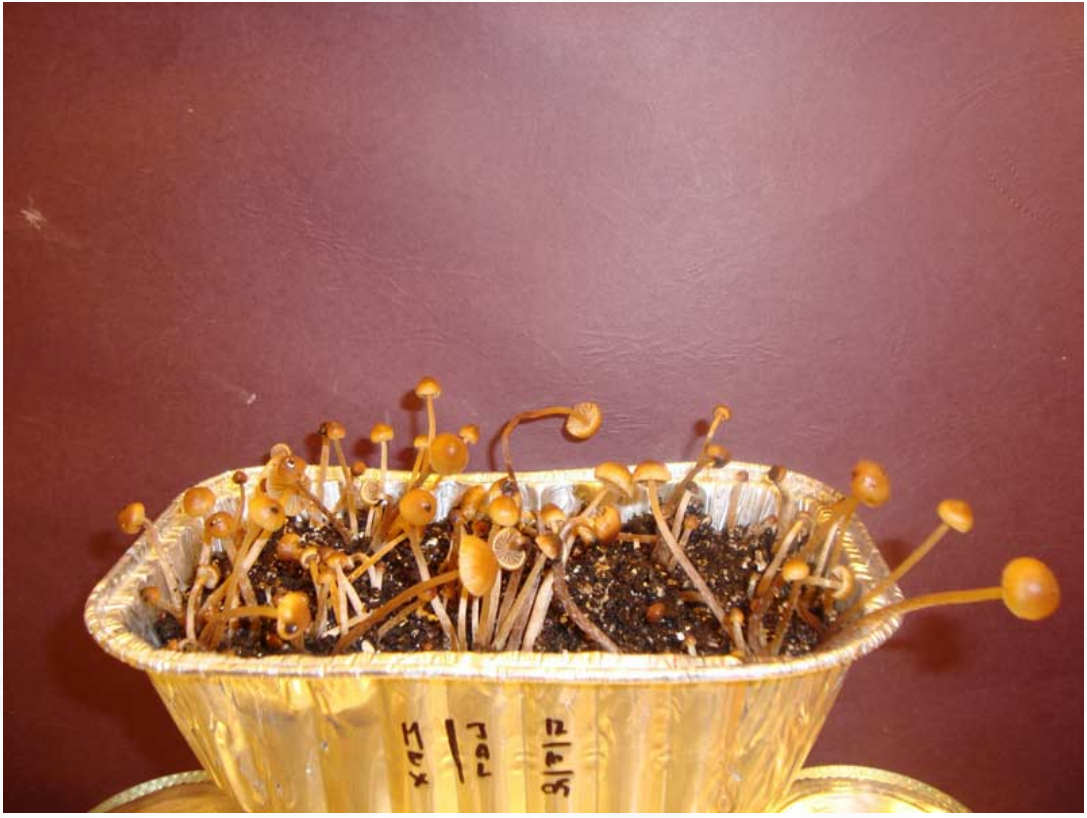
So now you have that leftover sub/very small stones mixture, ready to fruit.

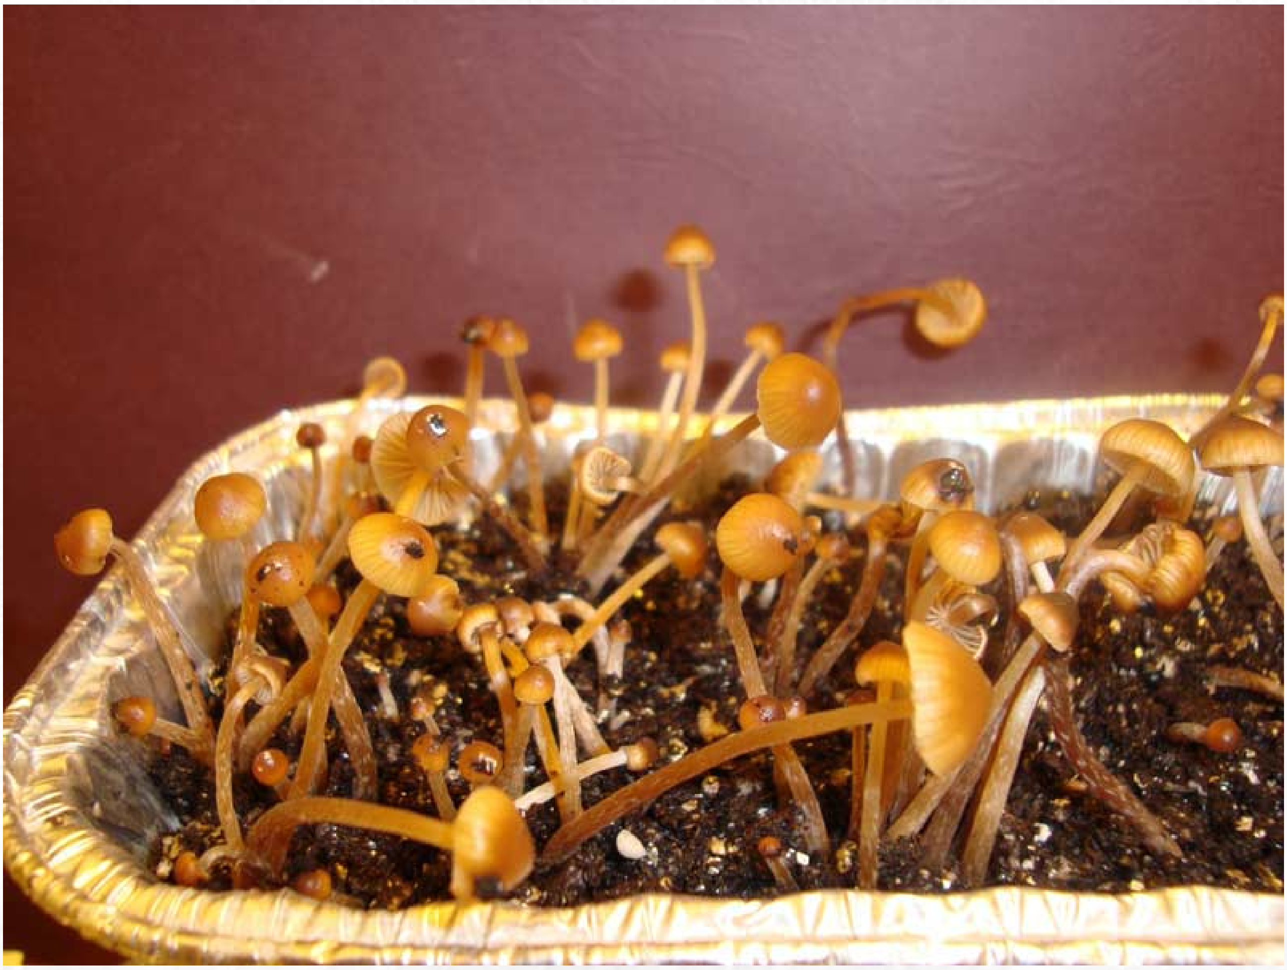
Fruiting Procedures

Cased Grain Substrate

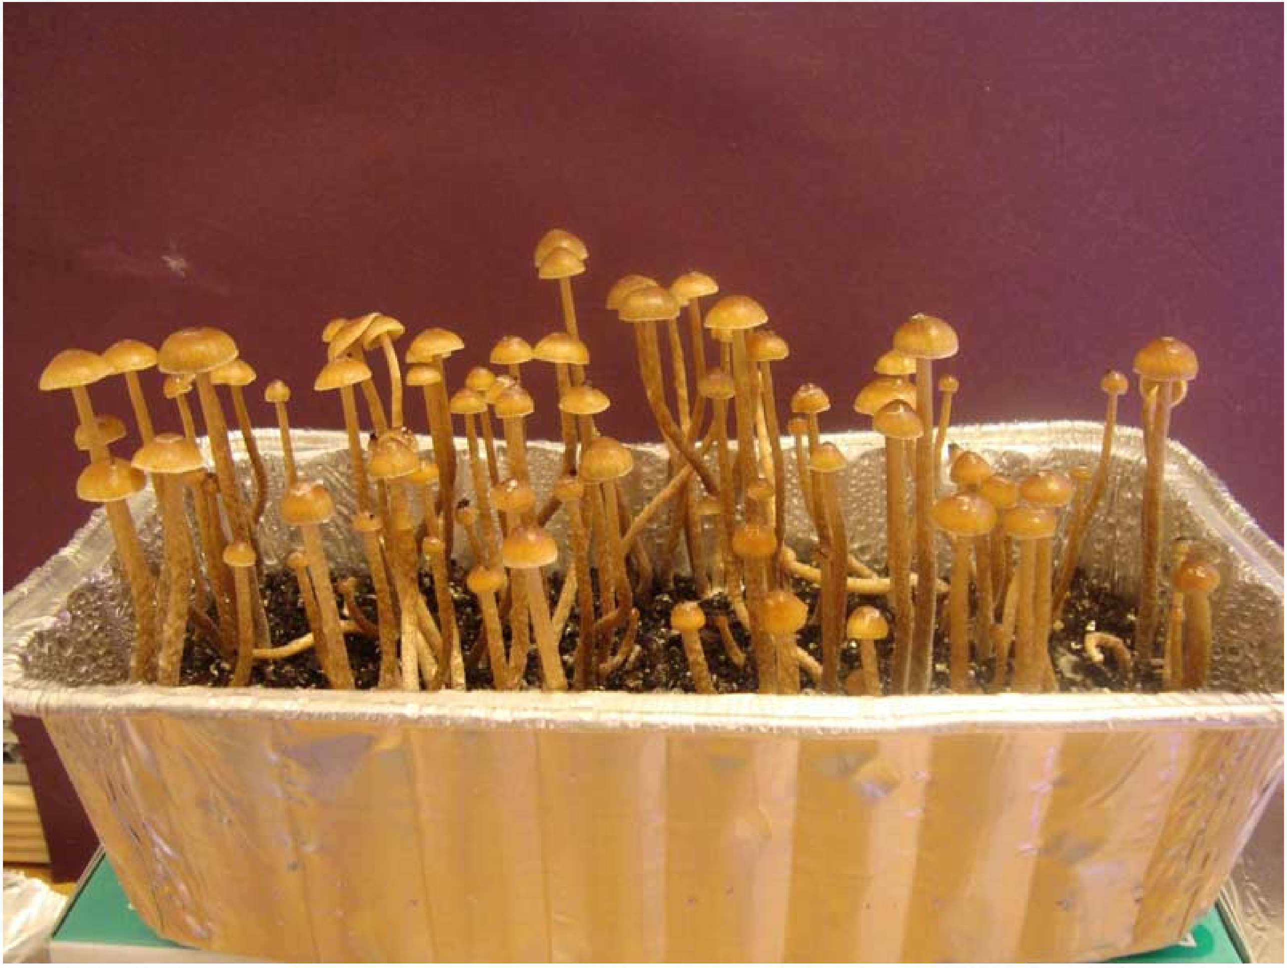
This is the easiest method to case the grains and fruit them as is.
I've had OK results by casing RGS.
Had great results by casing Rye.

Psilocybe mexicana/Jalisco fruiting on cased RGS

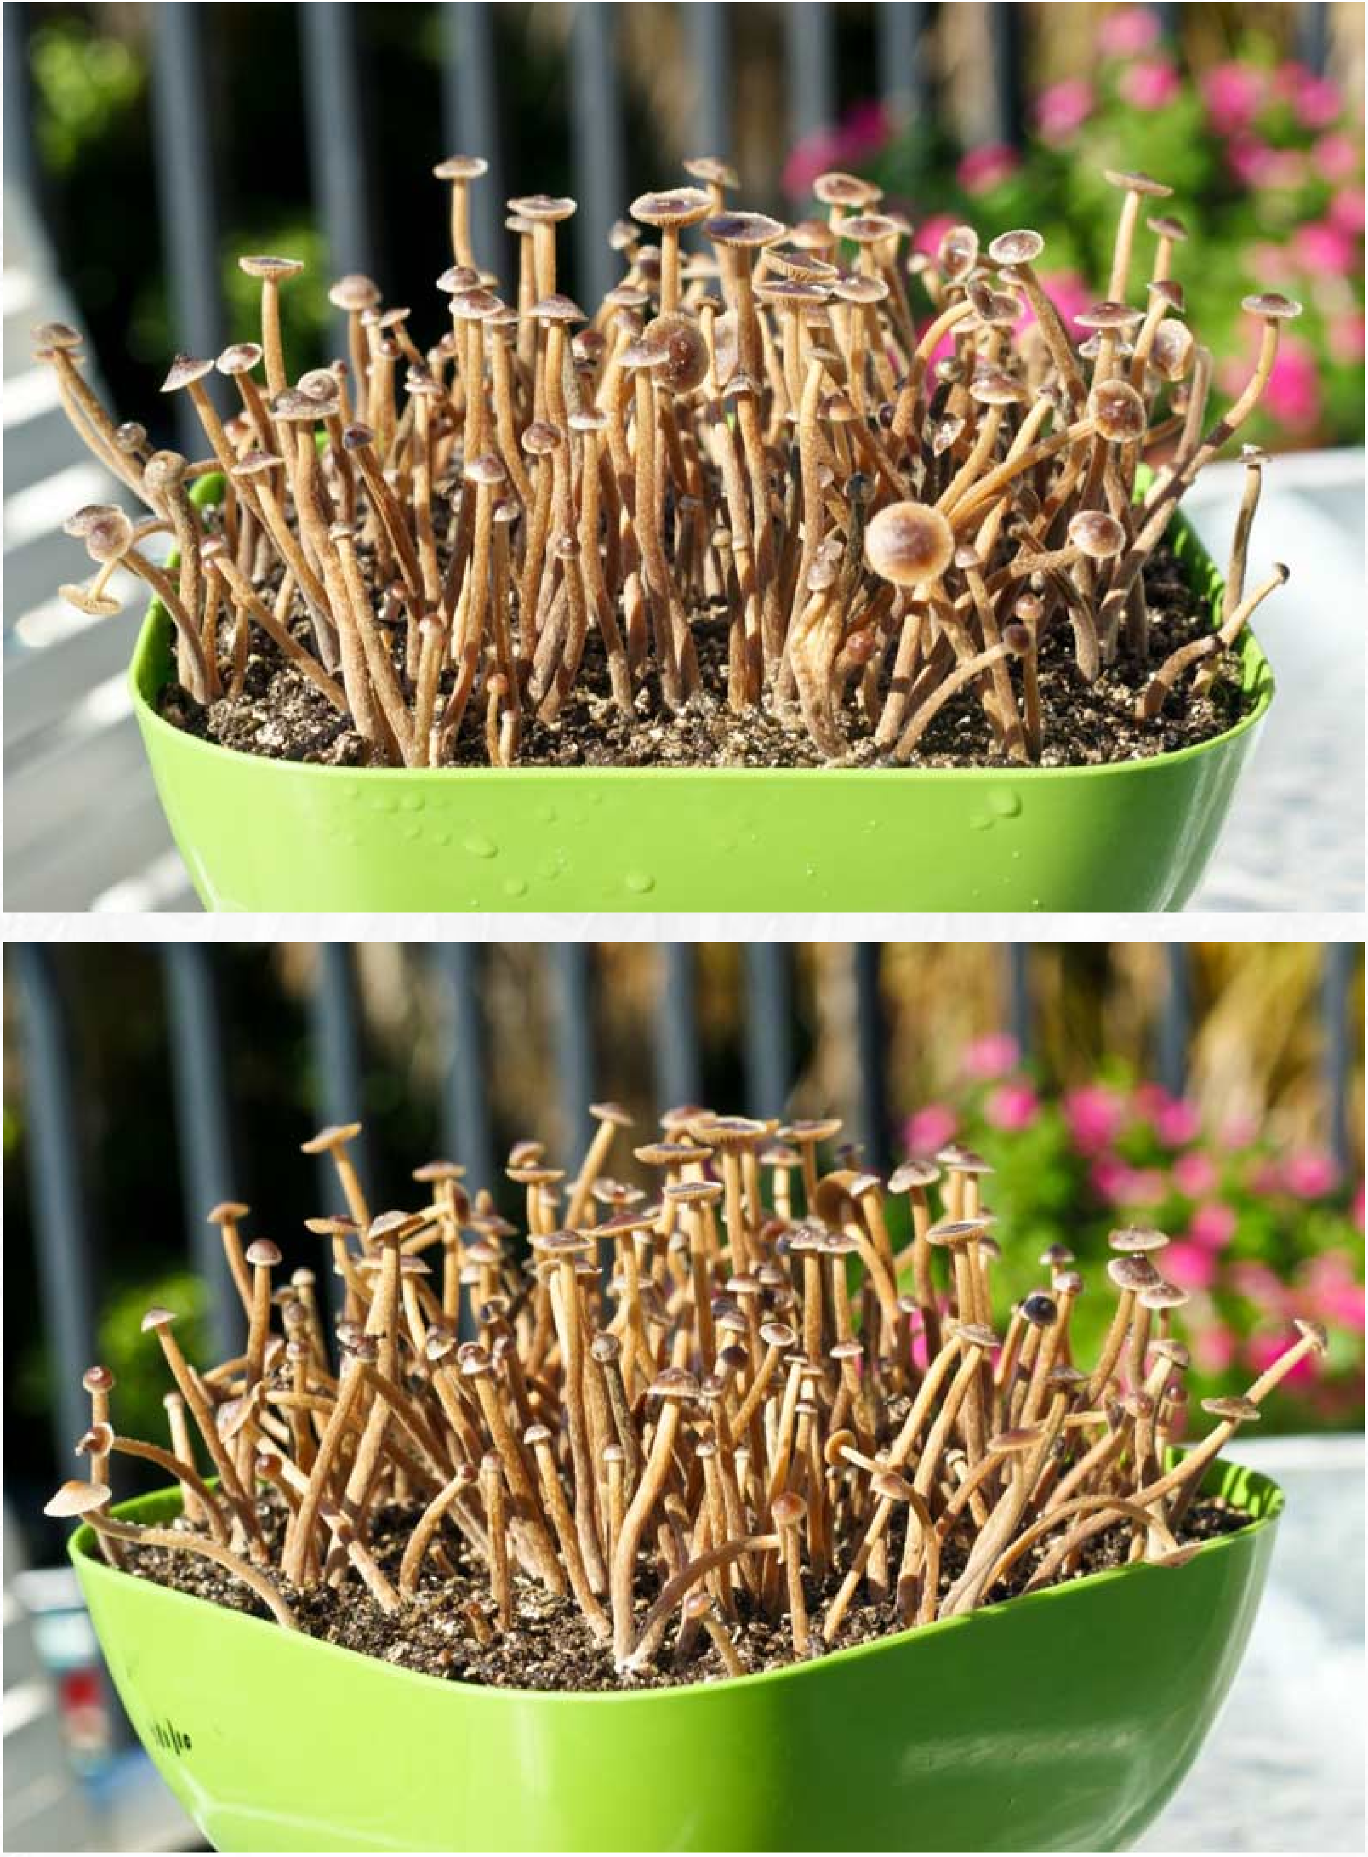




Psilocybe galindoi/ATL#7 fruiting on cased RGS



Psilocybe galindoi/ATL#7 fruiting on cased Rye Berries



They don't require a special casing layer, I've used pasteurized 50/50, 50/50+, Jiffy Mix and Plantation Seed Starter Mix with equally great results.
Make sure that you use a thin (~1/4") layer of your mix.

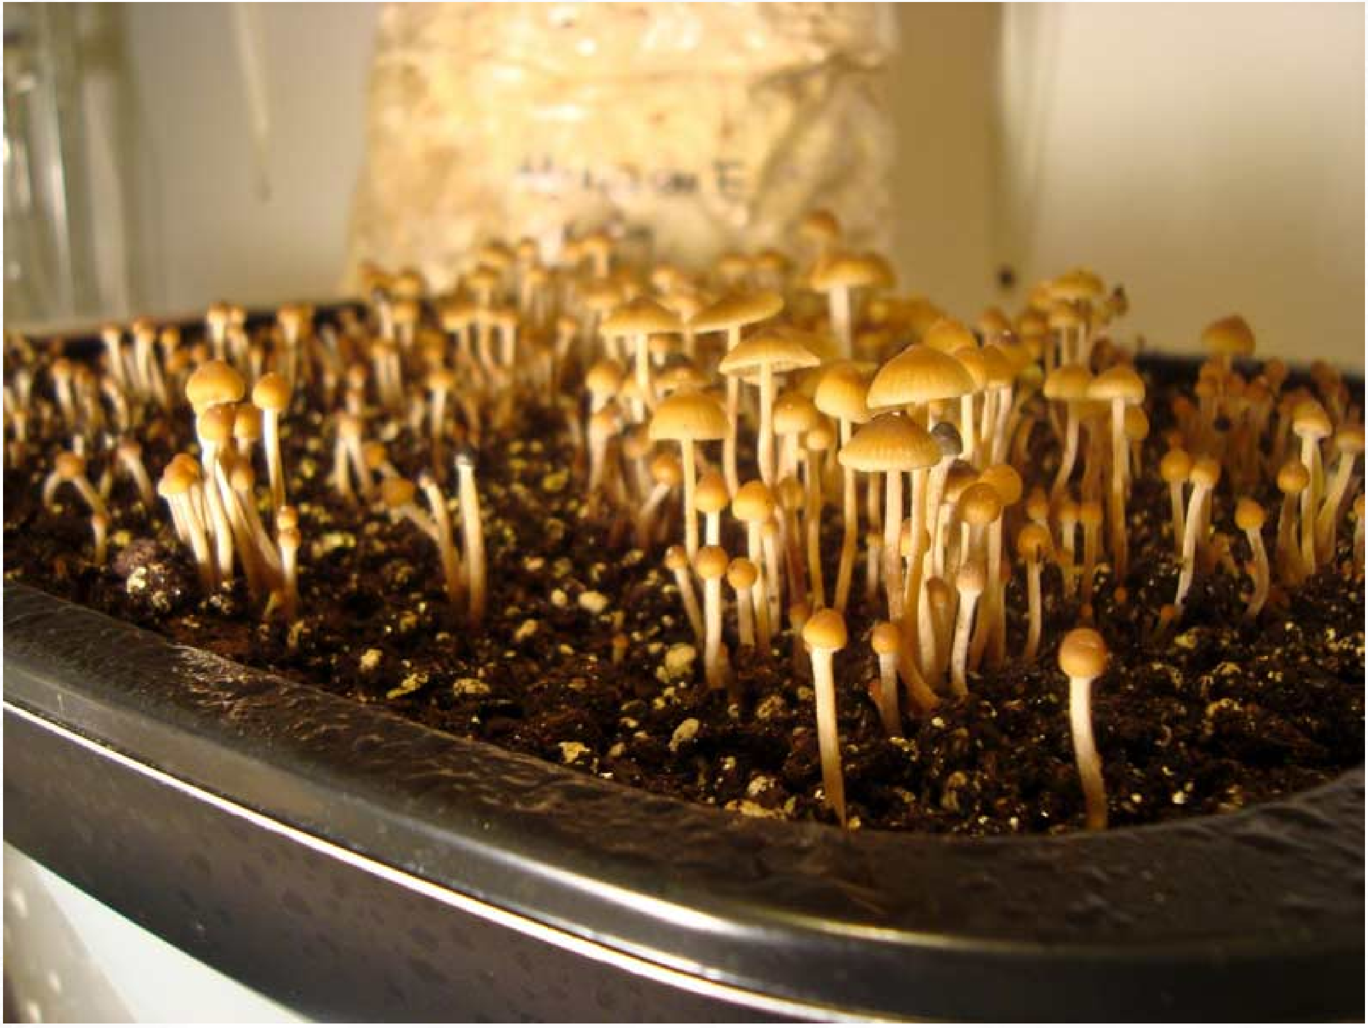
Spread it evenly on the top of the substrate and put it into your fruiting chamber.
I've used a SGFC and Greenhouse and they both perform good.
Keep high humidity and lots of FAE throughout the whole fruiting.
Keep your temperature between 65-80F.
I've had them to fruit on constant 65F and constant 80F and anywhere in between.
Light temperature of 6500K is preferred (although I experimented with a 8200K light too with good performance as well) with a cycle of 12/12.

Pins should appear within 10-14 days in optimal fruiting conditions.

Grains Spawned to Bulk Substrate

You can spawn your grains to any pasteurized manure or coir based bulk substrate.
My favorite mix is horse manure/straw/coir/vermiculite/gypsum (40/20/20/15/5).
Let your bulk colonize, case and fruit it as above.

Psilocybe mexicana/Jalisco rye berries spawned to pasteurized coir/coffee/verm/gypsum



Psilocybe tampanensis spawned to pasteurized horse manure/straw/verm/coir/gypsum

Fruiting BRF Cakes

With this method I don't harvest the sclerotia from the substrate.
After full colonization birth the cake and wash off the vermiculite barrier.
After this I like to dry the cakes out in the front of the flowhood or a fan.
Dry it for a few hours at least or overnight.

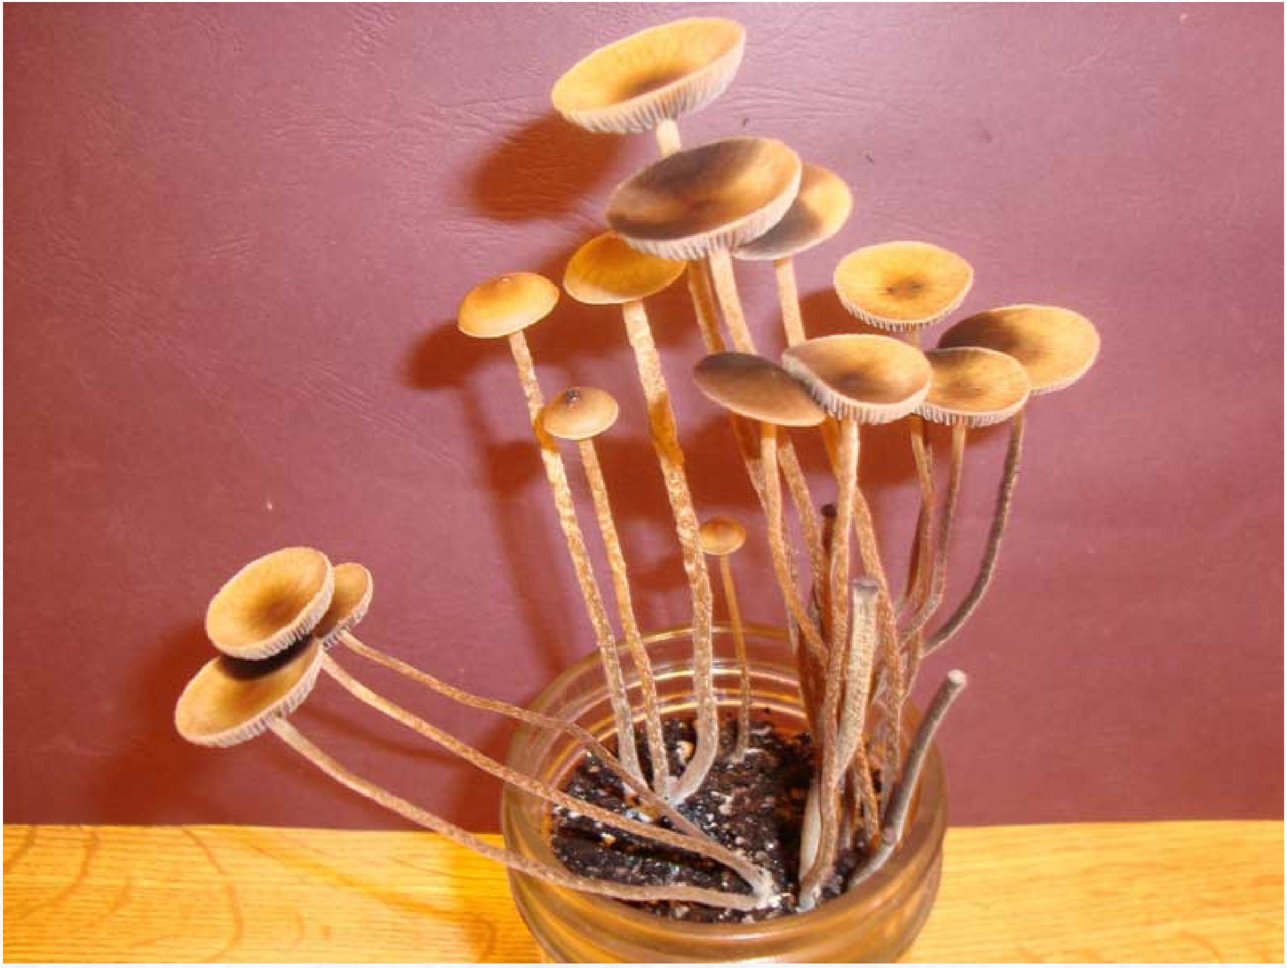
Psilocybe tampanensis cakes drying

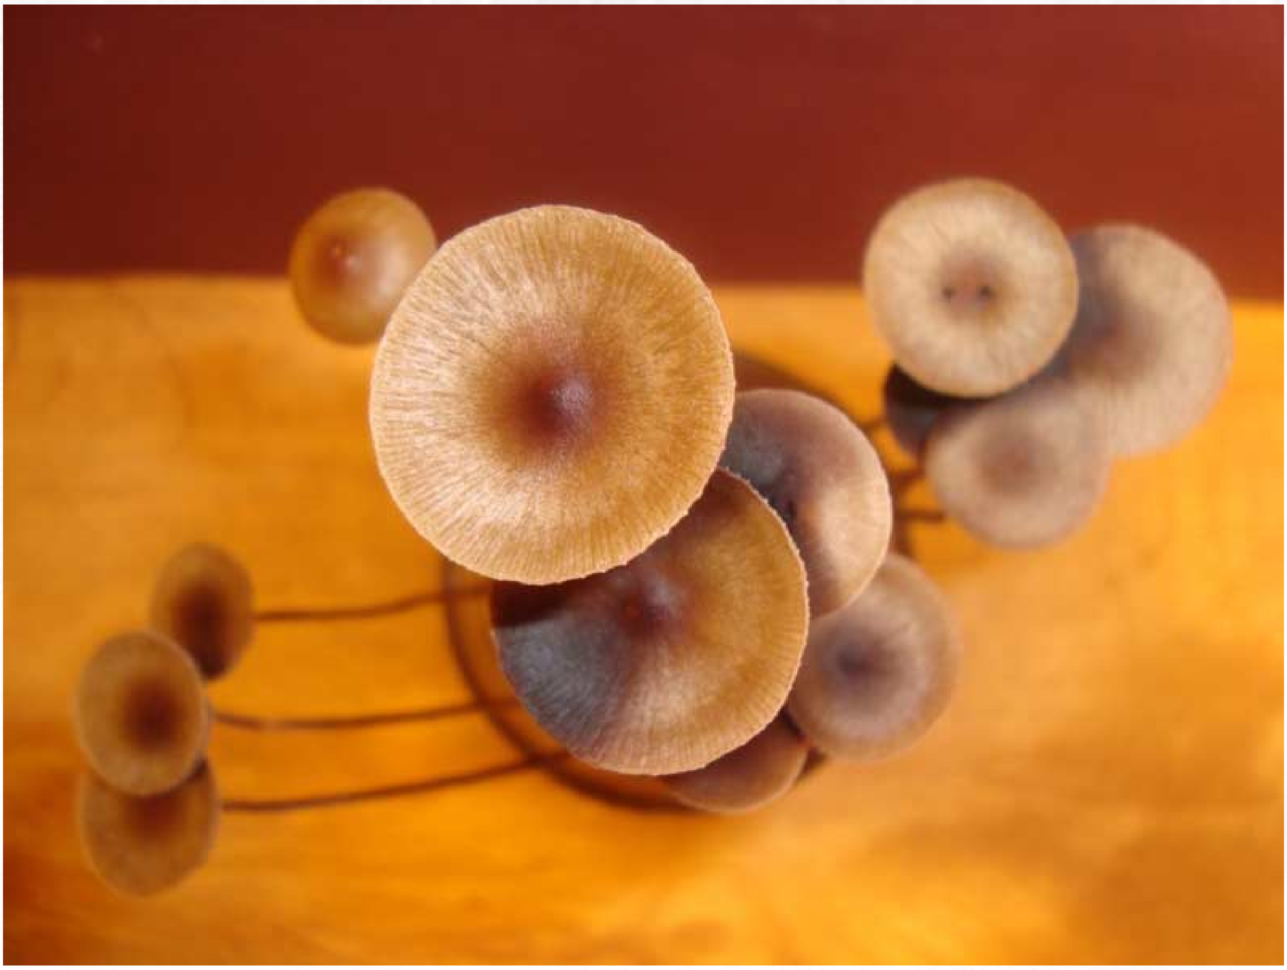
Please note that the above step is not necessary but IME it will give you a better flush/pinset.

Now that the cakes are dry you can go ahead and dunk them for 24 hours.
Put them back in the jars and case/fruit in the same manner as with grains (described above).

Psilocybe tampanensis cakes dunking and cased

Psilocybe galindoi fruits on BRF substrate





Alternative Fruiting Method

If you're after the fruits and don't care about sclerotia this is the TEK for you!
Prepare a bulk substrate mix in a spawn bag and sterilize it, then inoculate it directly with LC.
Here's how I prepare my bulk.

Shred the horse manure with a small food processor.
I can't believe that some people still breaking up manure with their hands...

Shredding the manure

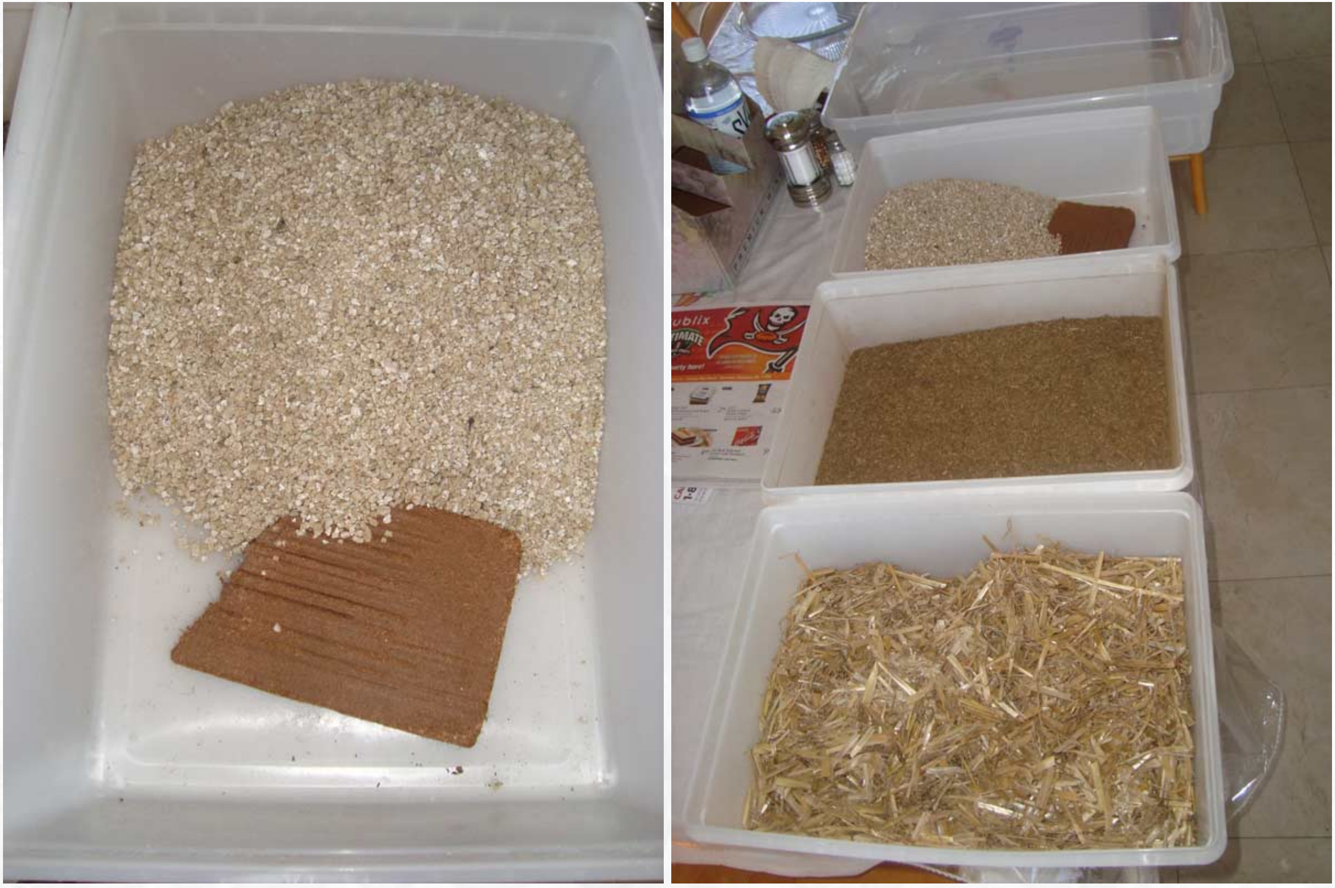
Ultimate Chopper

Chop up some wheat straw and submerge it in water for a couple of hours.

Prepping wheat straw

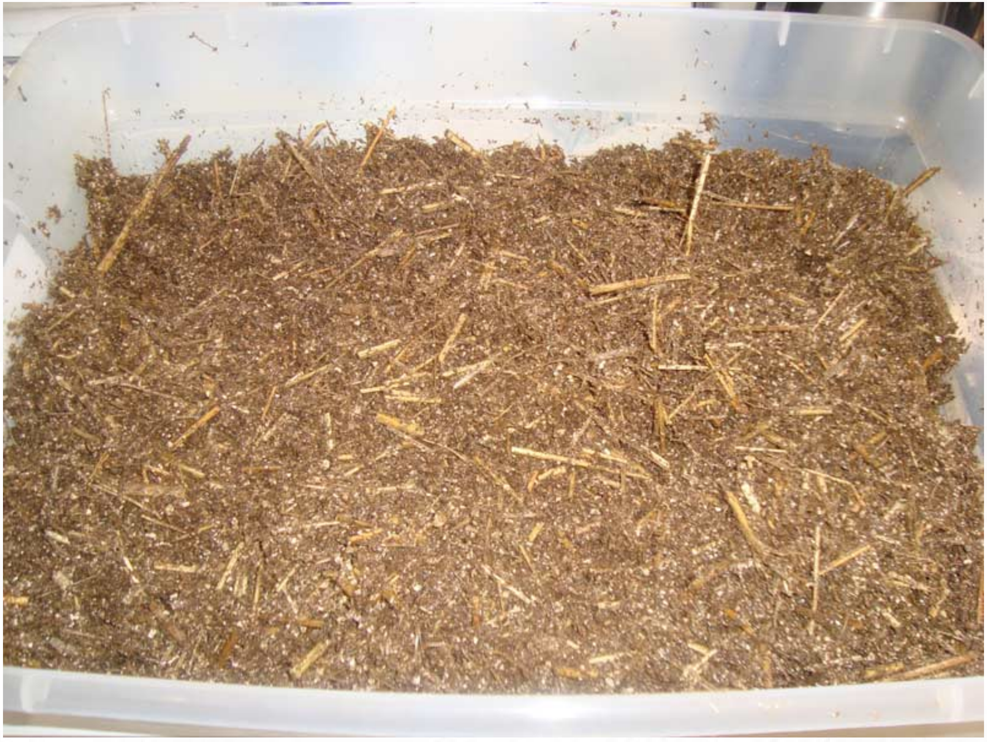
Hydrate some coir, and get the vermiculite & gypsum ready.
I don't measure anything exactly just eyeball it.
It's not that important, just be somewhere in the ballpark of the above mentioned ratio...

Ingredients for the substrate



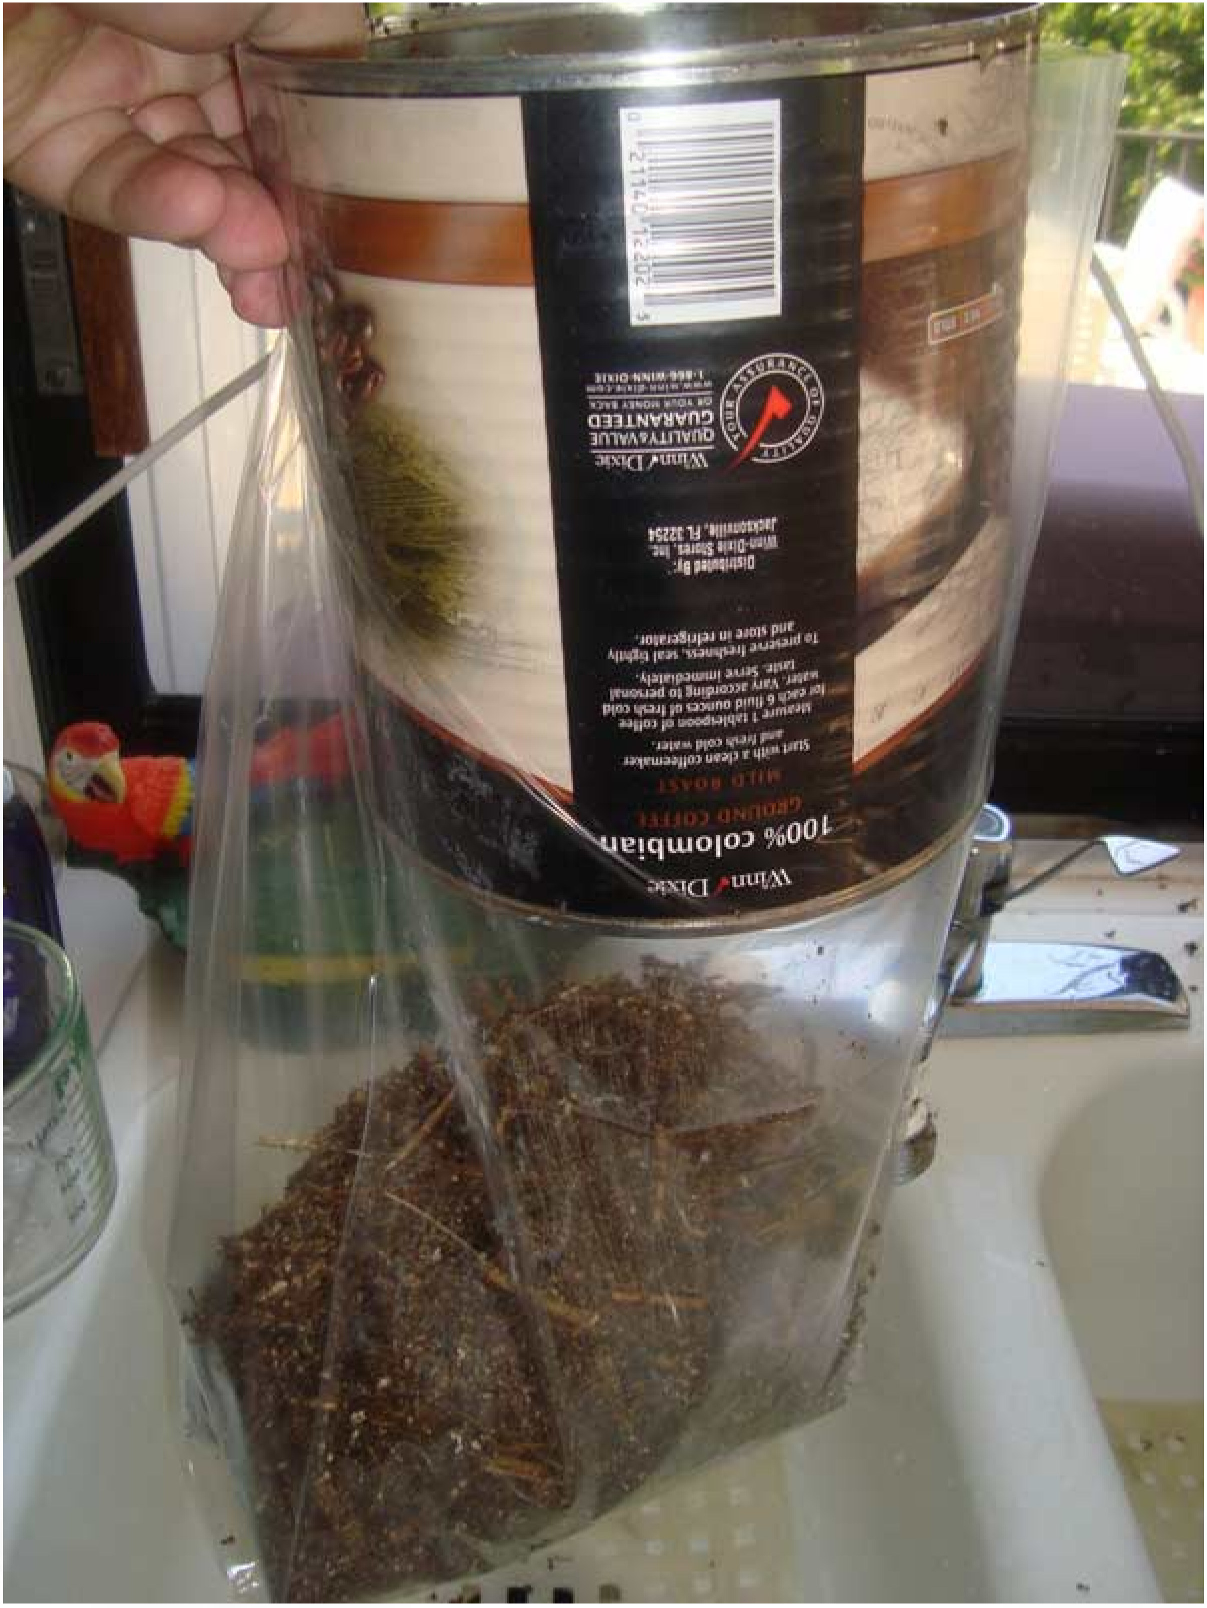
Now mix your dry ingredients (manure/verm/gypsum) then mix in coir and straw.
Hydrate the sub to field capacity and fill into gusseted spawn bags.
I fill the bags with 2-4 quarts of substrate.

Mixed and hydrated substrate



I love RRs idea with the tyvek sleeves inserted in the bags, you don't have to worry about contamination while your PC cools.

Prepping the spawn bags

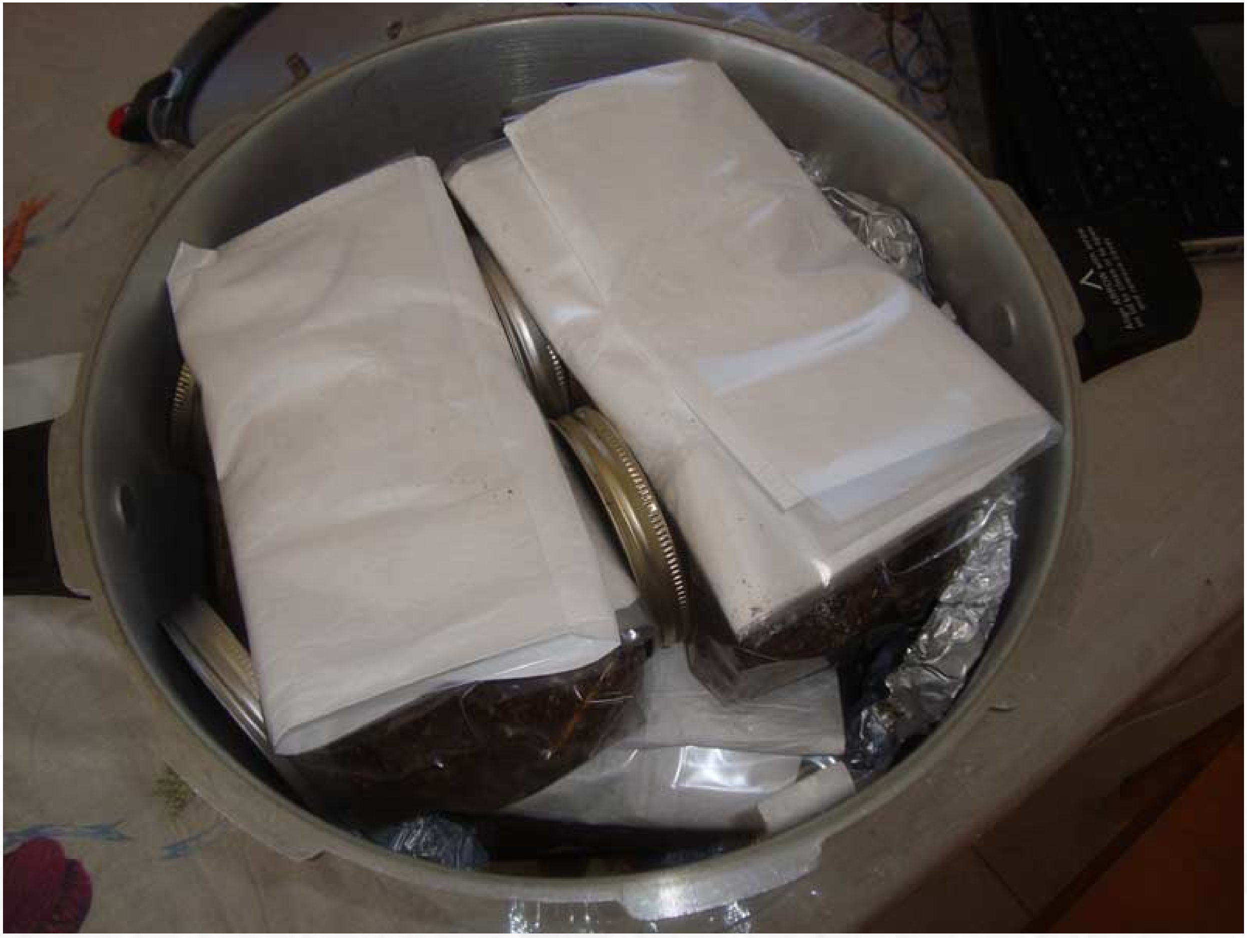


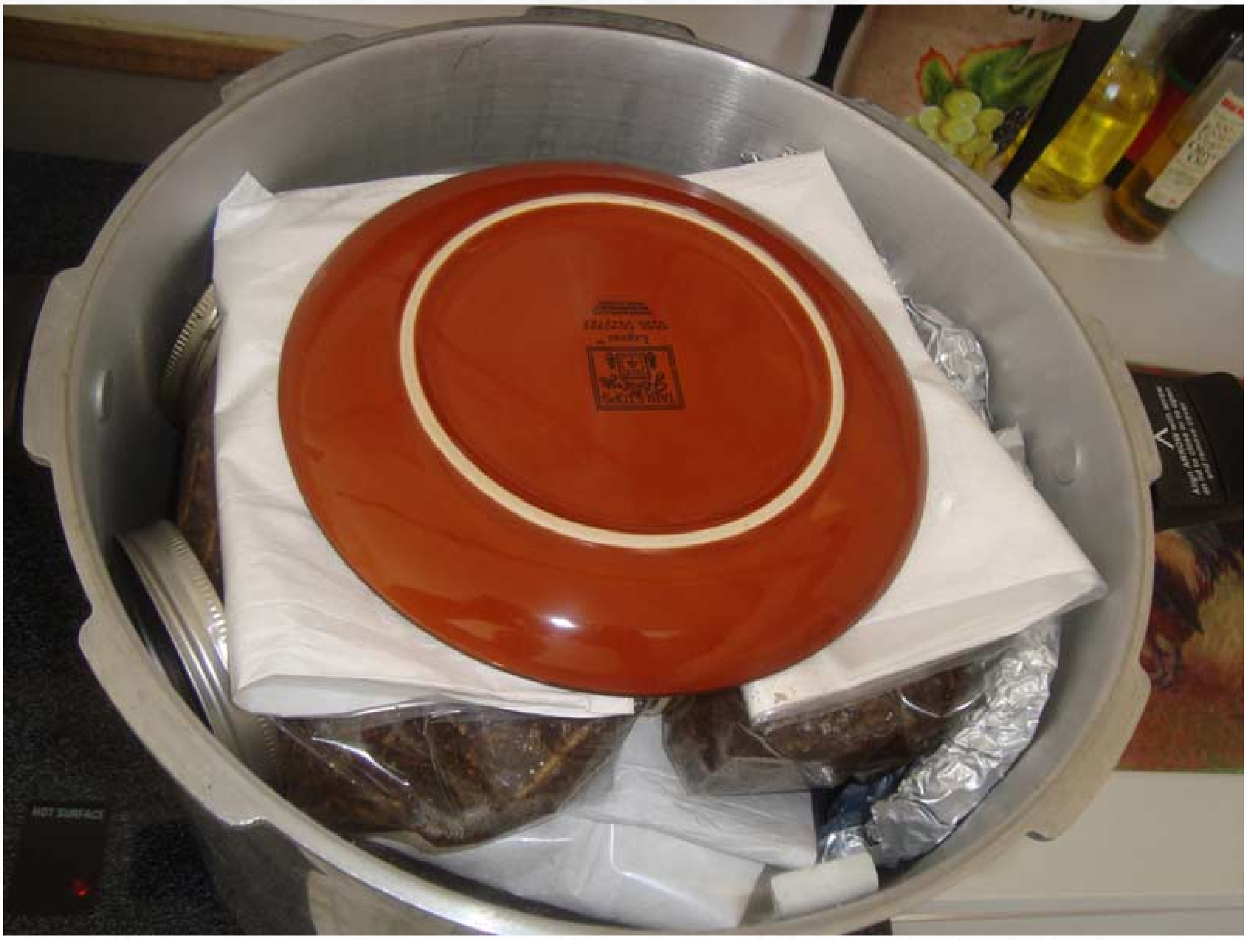
PREMIUM

PREMIUM

Fill your PC with the bags, and PC them for 120 minutes @15psi.

Bags before and after PCing





When the bags are cool I open them in the sterile laminar airflow and inoculate the bulk with 20-60cc of LC.
Inflate it with the sterile air and tie them up.
When fully colonized, cut the top of the bag just above the substrate level.
Case it thin with your favorite casing layer and fruit it.

Psilocybe galindoi bag fully colonized, top cut off and cased

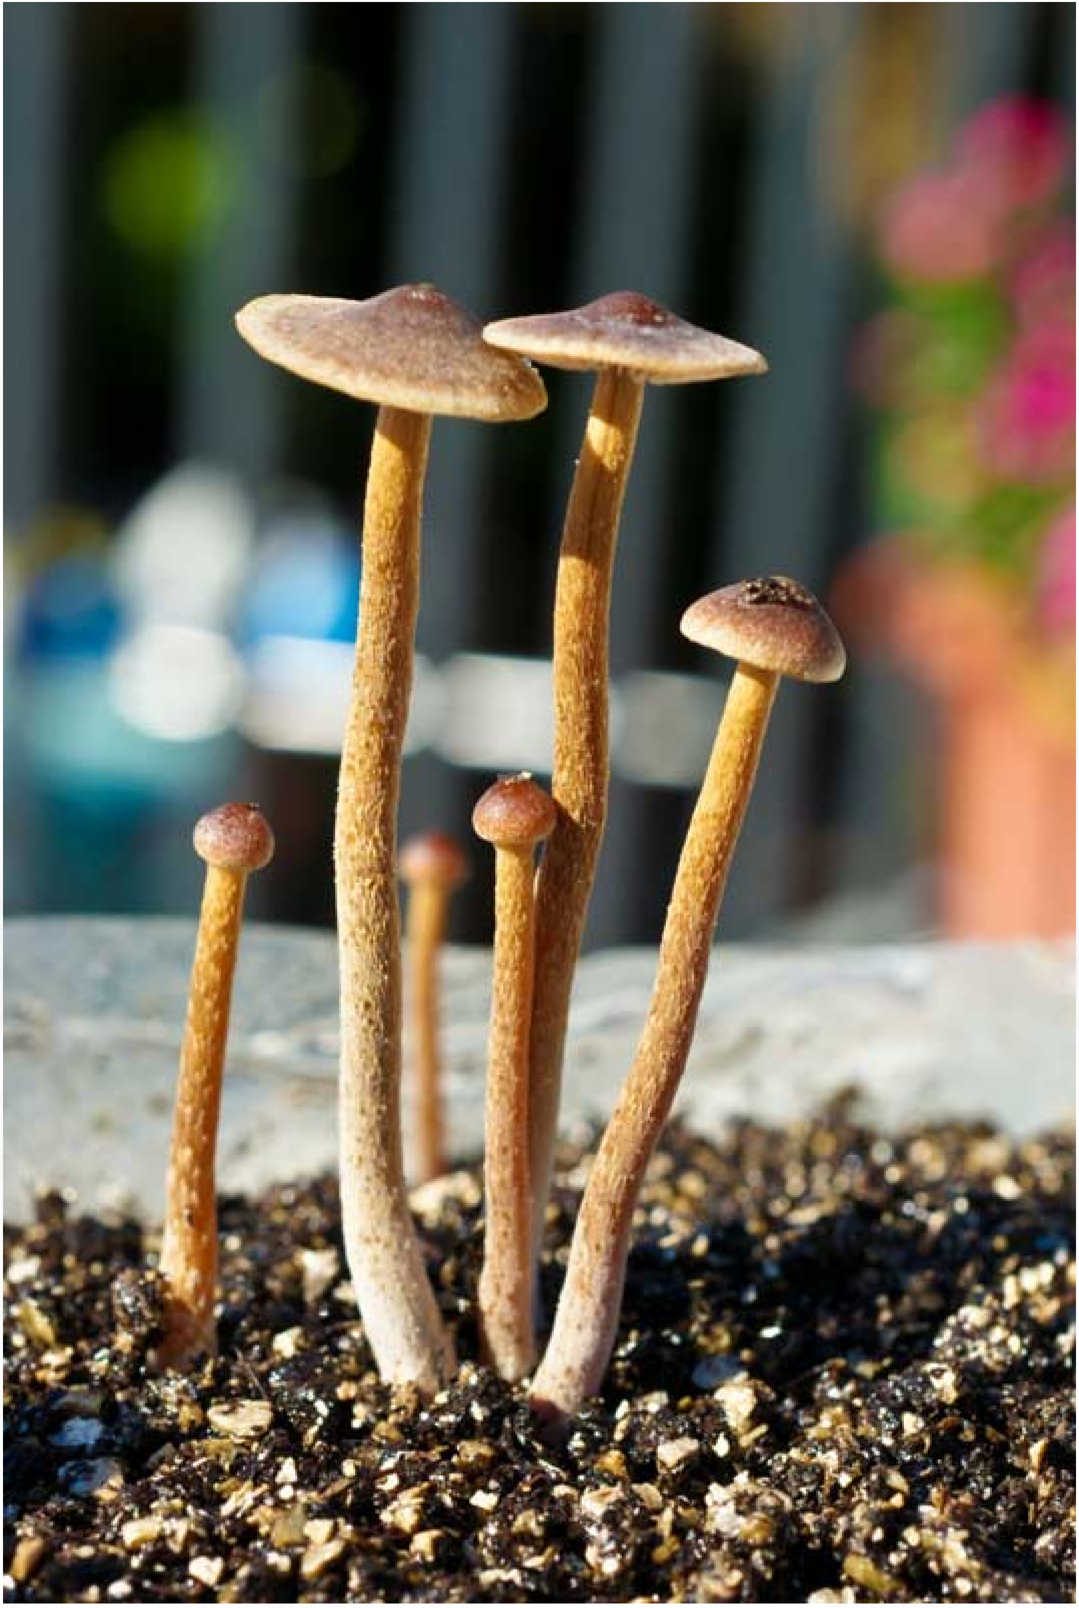
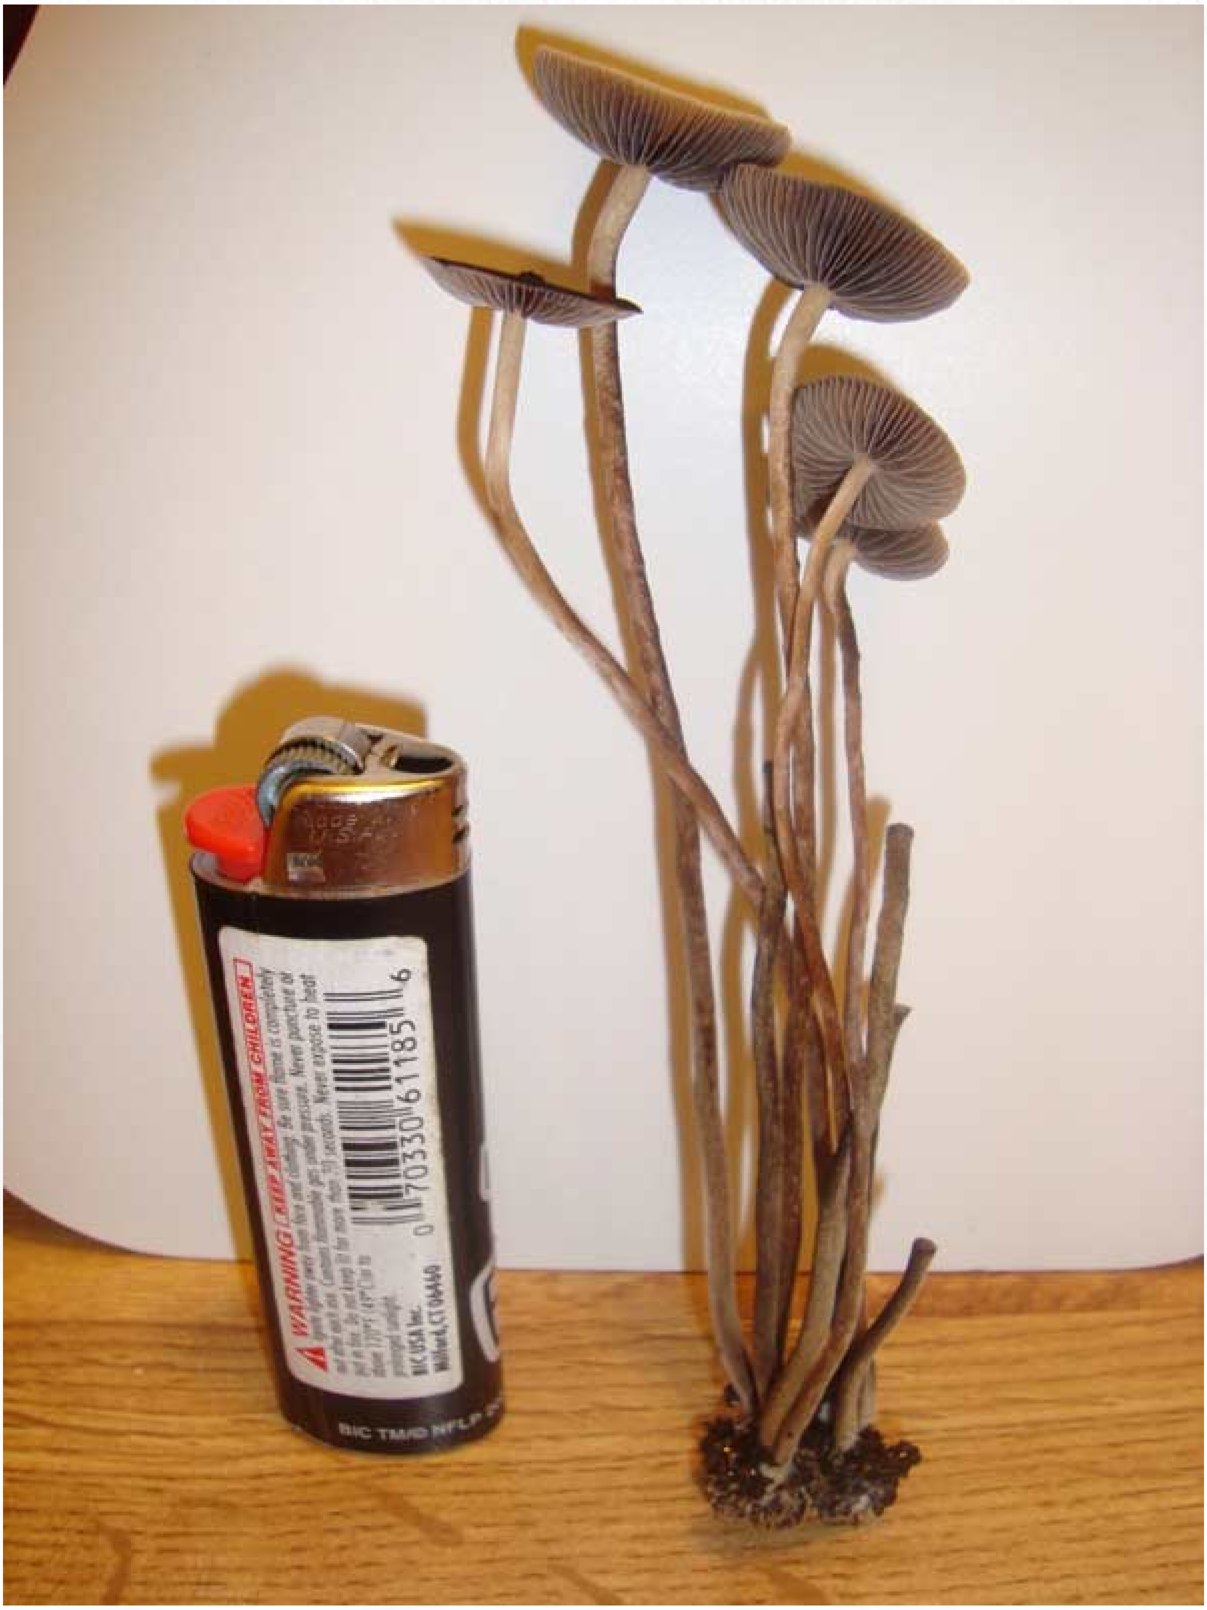
Psilocybe galindoi fruits on the above mentioned bag



Harvesting & Spore Printing

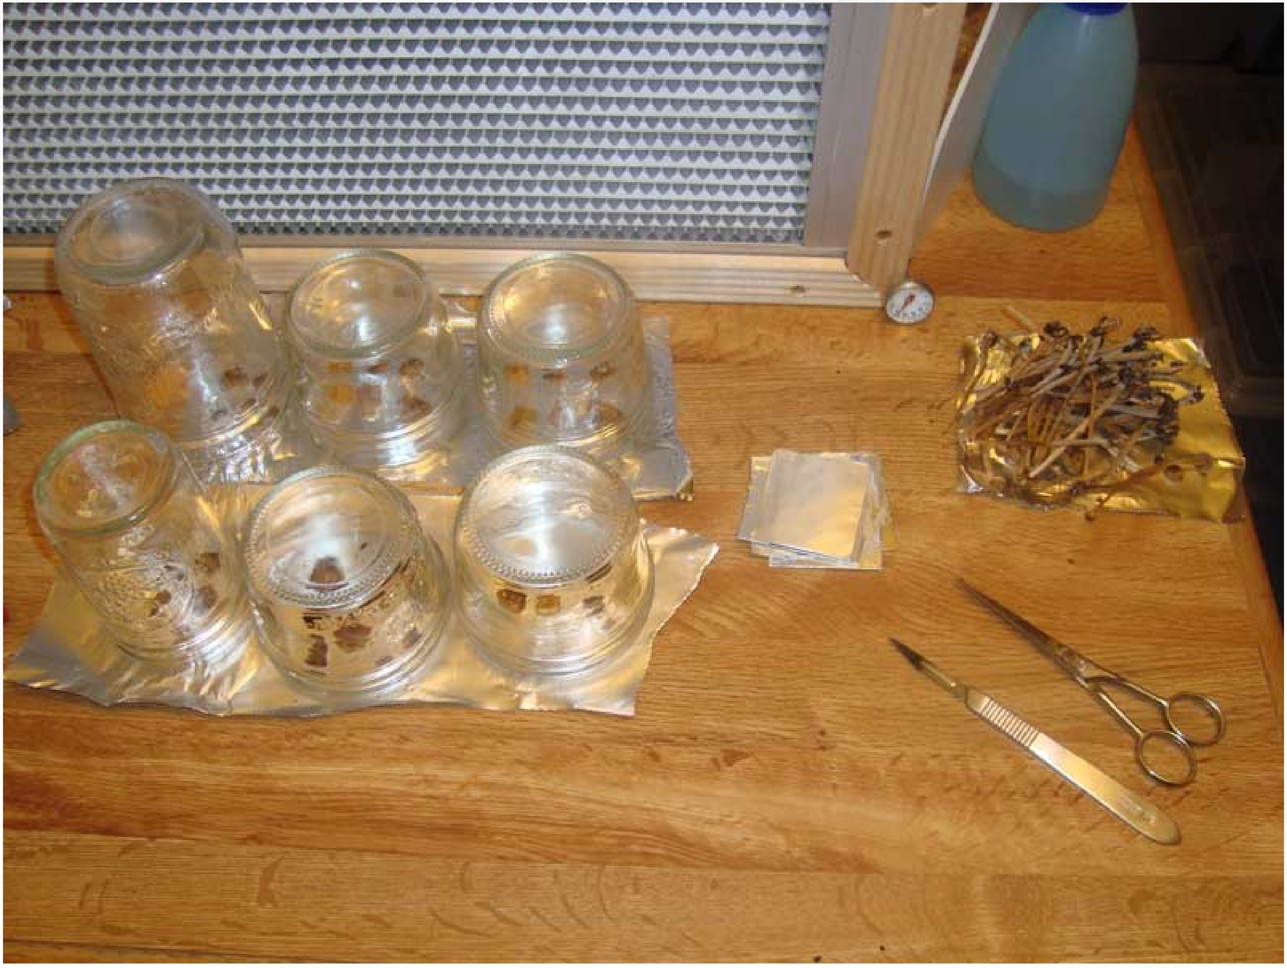
Now that the pins developed into mature fruits (anywhere between 5-10 days) you are ready to harvest them. This is the same as you would do with any other species of mushroom, but keep it in mind that these guys are pretty fragile.
Gently pull them off the substrate and set them aside.

Psilocybe galindoi harvest from BRF



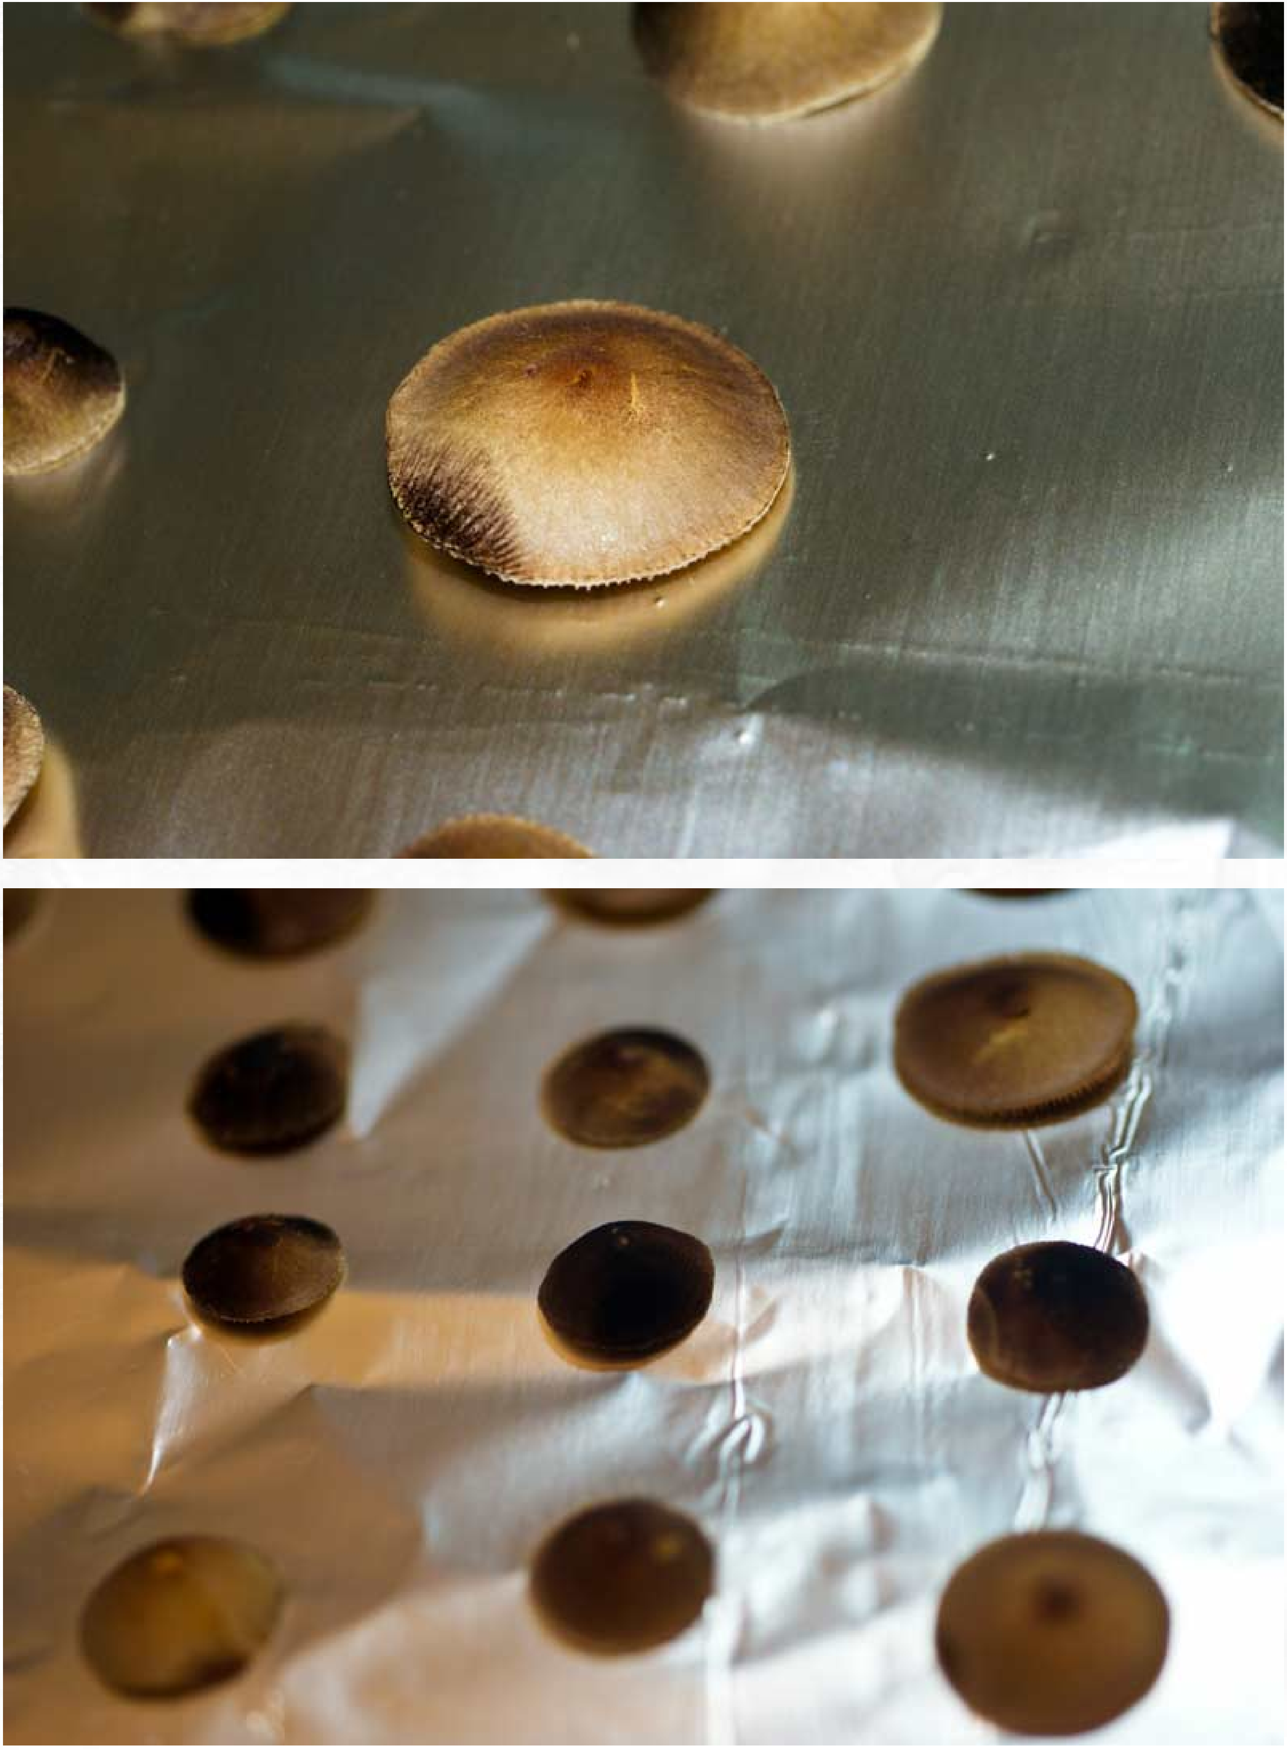
Cut the caps off the stipe as close as you can and place cap onto alcohol sanitized heavy duty aluminum foil. Do this in your glovebox or front of your flowhood.

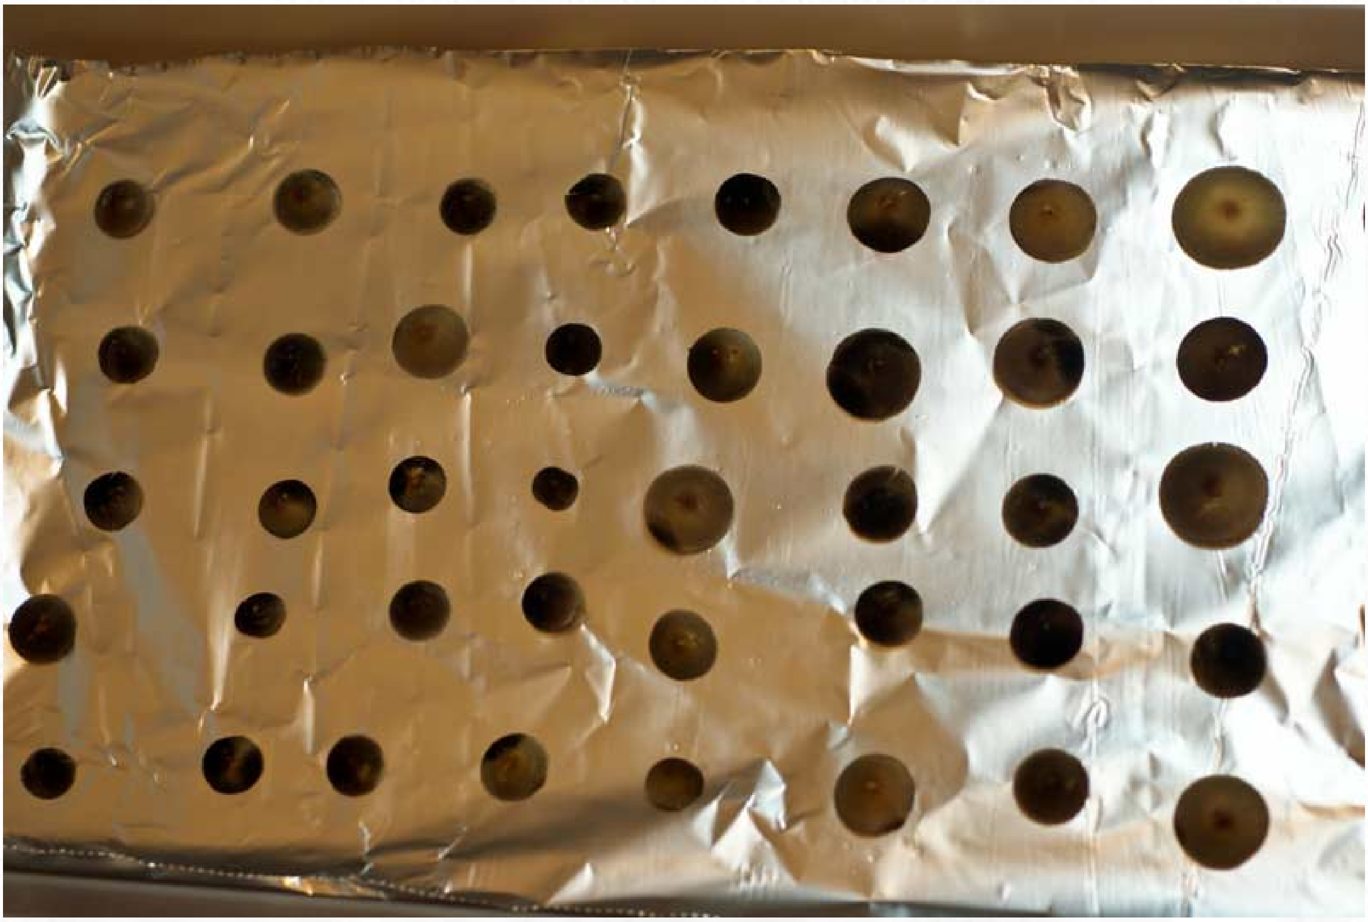
Psilocybe galindoi caps printing



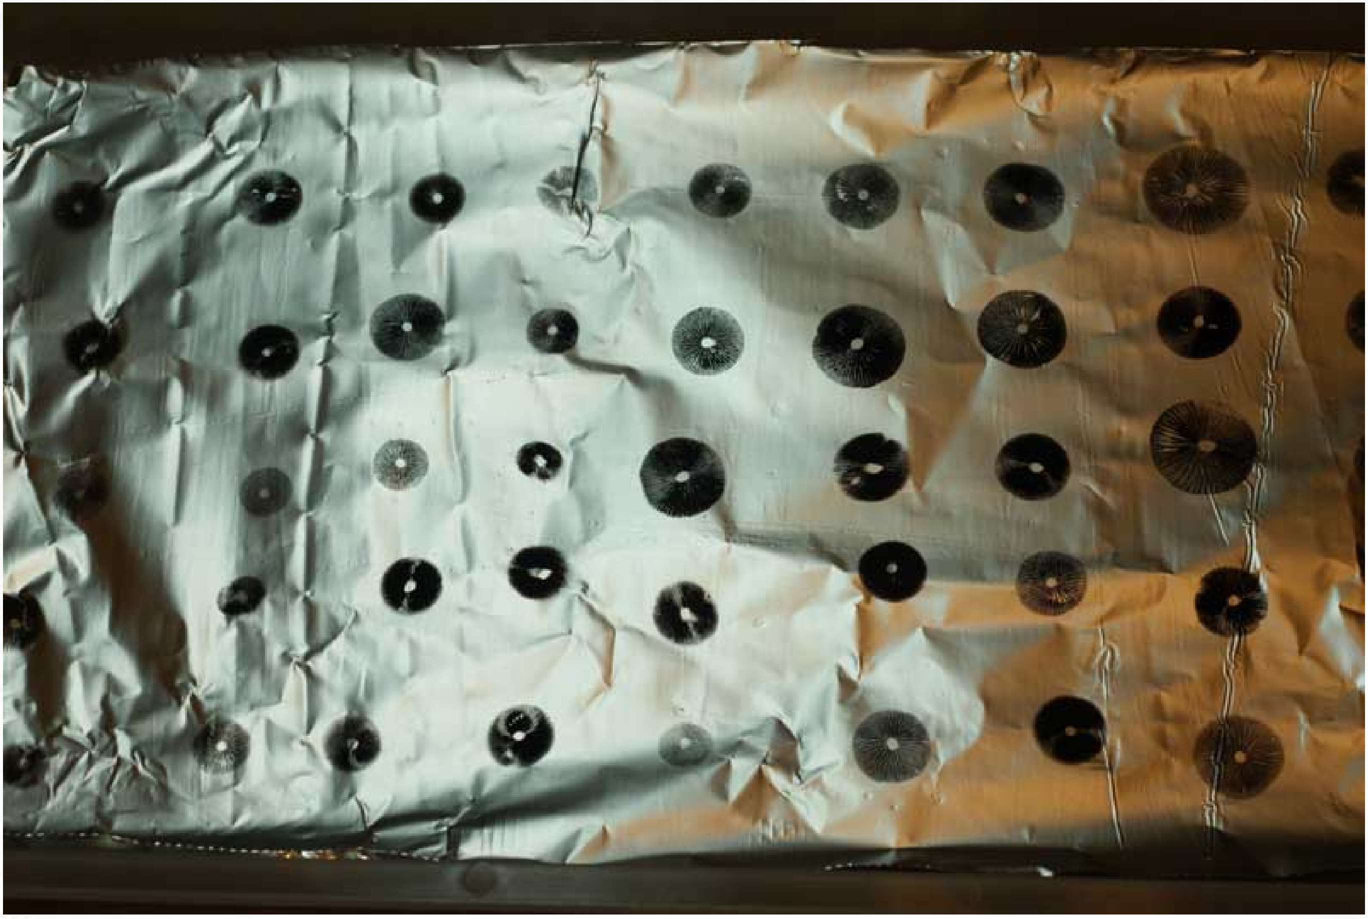
An other good method is to use a plastic shoebox.
Take the lid, and lay a sheet of sanitized foil in it.
Put the caps on the foil and place the bottom of the box on the top of the lid.
You'll have a nice sheet of good quality prints.

Psilocybe tampanensis caps mass-printing on foil in a shoebox





Finished prints of Psilocybe tampanensis



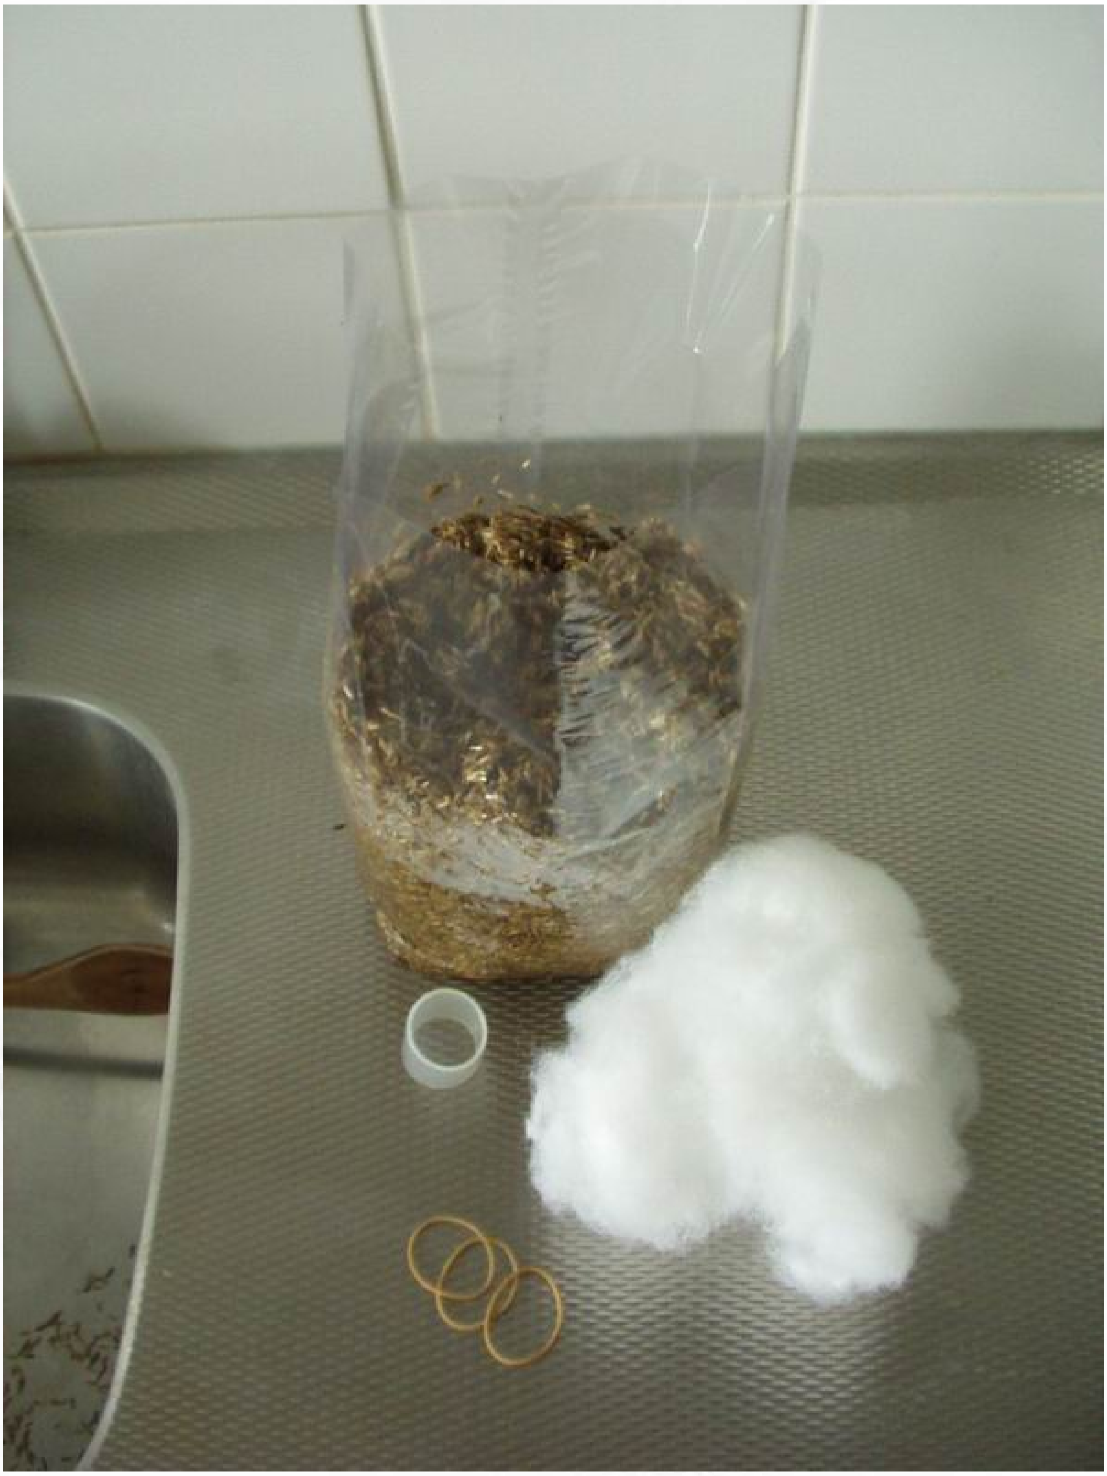
Thanks for reading.

Do it yourself - spawnbags

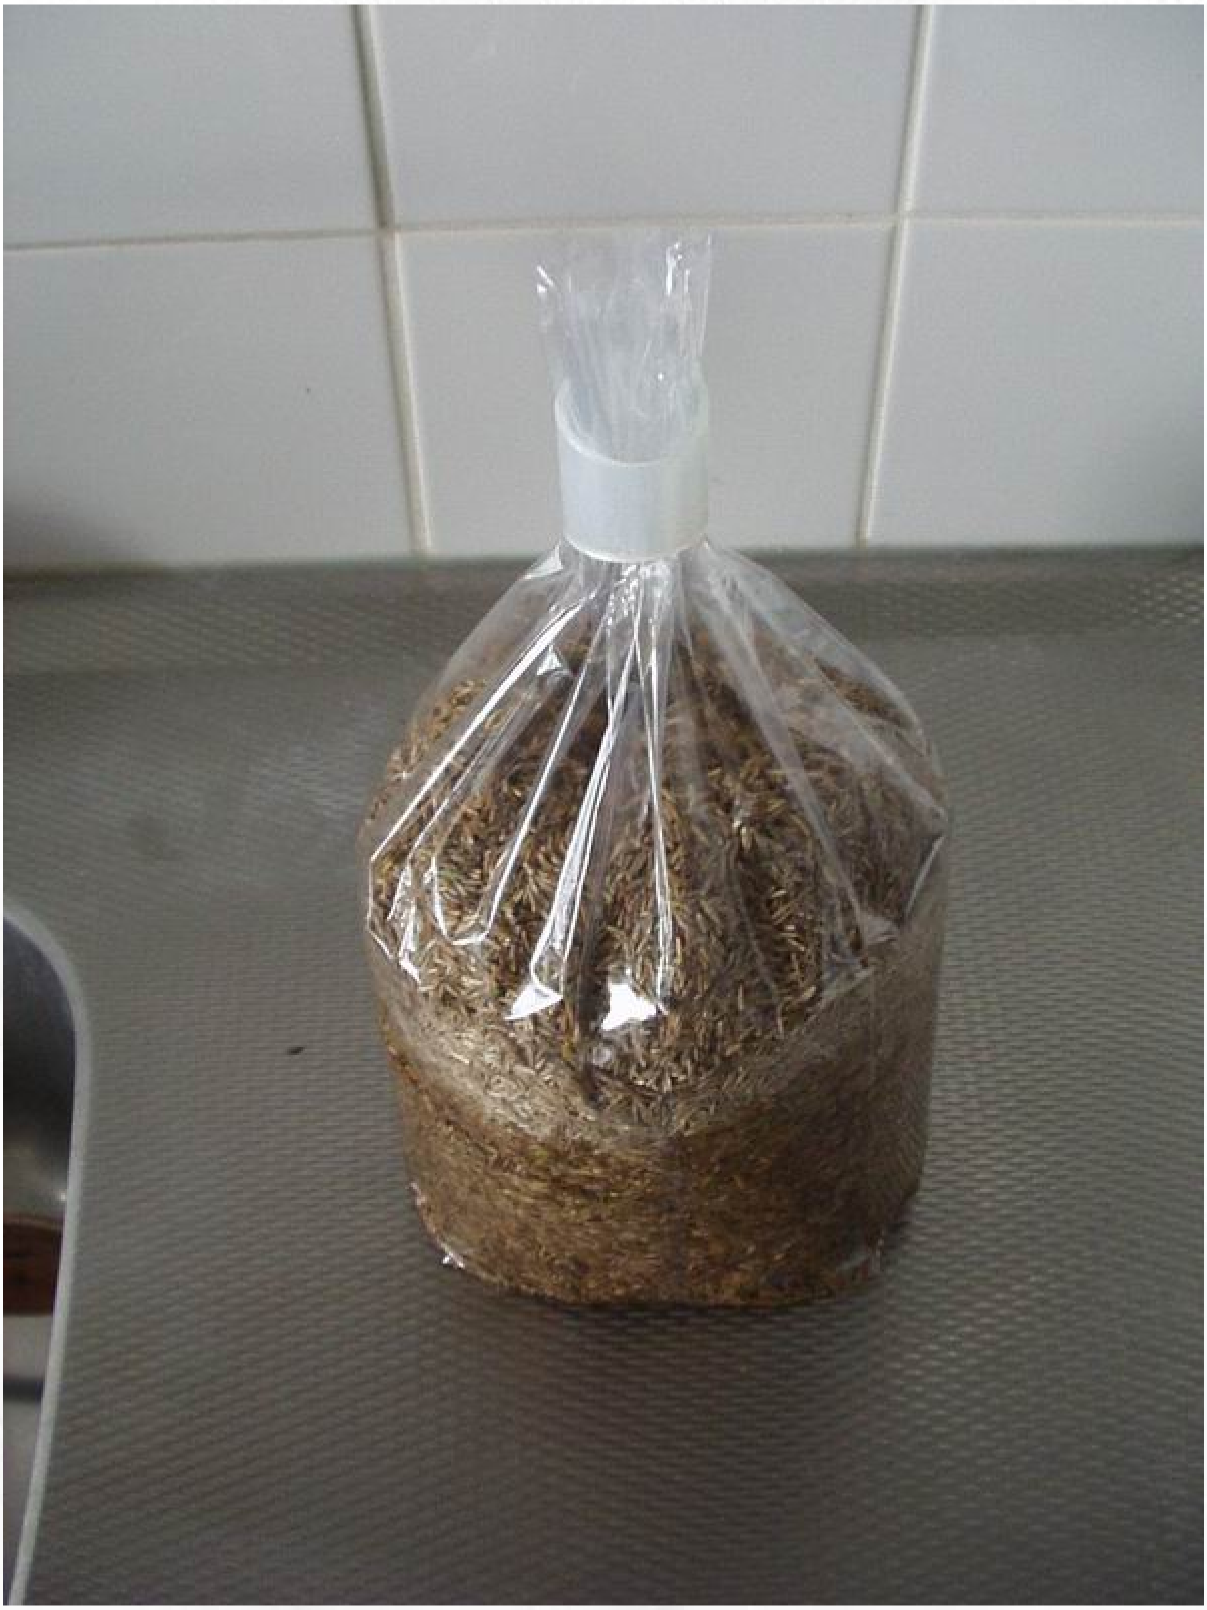
by

Una

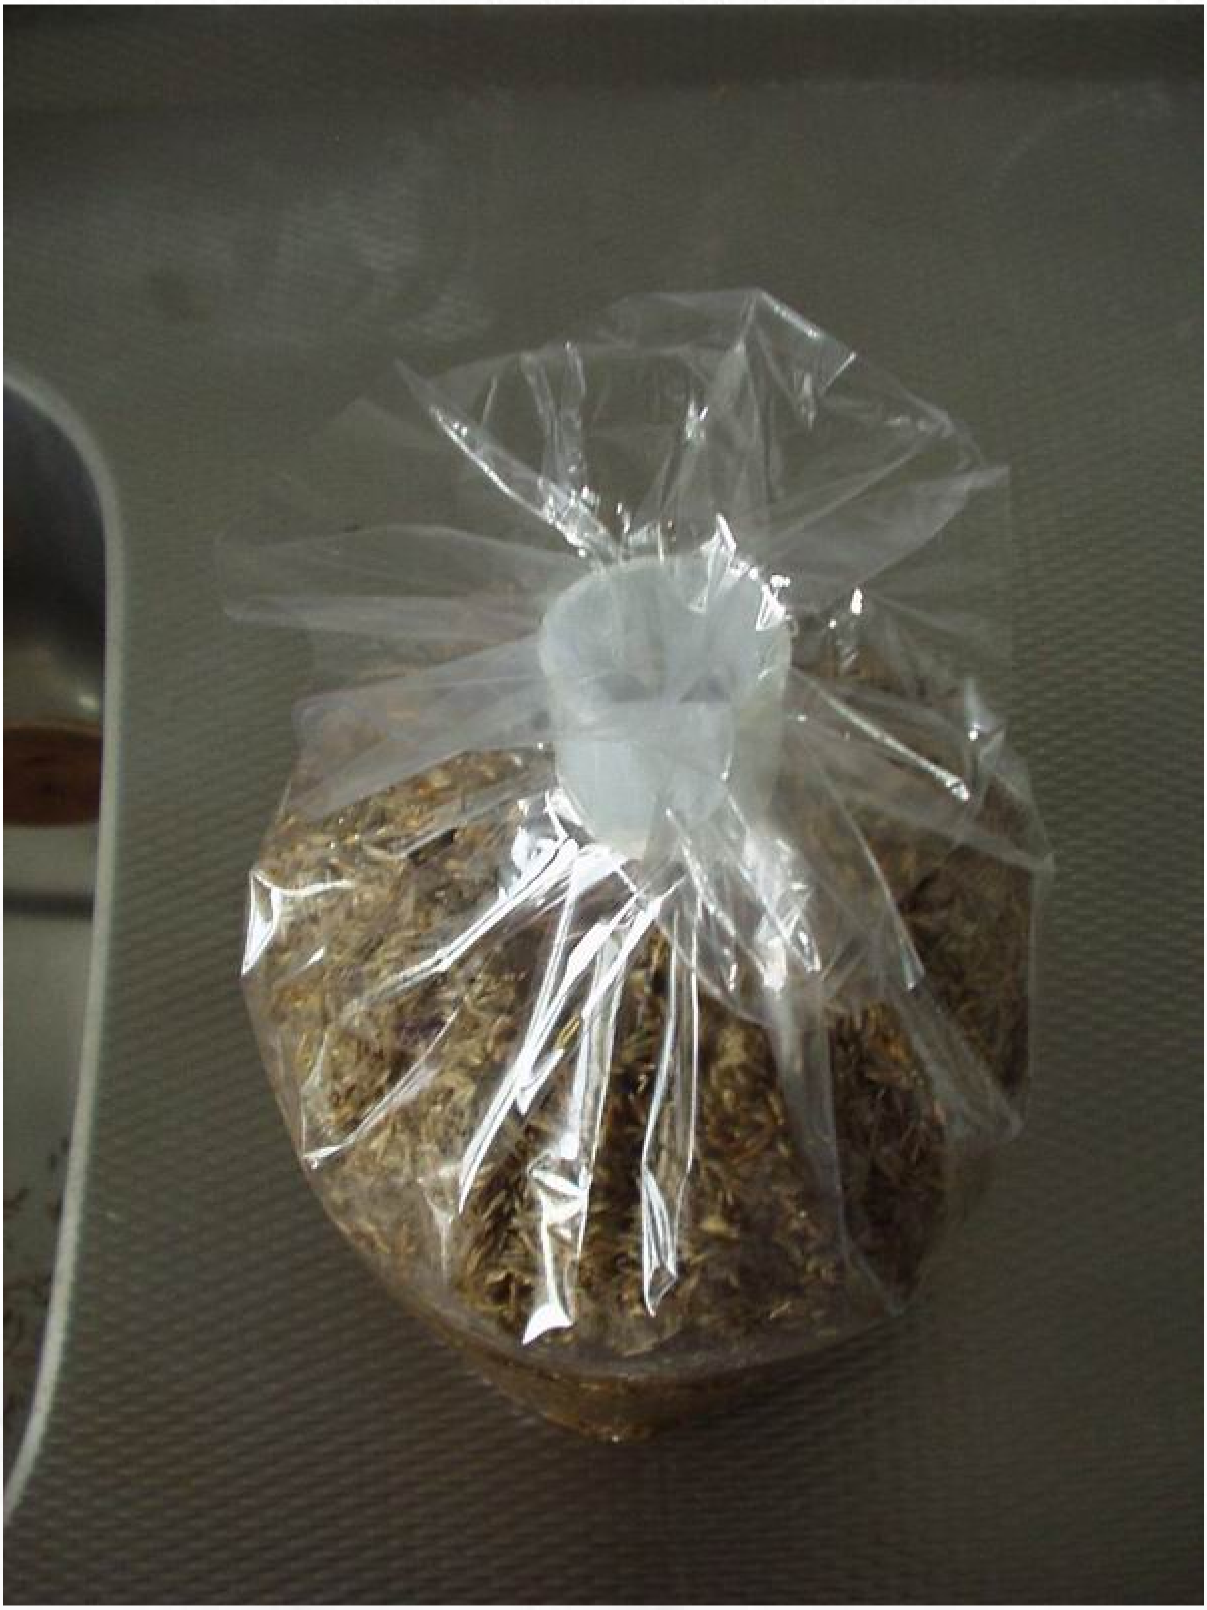
original source: http://www.shroomery.org/forums/showflat.php/Number/562556/fpart/all/vc/1



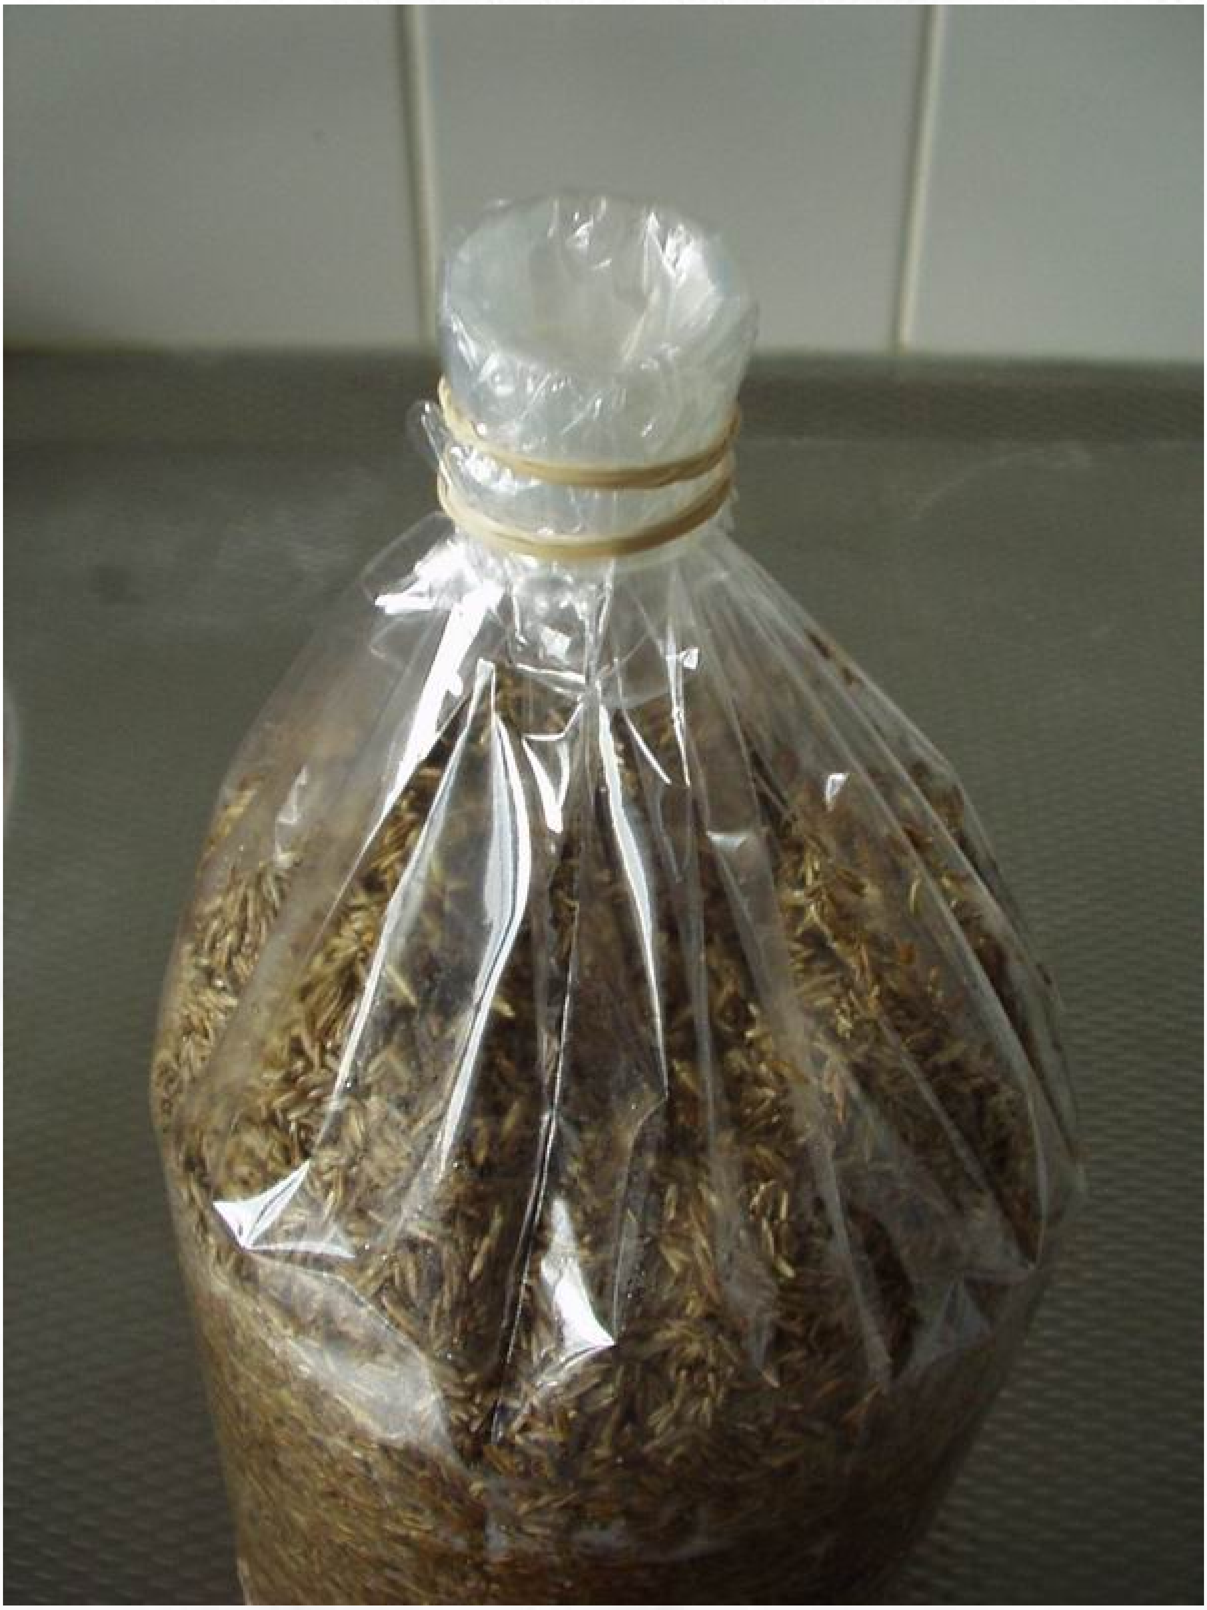
Grass seed (2 liter) and water (1 liter) combined in a polyproylene bag.



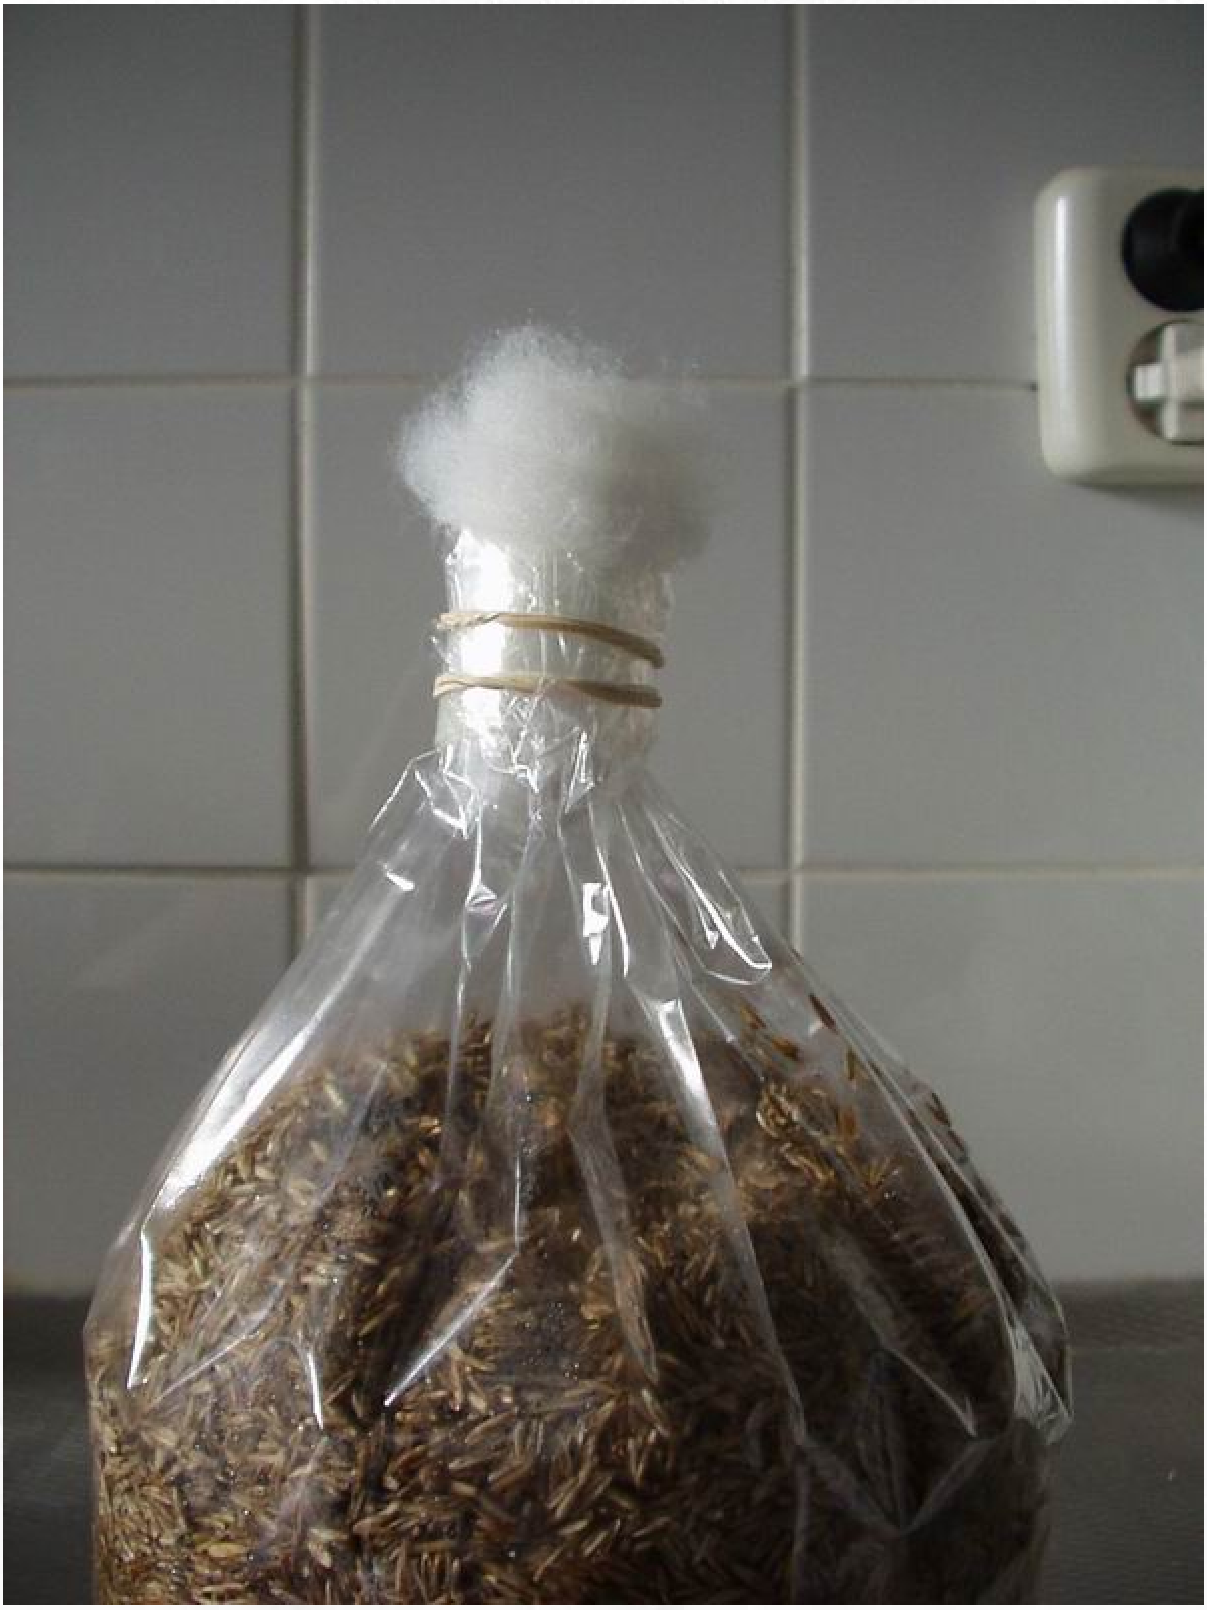
Bag is pulled thorugh a polypropylene ring (cut from a big syringe).



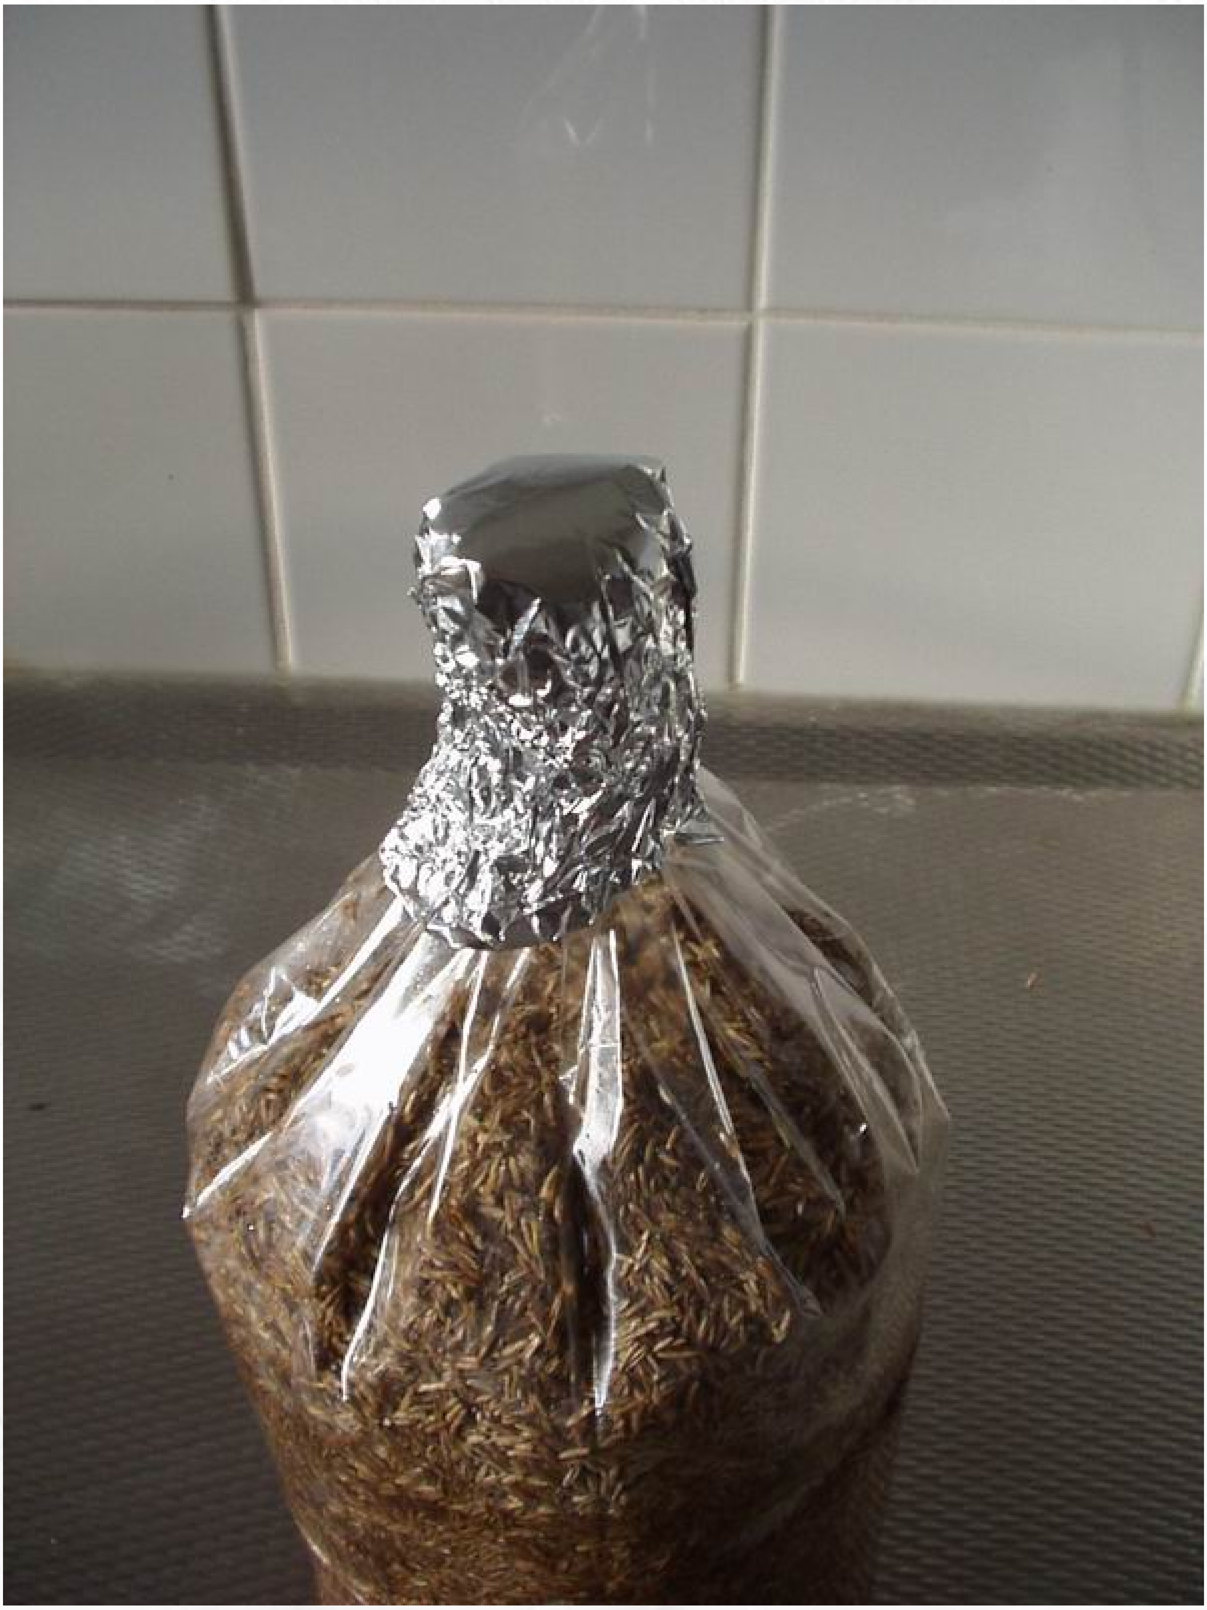
Bag is folded back...



...and secured with two rubber bands.

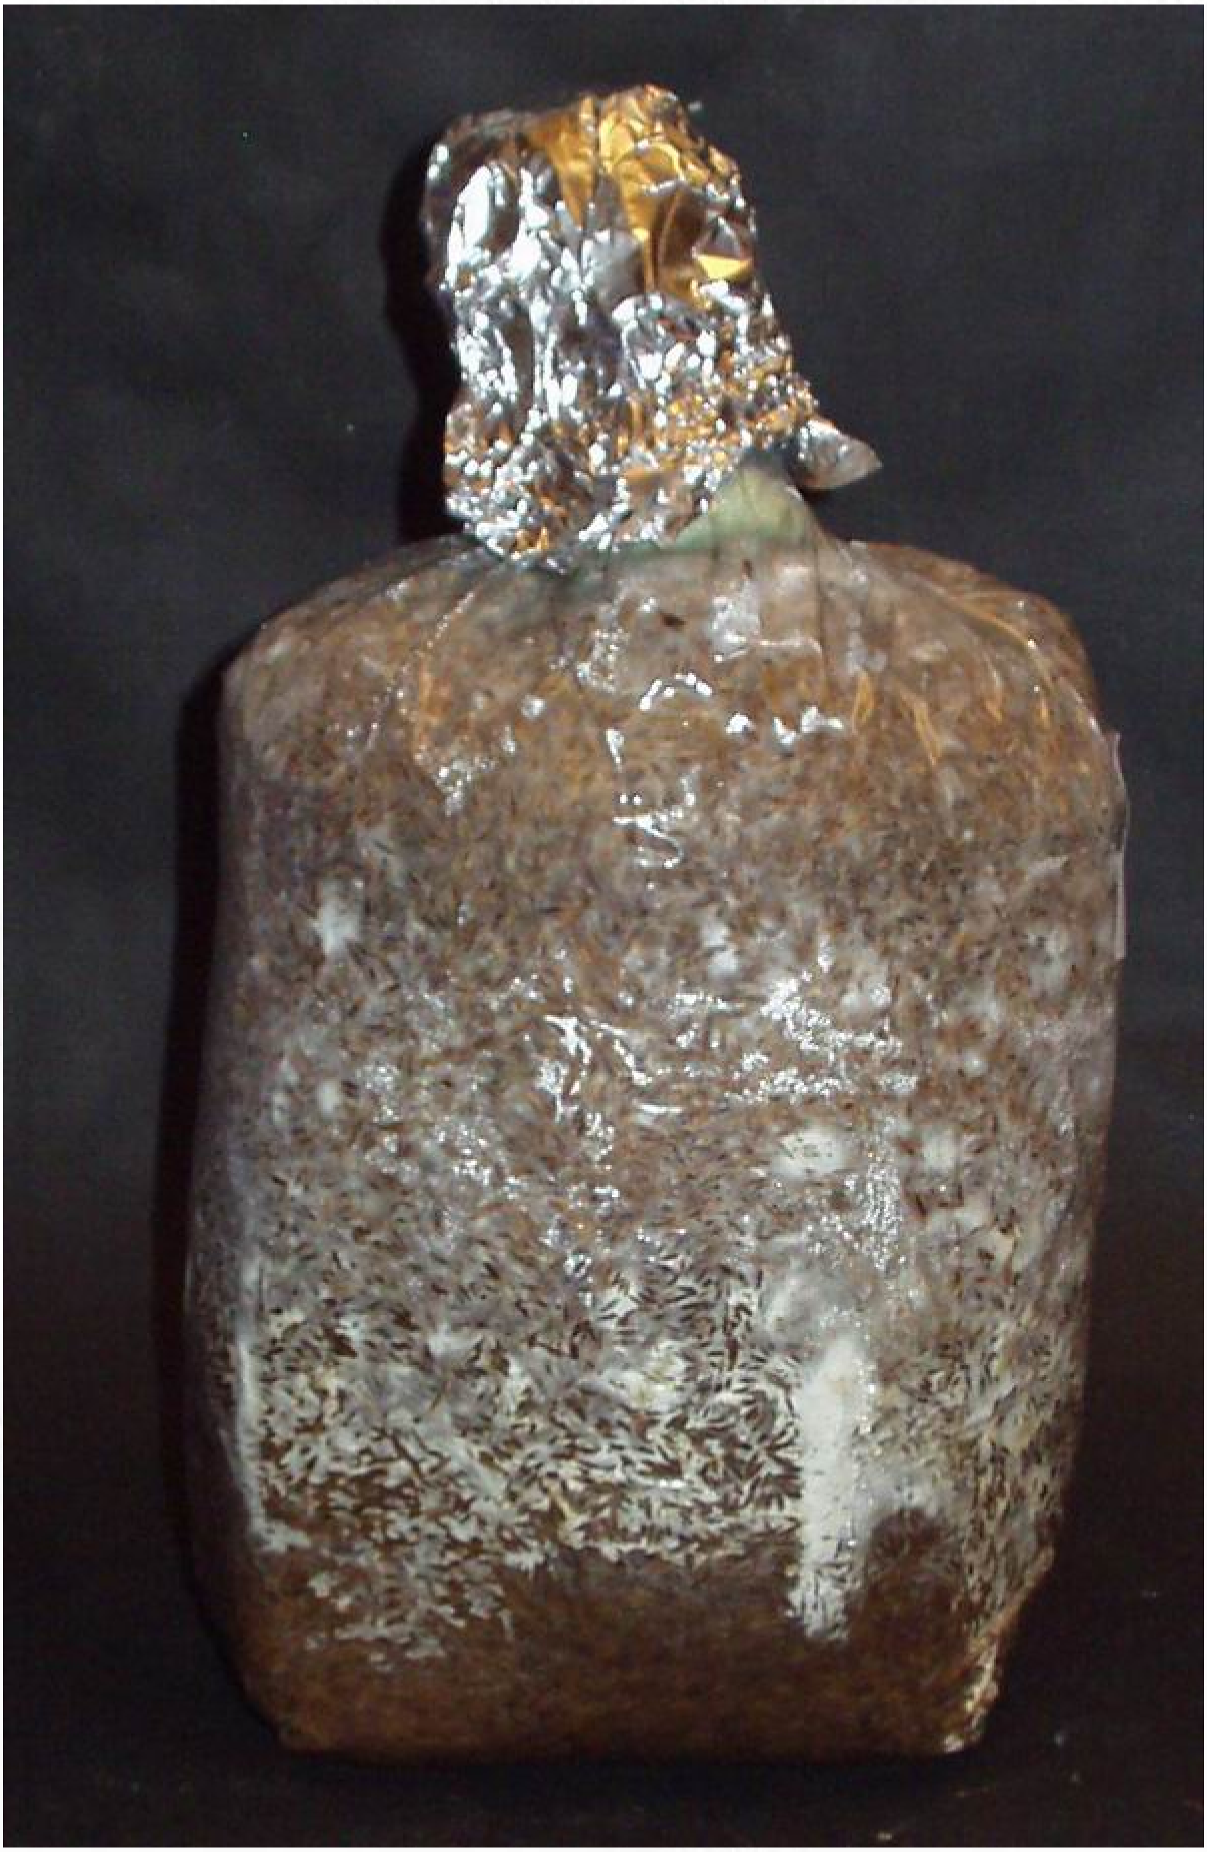


The openeing is stuffed with polyfill.

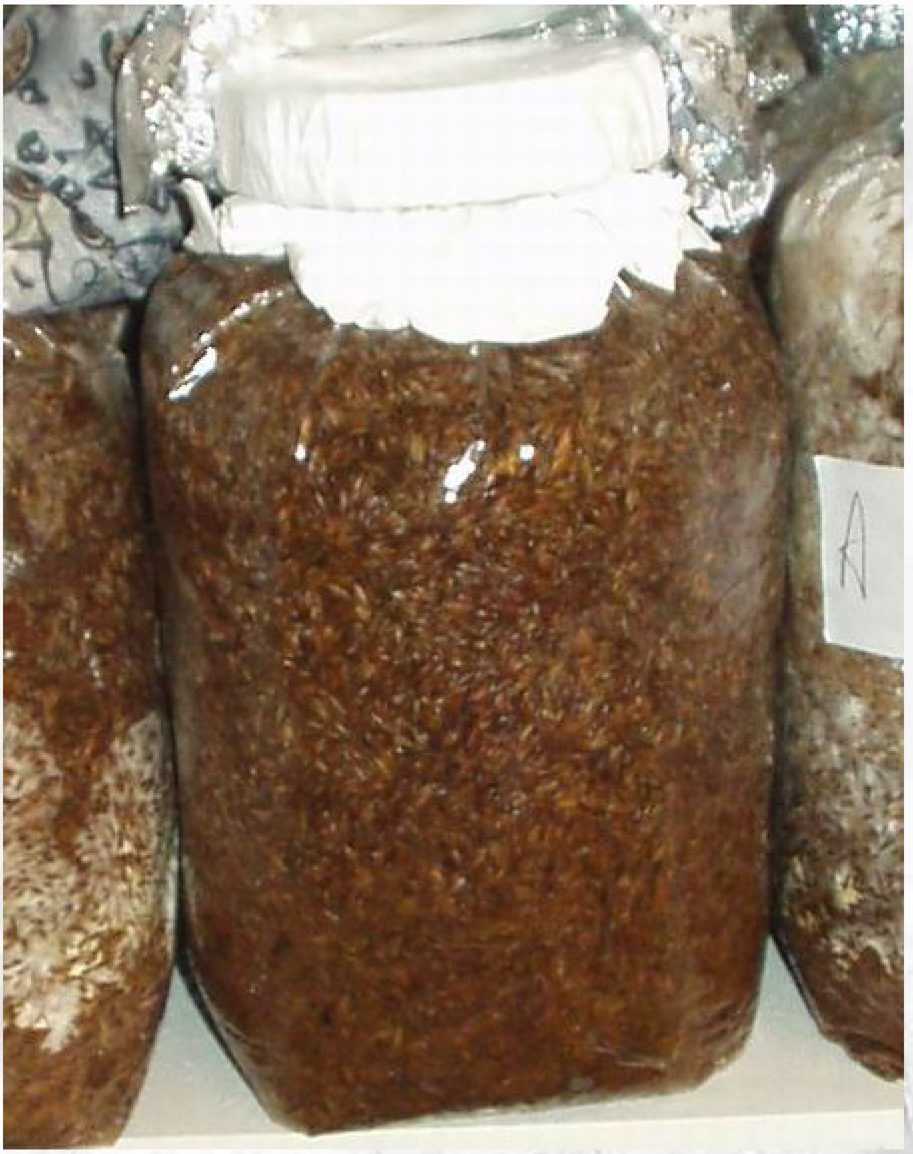


And this is covered with aluminium foil to prevent it from getting wet in the pressure cooker.

Bags after autoclaving (2 1/2 hours).



These bags should be inoculated with liquid mycelium since they cannot be shaken. Here's a picture of an (almost) fully grown bag, two weeks after inoculation. Some small scattered sclerotia are already starting to form.



Instead of using PVC pipe i used special cardboard rings that withstand autoclaving. Inoculation was done with 50 ml of mycelial suspension injected with a syringe through the tyvek filter. The hole was taped.

Magnetic stirrers

by

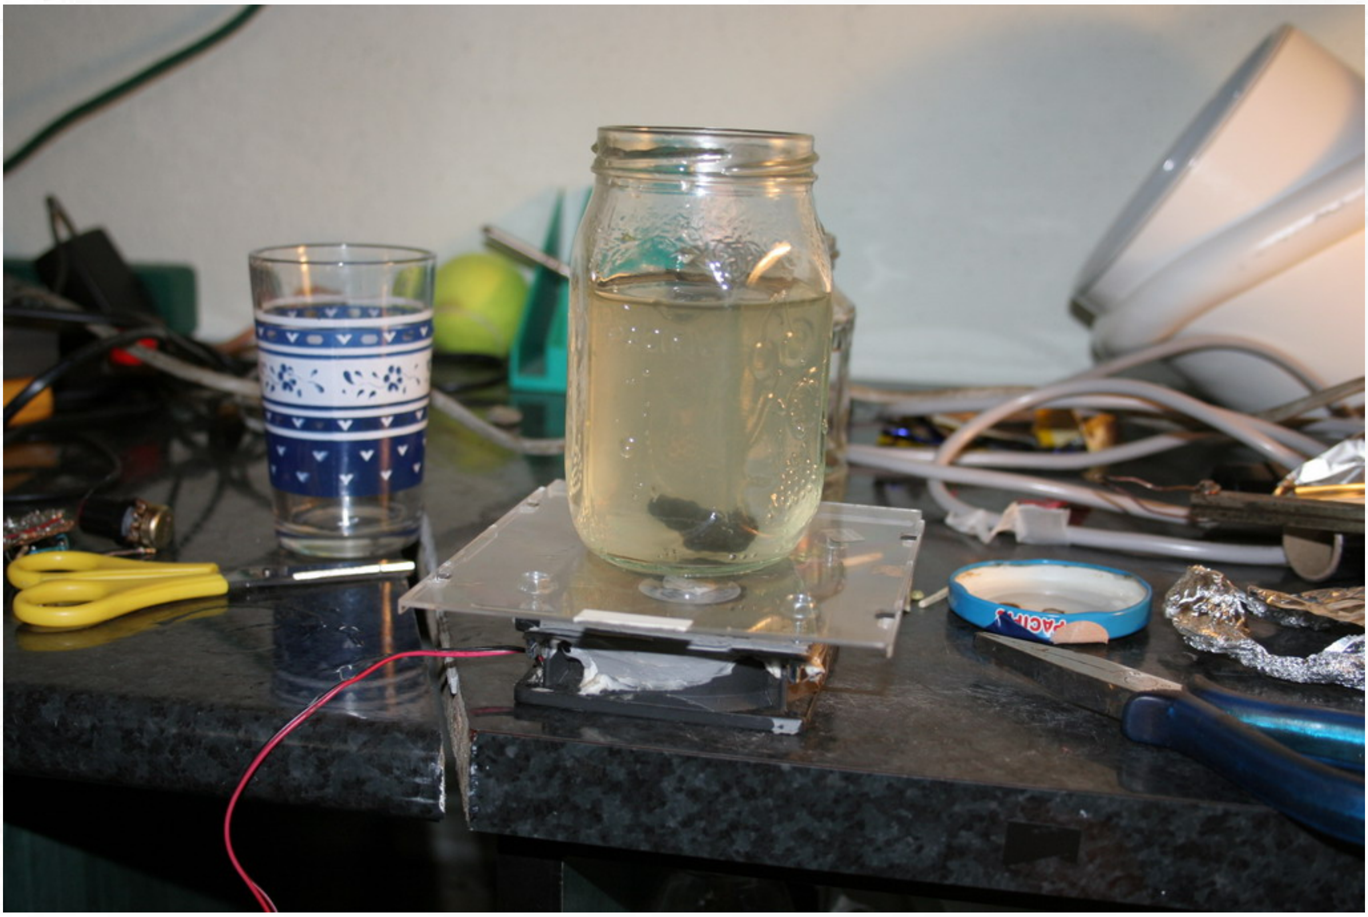
calavera, blacklabrat, splifner180

original source: https://www.shroomery.org/68/Do-it-yourself-magnetic-stirrers

by **calavera**:
http://www.shroomery.org/forums/showflat.php/Number/5585251

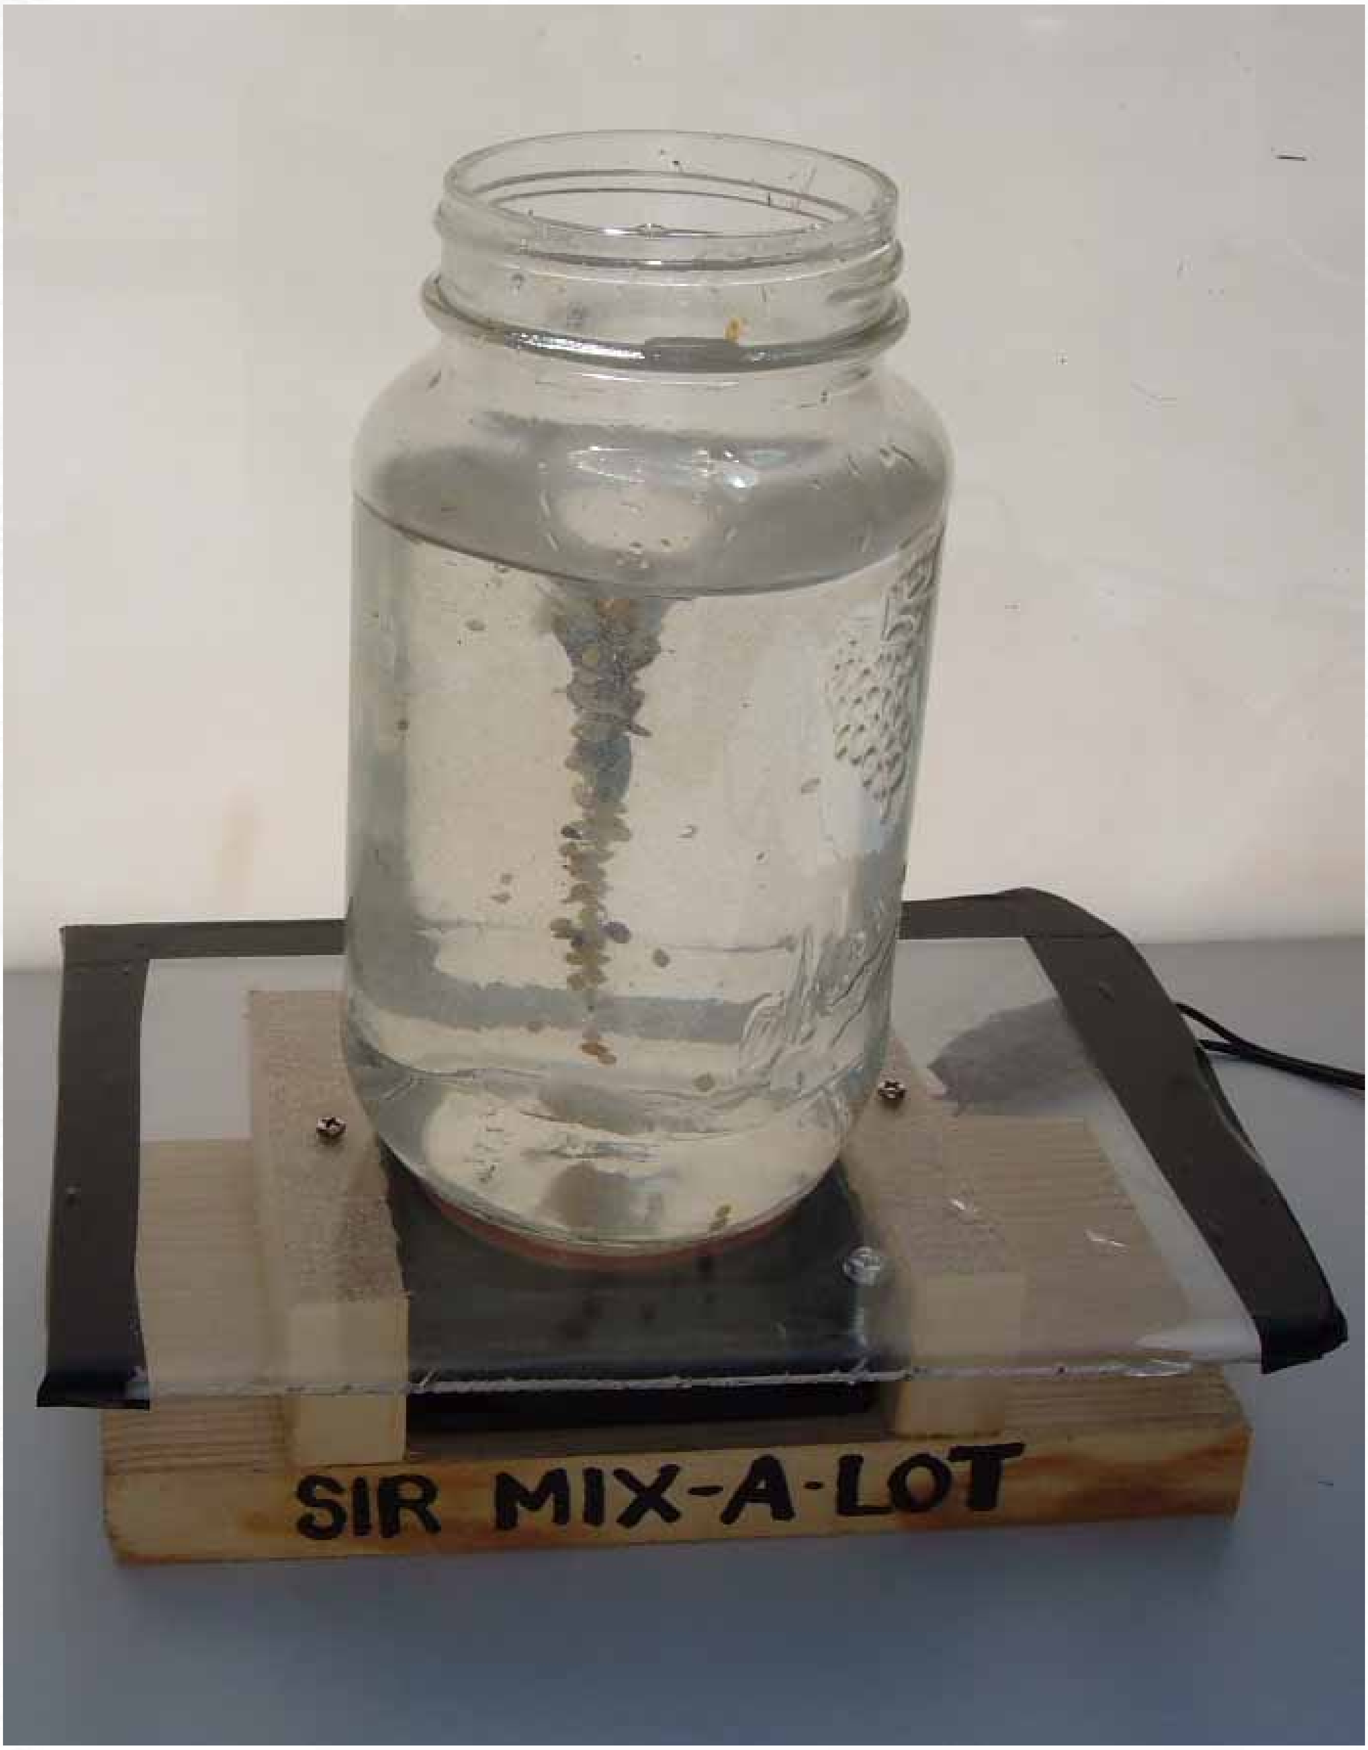
1 big computer fan with speed control
4 screws that fits in the fan's four hole
2 magnetic steerer stick's (original)
1 cd case
1 12v power supply for the fan
1 little piece of bluetech

stick one of your magnetic sticks on the center of the fan. screw in the 4 screws. the smaller part of the cd case goes on the top of the screws, adjust the screws until the cover is as close as possible, but not touching the case.



plug in, adjust the speed have fun!

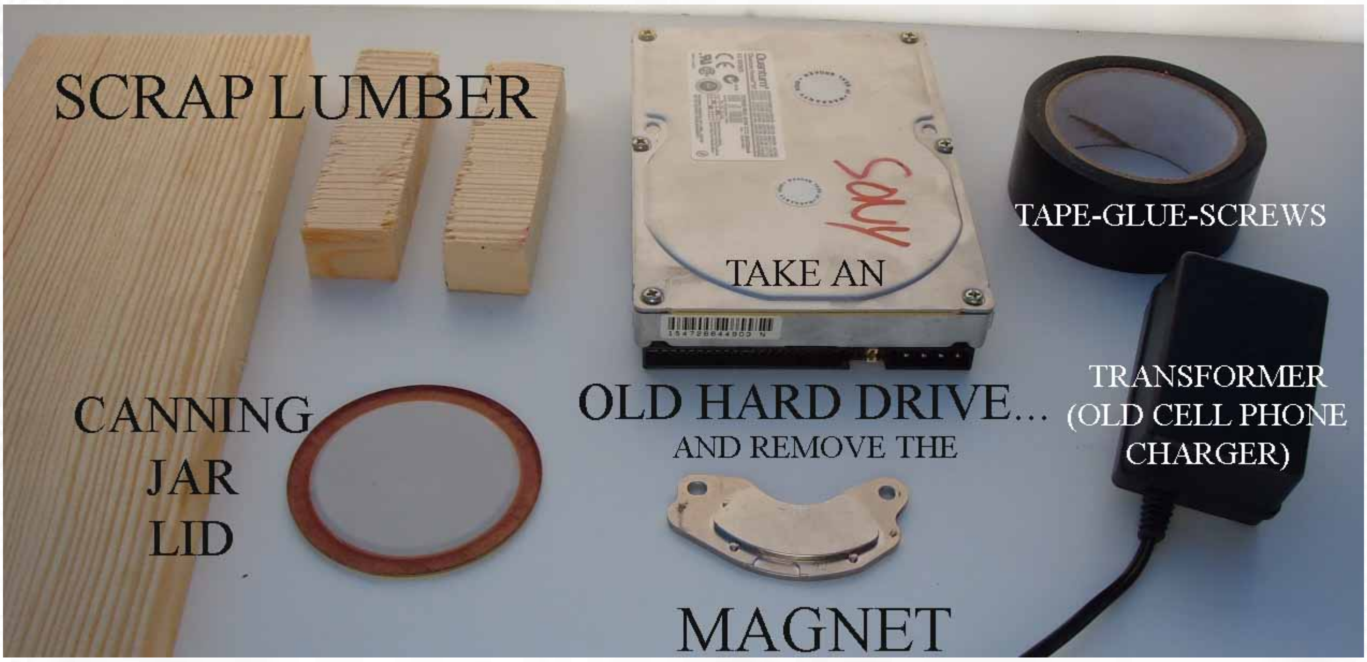
by **blacklabrat**:
http://www.shroomery.org/forums/showflat.php/Number/5568724 I would like to introduce my new little friend...........



SIR MIX-A-LOT.

OK, Right off the bat let me make it clear that I can take no credit for this. It is an idea that has been ripped off and inspired by several others who have done the DYI magnetic ***stirrer*** plate method. It works great, took me less than an hour to make and the best part...it didn't cost me a dime. FREE! Just scraped up a few items I had laying around the house.

Here's how it was done:

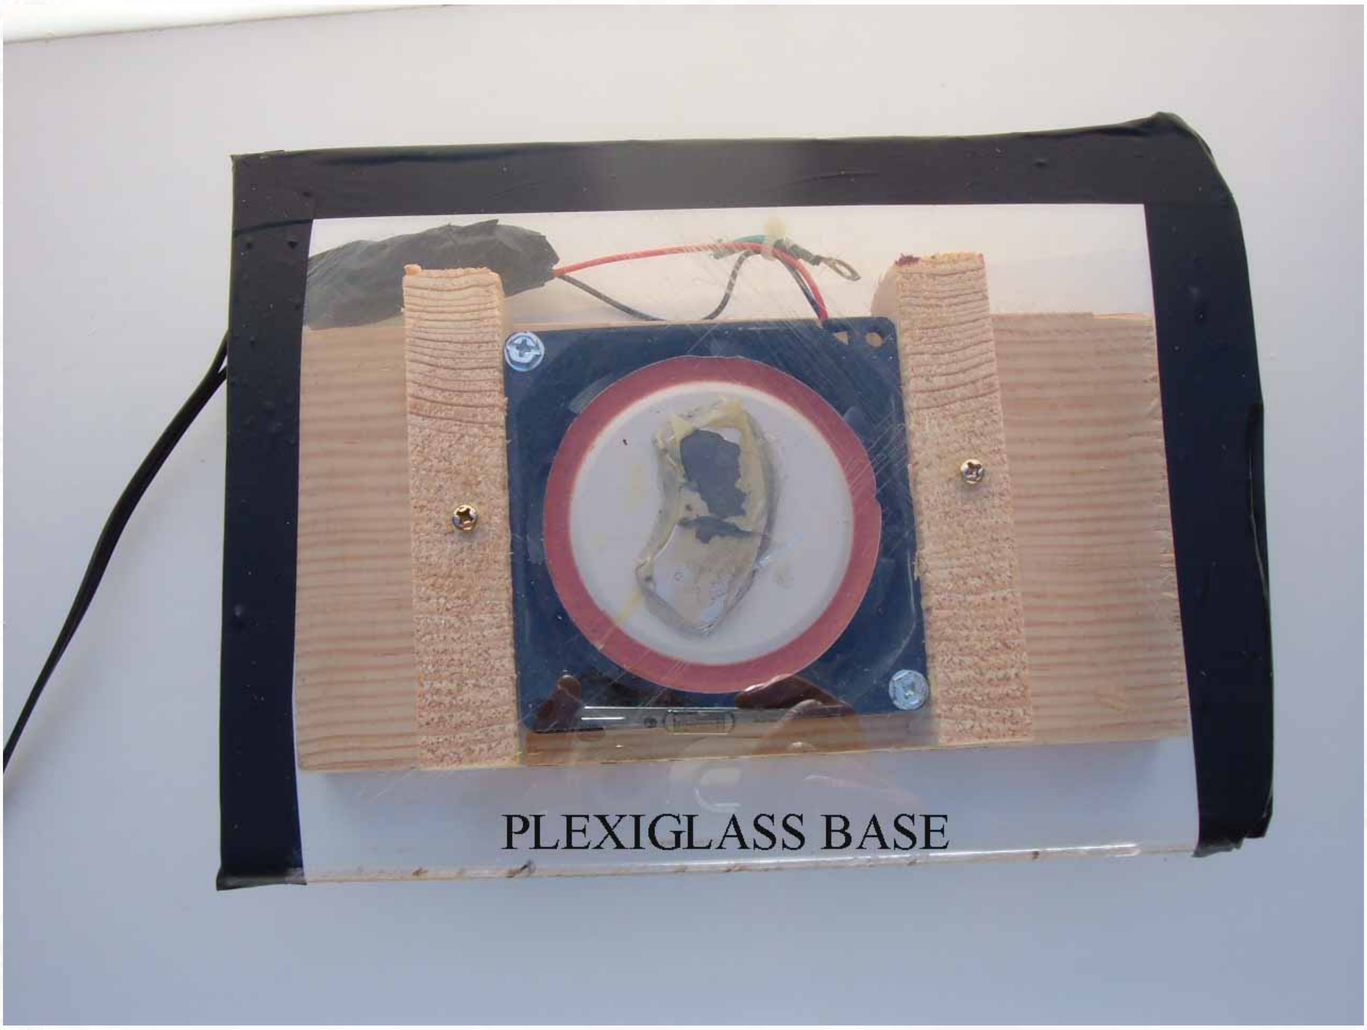


SCRAP LUMBER
TAKE AN
OLD HARD DRIVE...
AND REMOVE THE
MAGNET
TAPE-GLUE-SCREWS
TRANSFORMER (OLD CELL PHONE CHARGER)
CANNING JAR LID

COMPUTER COOLING FAN
AAVID
THERMAL TECHNOLOGIES INC
MADE IN CHINA

~ Started off by mounting the fan to a block of scrap lumber. Connected the fan to the transformer. Originally I was going to add a dimmer switch, but after testing I deemed it unnecessary.

~ Next, I took a canning lid and hot glue gunned it to the top of the fan. Place the magnet in the center of the canning jar lid. Tested placement by plugging unit on to make sure there was no wobble. Hot glue gunned it once the magnet was properly centered.



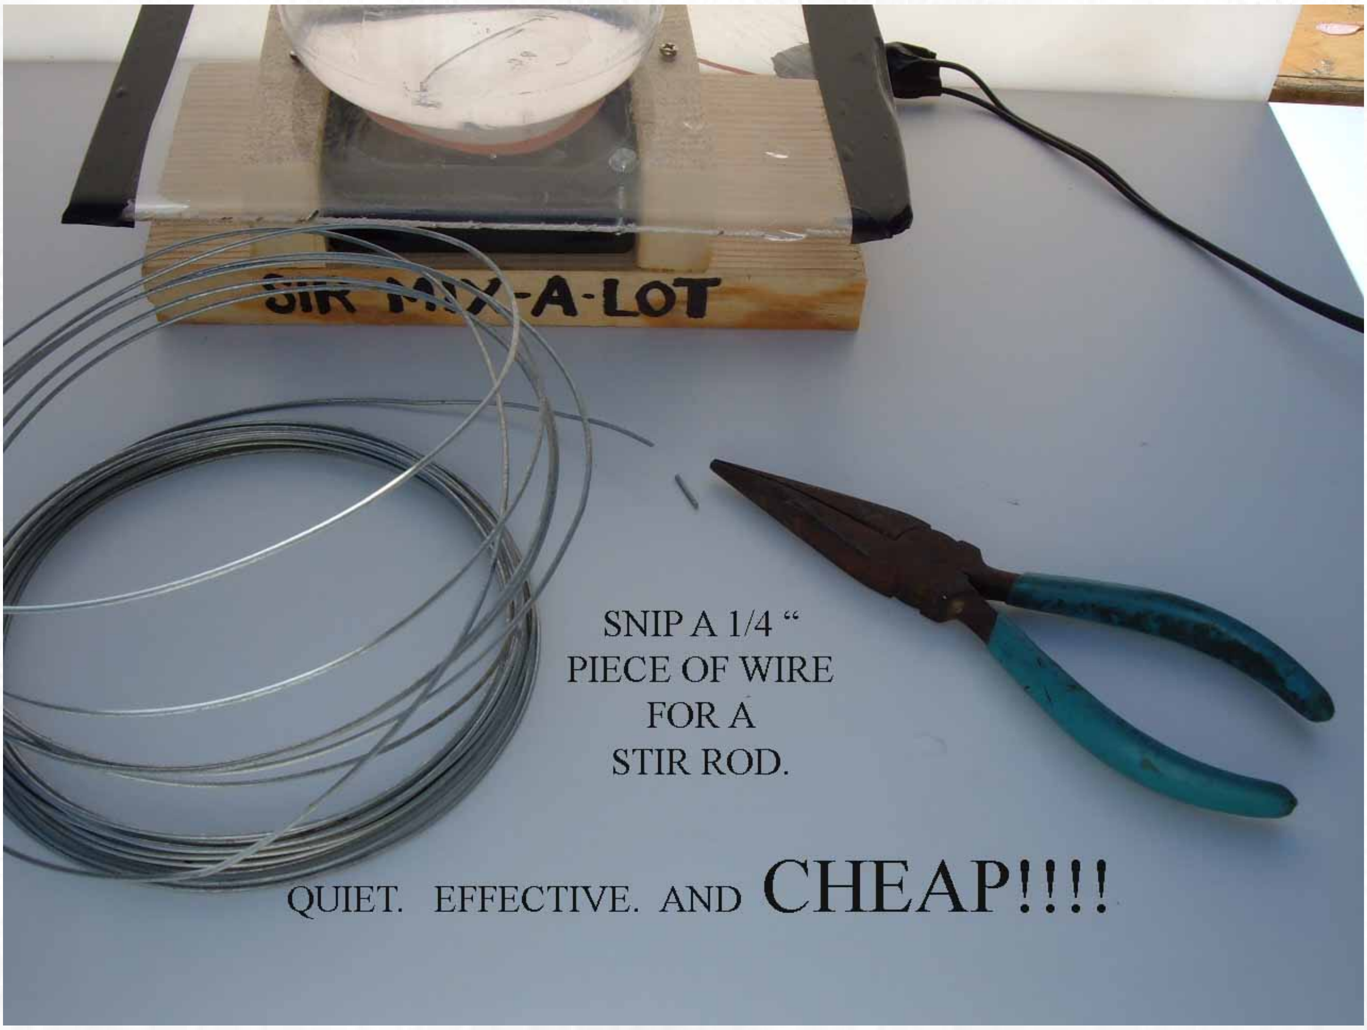
~Then I cut two blocks of lumber about 1/8" taller than the height of the fan/jar lid/magnet assembly. Mounted these to the side of the fan with glue and screws. Fixed a square of plexiglass to the blocks. This is the base surface where the LC jars sit.

Turned on to make sure that the fan was spinning freely.

Check. Everything is running quiet and smooth.

Now I need some stir rods................Hmmm. Ebay? Nah. Screw buying them!
I was now determined not to shell out any cash for this project. After playing around with several ideas, many which were too loud, slow or would require me spending some of my precious beer money.....

I was reminded how sometimes the simplest solutions are the most effective.



A small piece of wire about 1/4" long is quiet, effective and best of all CHEAP!

I tested it by placing a small piece of toilet paper in the jar w/ H2O and with in an hour it had broken it into small fibers.

Yeah yeah. I can hear it now. "Isn't the wire going to rust?"

Eventually. But not before the LC is done. They are essentially disposable, costing you about 10 cents per 100!

And there you have it.

How well does it work? Check out the first pic!

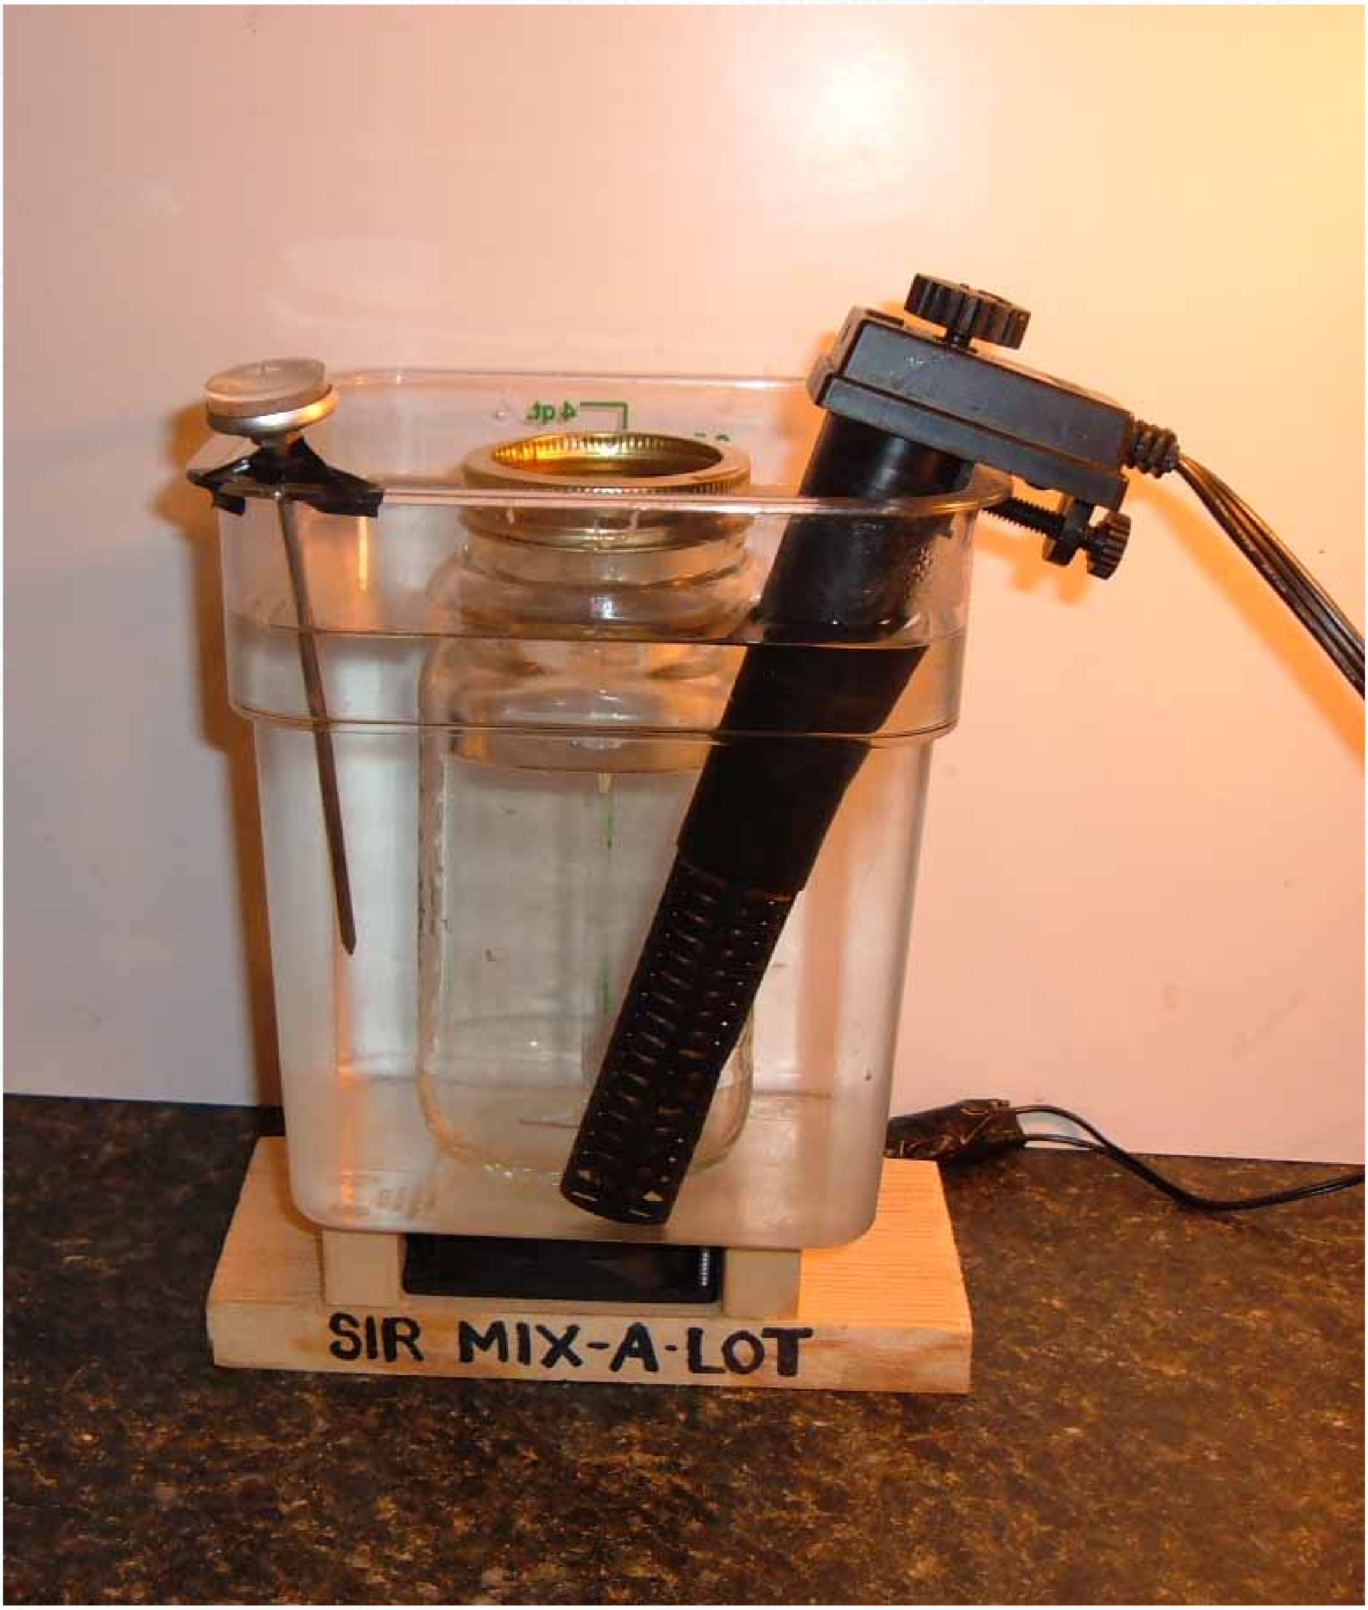
It spins like Dorthy in a tornado.

JUST ADDED

Need to warm up the temp of your LC? Try this:

Made one minor improvement to the Sir Mix-A-Lot magnetic ***stirrer***.

I usually do my LC in temps around the high 80s. Currently temps in my neck of the woods are about 20 degrees too cold & I'd rather not put the stir plate in the incubator, so........................



My solution:

I removed the plexiglass base plate and temporally replaced it with a 4 quart lexan tub. The tub is outfitted with a aquarium heater set to 87 degrees and a thermometer. (I realize that the heater is a little too large for this particular application..going to get a smaller one this weekend)
I can now dial in to the exact temp I need.

If you are not sure how to do this, or if you are unsure if the fan/transformer combo you have will work, don't ask me. I'm no electrician. Besides even if I was, you gonna trust an anonymous druggie electrician who posted some shit on the web with your life?

I suggest you read up, use google, use the shroomery search function and take a trip to Radio Shack or a hardware store and ask them. You don't want to go burning your house down or electrocuting yourself. There ain't no fungus worth that!

by **splifner180**:
http://www.shroomery.org/forums/showflat.php/Number/5567819

I should mention that this idea was stolen wholesale from blacklabrat and this thread. Five shrooms for him.

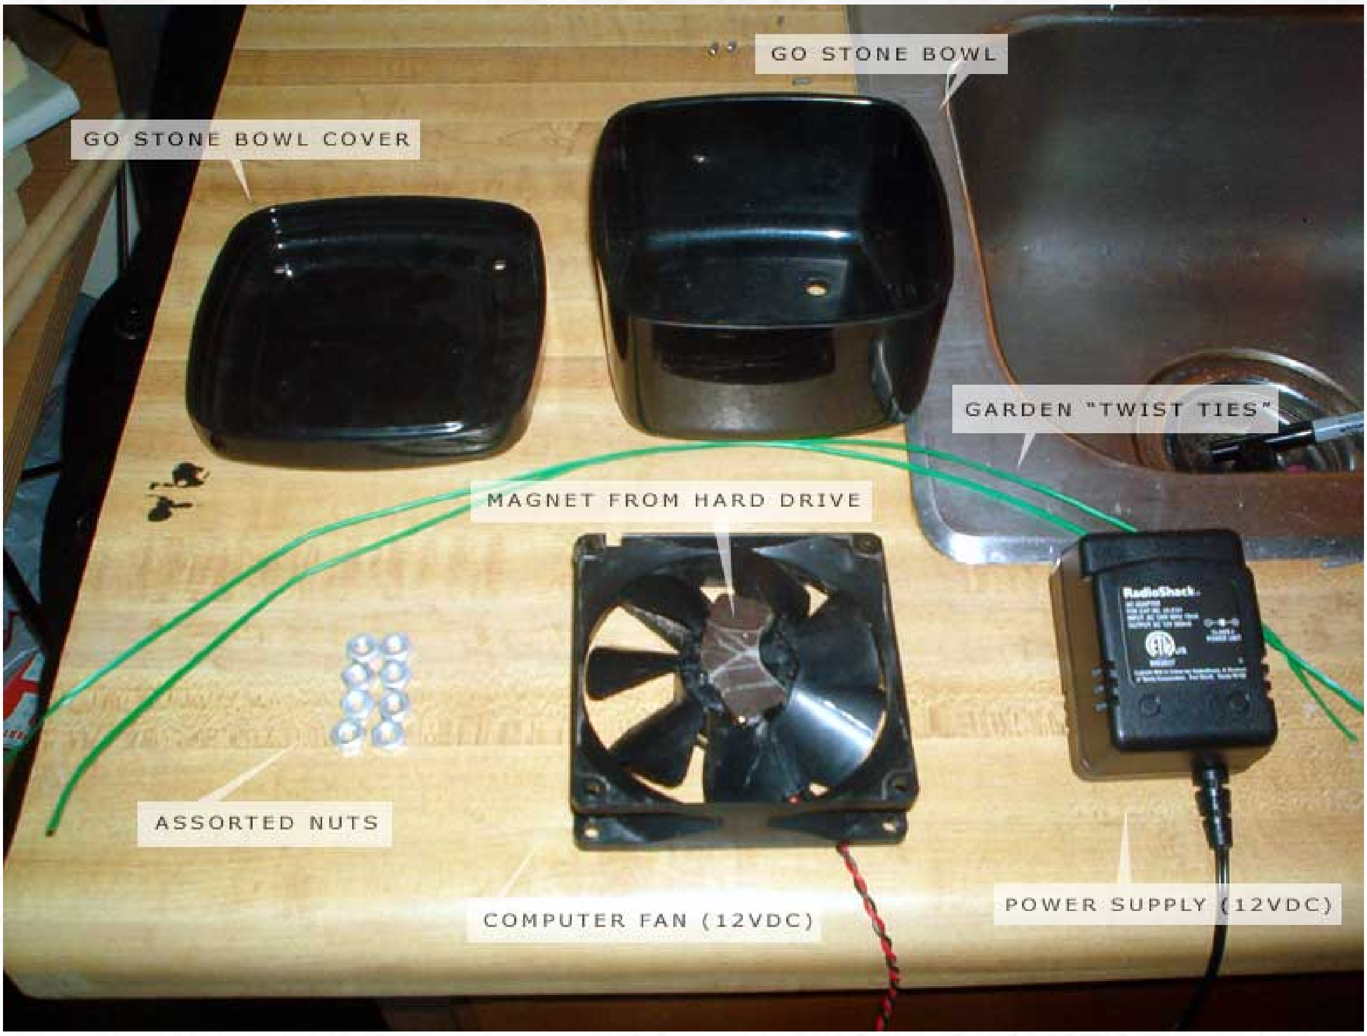
So I've been desperately wanting to have a magnetic stirrer but my $$ was tied up in necessary things like the PC, jars, etc. So when I read that thread I thought to myself "no frickin' way, I have at least five spare fans kicking around this room and probably twice as many power supplies."

And I was right.

So I made myself a working magnetic stirrer using only stuff I had kicking around the room. The only "exotic" thing used was a spare go stone "bowl" (though it's square-shaped). The whole thing from start-to-finish was roughly 30-40 minutes.

Obtaining the magnets are only a problem if you *aren't* someone who has spare hard drives kicking around as a matter of *principle*.

Ok, so here it is. The parts all in one spot:



There you can see the enclosure (go stone box), some arbitrary-length garden ties (use string if you want, doesn't matter), the computer fan with the magnet already attached, superglue (not shown), some washers (to stand off the fan from the work surface) and a 12v power supply pinched from a humungous box I have stuffed with such things.

The assembly was simple.

* Match fan up to lid. Use sharpie to mark four holes. Drill holes.

* Strip wires on both the fan and the power supply. Attach. If the fan spins in the "wrong direction" you have the wires hooked up backward but I don't think it'll harm anything if you do.

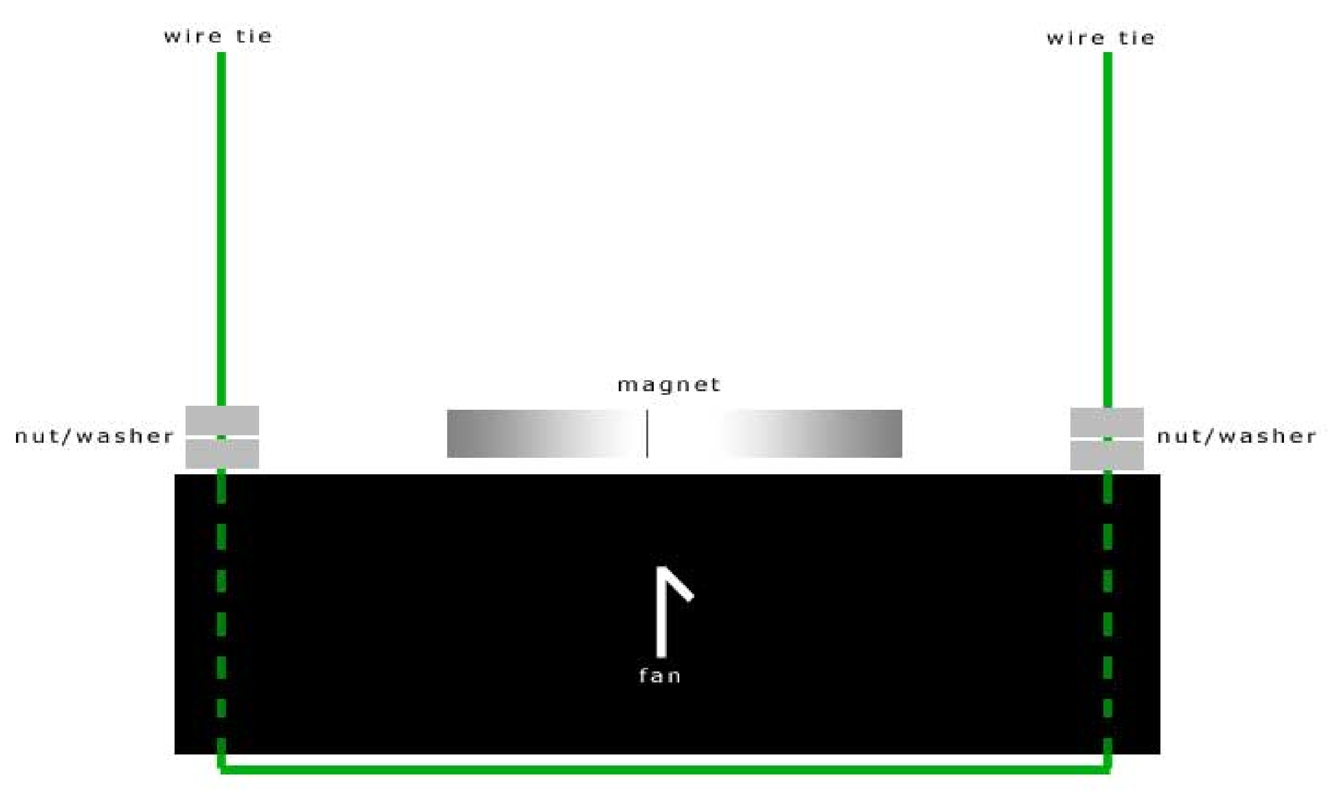
* Attach HD magnet to the fan. It should stick since it's an extremely powerful magnet and the fan has metal inside. Power up fan.

* The goal at this point is to find the "sweet spot" for the magnet, the placement that will cause the least wobble in the assembly. A millimeter can mean the difference between a kitten purr and the magnet being flung from the fan so make small adjustments.

* Once you find the sweet spot, superglue that mofo down. I didn't bother with the jar lid like blacklabrat did.

* With the fan pointed "up" (the magnet facing up), take one wiretie end and thread it through the fan holes from bottom to top. Take the other end of the wiretie and thread it through a parallel hole in the fan. The wire tie should look like the rope on a swing set and the fan/magnet should be the wood swing itself. The wire tie cradles the fan.

* Thread enough nuts unto the wire tie so that the spinning fan will not hit the lid when pressed against. Sorry no pics for this - my camera batteries died. Here's a drawing.



* Do the same through the other two holes. Now you'll have four wires cradling the fan with washers dropped over the wire to act as a standoff.

* Place the cover over the fan, threading the wires through the holes you drilled. Twist the ties together to secure the fan assembly to the lid.

* Place the lid over the box. Make a notch for the power wires if you want. I didn't.

That's it. All done. Here is the stirrer in action.

I should have taken multiple pictures. That one does it no justice. There is a righteous vortex in the container right now. The one in the picture is pretty small.

I should mention that there are TONS of ways I could have done this differently. I justed wanted to do it with the items I had on-hand and ...well ...these are the items I had on-hand. It's whisper quiet (calibrating the magnet is critical) and it's been running now for about 80 minutes without so much as a peep.

The stirring rod itself, like the other thread mentions, is just a 1" piece of ferrous (magnetic) metal. I just snipped a bit off a spool of ground wire I had kicking around. Heck, even a small nail might work perfectly. Tomorrow I'll pick up a bit of shrinkwrap to place around the rod. I tried different sizes (I think 1" is optimal) and I tried doing multiple bits of metal (it worked terrible for me, they all clumped together). Tomorrow I'll probably try to attach two bits of metal to polar ends of something non-magnetic, seal with shrink-wrap and see how that works. Who knows?

Chronic Invitro Tek

by

Chronic

original source: http://mycotopia.net/archives/discus/messages/5/7618.html
original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/6662.html

The Chronic Tek is a quart jar, mini terrarium technique that was developed to be as maintenance free as possible. It is a very simple tek that if followed properly will show the grower many of the benefits of a terrarium while eliminating the need for misting, fanning, and other such maintenance work.

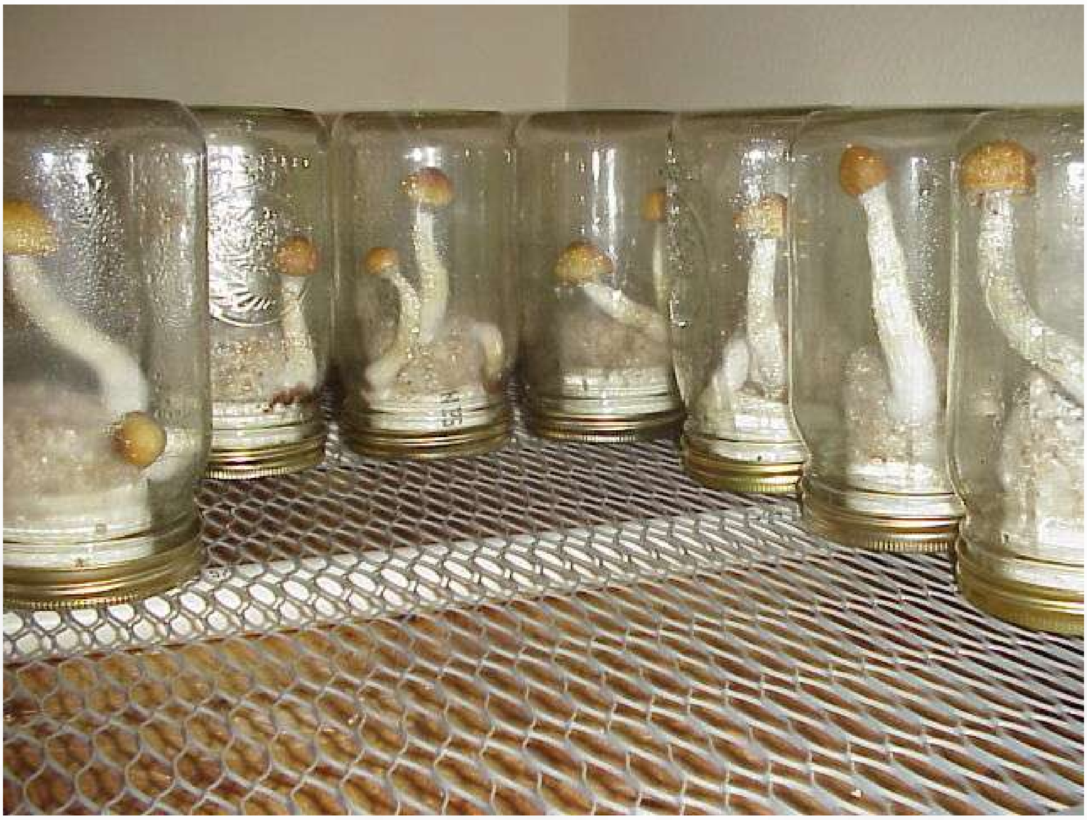
**keep in mind that this is a very open ended tek; the purpose for each piece of equipment will be noted and if you see fit to complete that piece's function with some other piece of equipment, that is your choice. I would however recommend completing this tek once as written before expanding as you will get a better feel as to how your mini terrariums will react to your changes.*

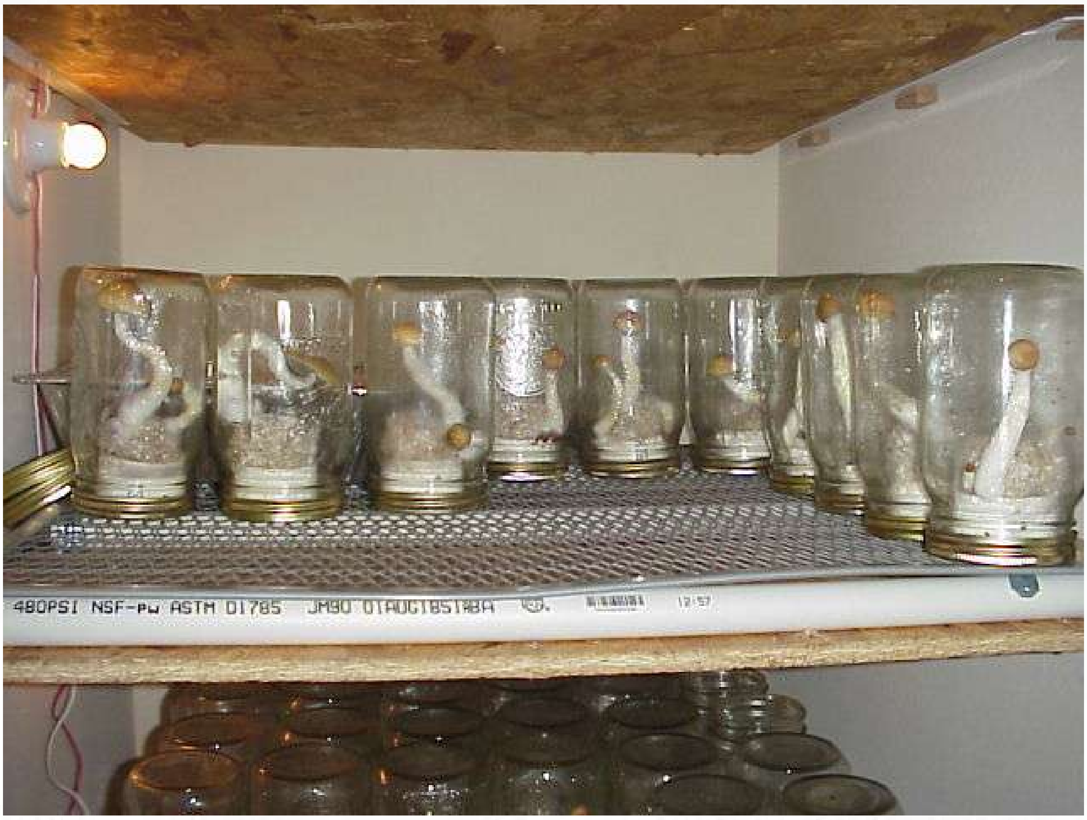
We will be making some very simple modifications to a quart jar that will enable the cake placed inside to create and maintain its own fruiting environment. The quart jars will also be acting as contamination buffer zones; holding contamination to one cake instead of spreading throughout the terrarium.

A few little things we will need:

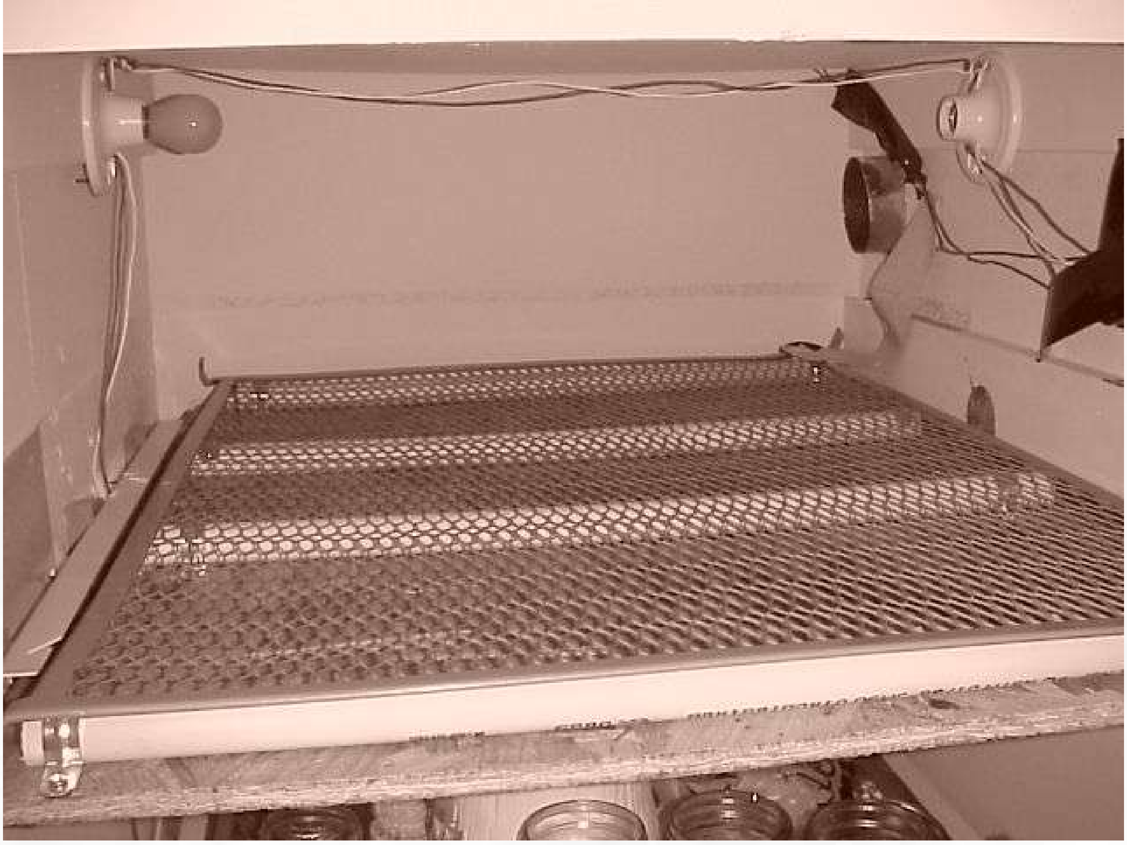
1. Wide mouth quart jar and normal dome lid with ring as used in PF jars.
2. Piece of 2" wide PVC pipe any length 2 or over will do.
3. A 1/8" thick nail.

OK, let's get started. First off our mini terrarium will be sitting upside down with the lid on tightly. To allow the cake to create a nice fruiting environment for itself we will allow airflow through four 1/8" holes equally placed around the lid. The temperature must be held as near to 76 degrees as possible for the proper fruiting environment to be maintained. I cannot stress this part enough folks; to hot and the cakes will dry out, to cold and you will not have proper humidity. Don't be fooled either, water condenses when humid air cools, this will give you the look of being humid but the water will be on the jar instead of in the air. **Keep it near 76 degrees and you will be happy**. The cake will be suspended on a 2" long by 2" wide riser to keep it out of pooling water and keep it from plugging our air exchange holes. Here is a quick picture of the finished product from the side so you can have a mental picture as I describe a few things more in depth.





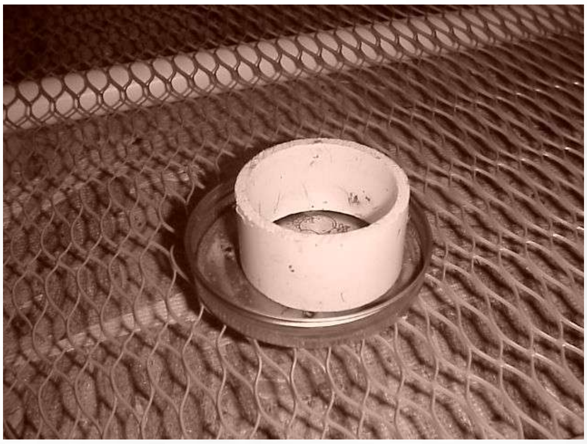
Here is an example of a shelf I place my jars on so that the holes are not plugged.



Well here is the fifth flush of a few of the cakes I displayed earlier in this thread. Not as awsome as the first few flushes and they definetly took longer to fruit but they're still giving it their all. They also straggle in at very different times when they get this old and wise. Bless their little hearts. I hate dumping cakes after they've worked so hard. Anyways someone asked what my contam rates were and how many flushes I got so here are the fifth flush girls.

The Lids: The screw on lid is the main factor in your mini terrarium that controls the environment inside. Many experiments were done with different hole sizes but 1/8" has most definitely proved to be the best. Four holes should be punched with your 1/8" nail around the dome lid just as in the PF TEK. If the holes are too large the jar will not be able to hold good humidity and the cake will dry out causing small and aborted fruits. If the holes are too small the cake will not be able to "breathe" efficiently and will begin graying and eventually die. As you can obviously tell by now the lids should be tight as air should only be entering or exiting through the holes. It is also very important to make sure the holes do not become covered which leads me right to the risers and surface on which your mini terrarium will be sitting.

Risers & Surface: The Risers we will be using to keep the cake from covering the holes will be 2" long pieces of PVC, cut from a 2" wide PVC pipe. The result will be a 2" long by 2" wide riser that will sit between the cake and the upside down lid of your mini terrarium. As well as keeping proper air flow throughout the jar, the riser will also be keeping the cake suspended from the water that will eventually pool inside the lid because of high humidity(*you may also get some dripping from the top of your terrarium, but I have never seen any significant negative results from this*). Do not worry if your PVC risers look as if they are covering your holes, the jagged edges from where you punched your holes will keep the riser from sitting flush on the lid and effectively blocking airflow (*this is why I prefer nails over drilling for making holes*). Having your jar lid sitting flush against a smooth shelf is equally as bad as having your cake sitting on the inside of the lid. Some sort of platform must be devised in order to allow airflow under your terrarium. You can get creative here, but as you can see from the picture below, the bottom part of a standard screen door works great when sitting on some horizontal 1/2" PVC pipe.

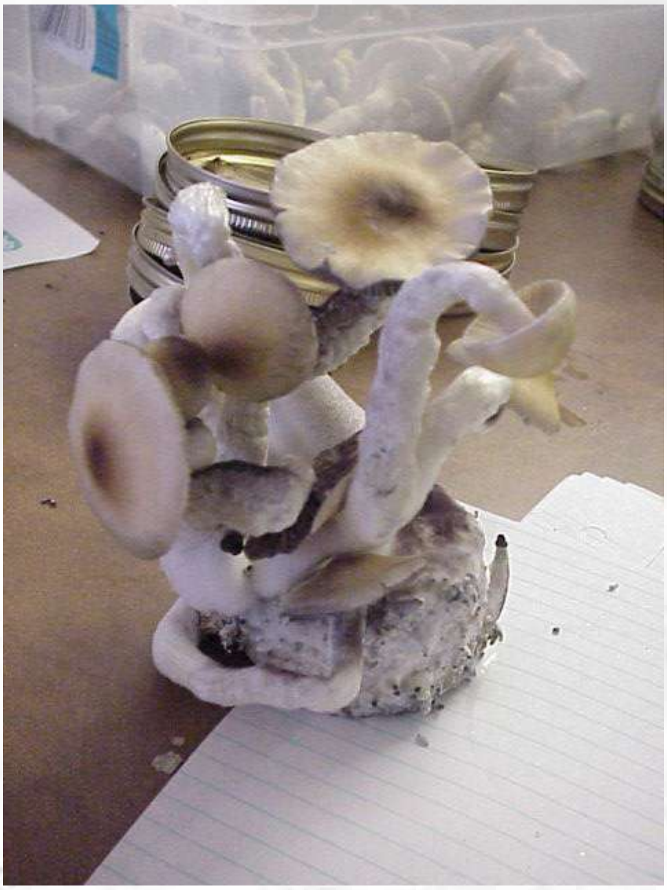


That is pretty much all there is to it. You can expect terrarium type yields with the ease of Hippie's Invitro tek (*The tek from which this one has evolved, great stealth tek*).

Now that you've built your mini terrarium it's time to test her out. So here are a few tips.

1. Dunking is a great tek. If you don't know anything about the dunk tek look it up and read away. I give a 16-20 hour dunk at birth and between every flush. Contamination is rarely a problem while using this tek so I just stack 3 cakes into one quart jar and throw a riser on top to hold the top cake under water and screw the lid on. Dunking is also great because your cakes have to be properly hydrated in order to create good humidity.
2. Keep temp as close to 76 degrees as possible. Hole sizes and all other factors are based off 76 degrees Fahrenheit.
3. If you are only doing a few jars PVC connector pieces can be bought as pre-made risers at Home Depot or other similar stores. If you plan on doing many jars cut your own to save money.
4. All pictures are of PF classics but remember your jars are mini terrariums and should work for all strains. I currently have Hawaiians doing great in my mini terrariums.
5. Give your PF cakes light through the entire colonization process to speed up fruiting. If you are inoculating 1 pint jars make sure to cut them in half before dunking and placing into mini terrariums since the ratio of air to space taken by cake in your jar is also a big factor.
6. I know cakes can be dunked safely with pins intact but I have realized greater success when cakes are scraped before being dunked right after birth. This may be just coincidence but you can find out for yourself.

Well that's all folks. You should be seeing results like the below picture in no time.



Have fun and be safe.

Cybers Martha Tek

by

Cyber

original source: http://www.shroomery.org/9664/Cybers-Martha-Tek

This setup was originaly done by Magash. As there was no TEK on it I decided to write one.

A Martha is a large fruiting chamber that maintains it's own humidity and air exchange, no fanning, no misting, just load it up add water and wait .

It was named for the Martha Stewart portable closet from K-Mart. This is what the first ones were made from.

Things you will need.

- 1 portable closet (Must be made of plastic)
- 1 COOL MIST humidifier
- 1 length of 3/4" ID hose (Hardware store)
- 1 90deg hose to pipe thread fitting (Hardware store)

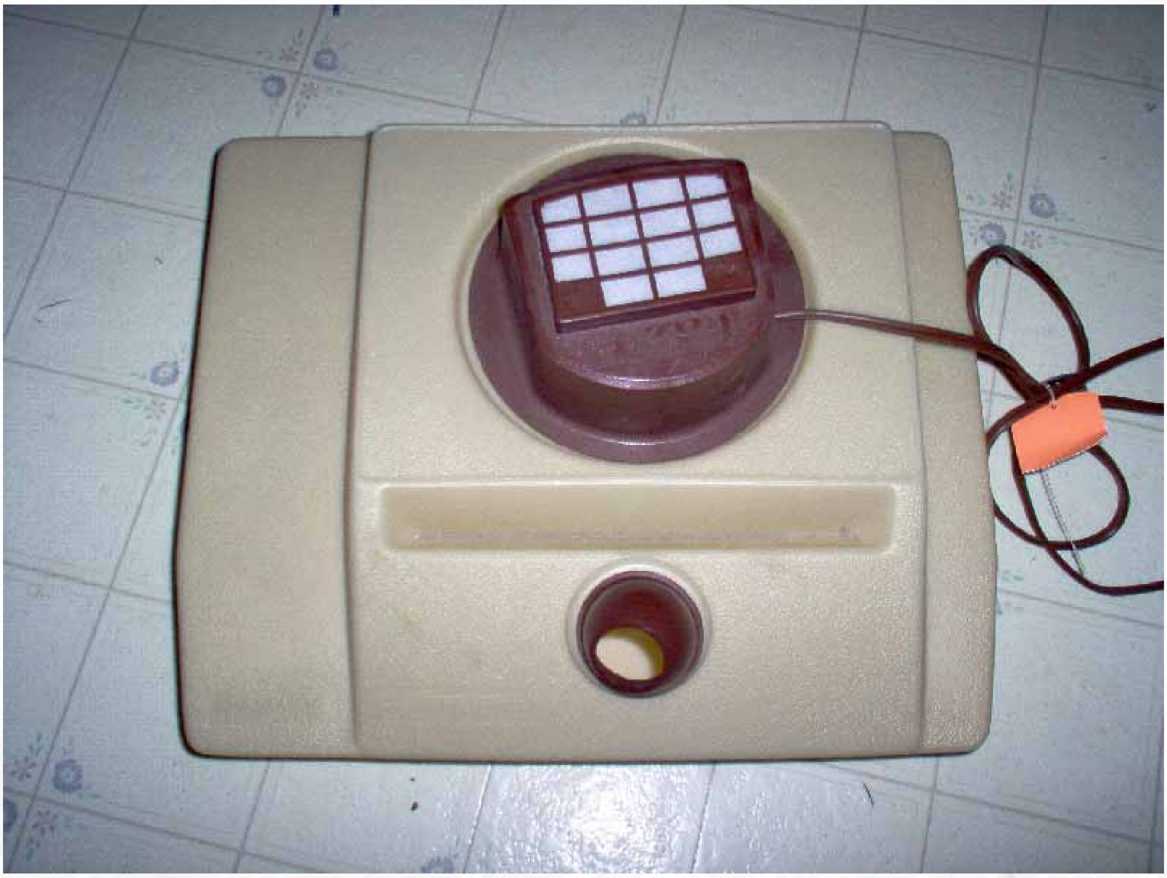
- 1 hose to 3/4" pipe thread fitting straight through (Hardware store)
- Other fittings to attach the hose to the humidifier (Hardware store)
- Duct Tape
- Some extra plastic.
- (The following is for the shelves. You can use anything you want)
- 4 pieces of chain
- 20 S-Hooks
- 4 36"x17" pieces of metal shelving

We start with the closet.

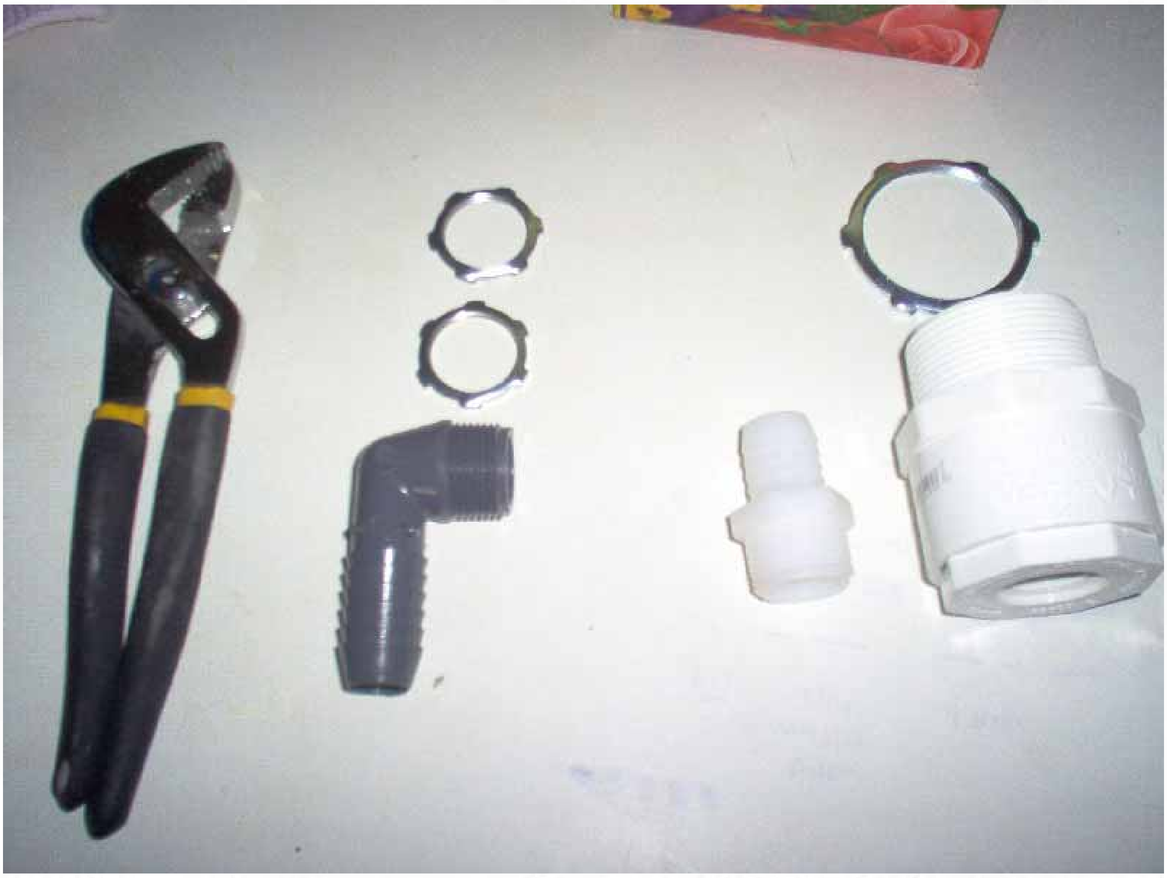
36" Clear
Storage Closet

I picked mine up at Bed, Bath, and Beyond for 30$ This model does not have a bottom, but we can fix that.

Next we get a humidifier. I picked this one up at the local thrift store for 3$.
I prefer the ones with the little round nozzle on them. It makes it essayer to fit the PVC fittings to them.

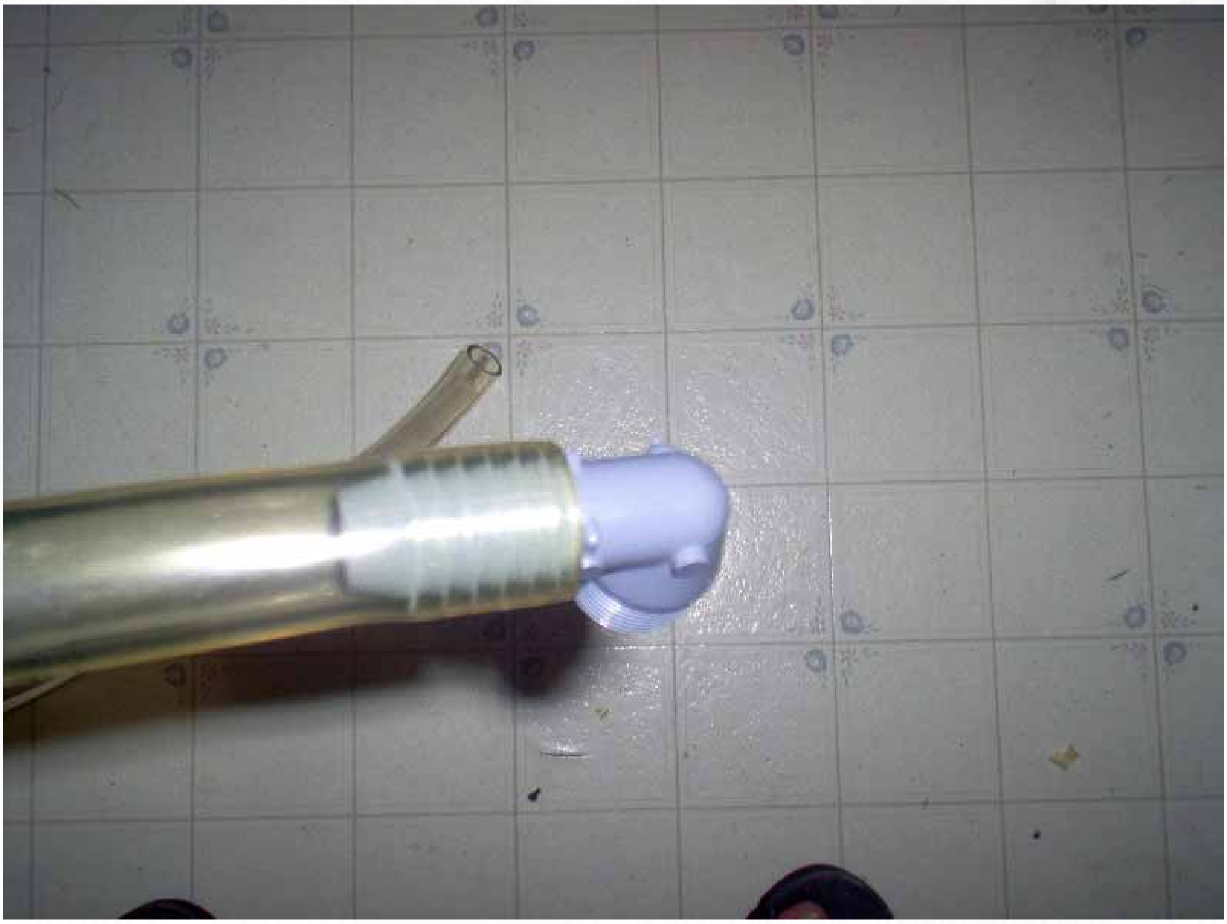


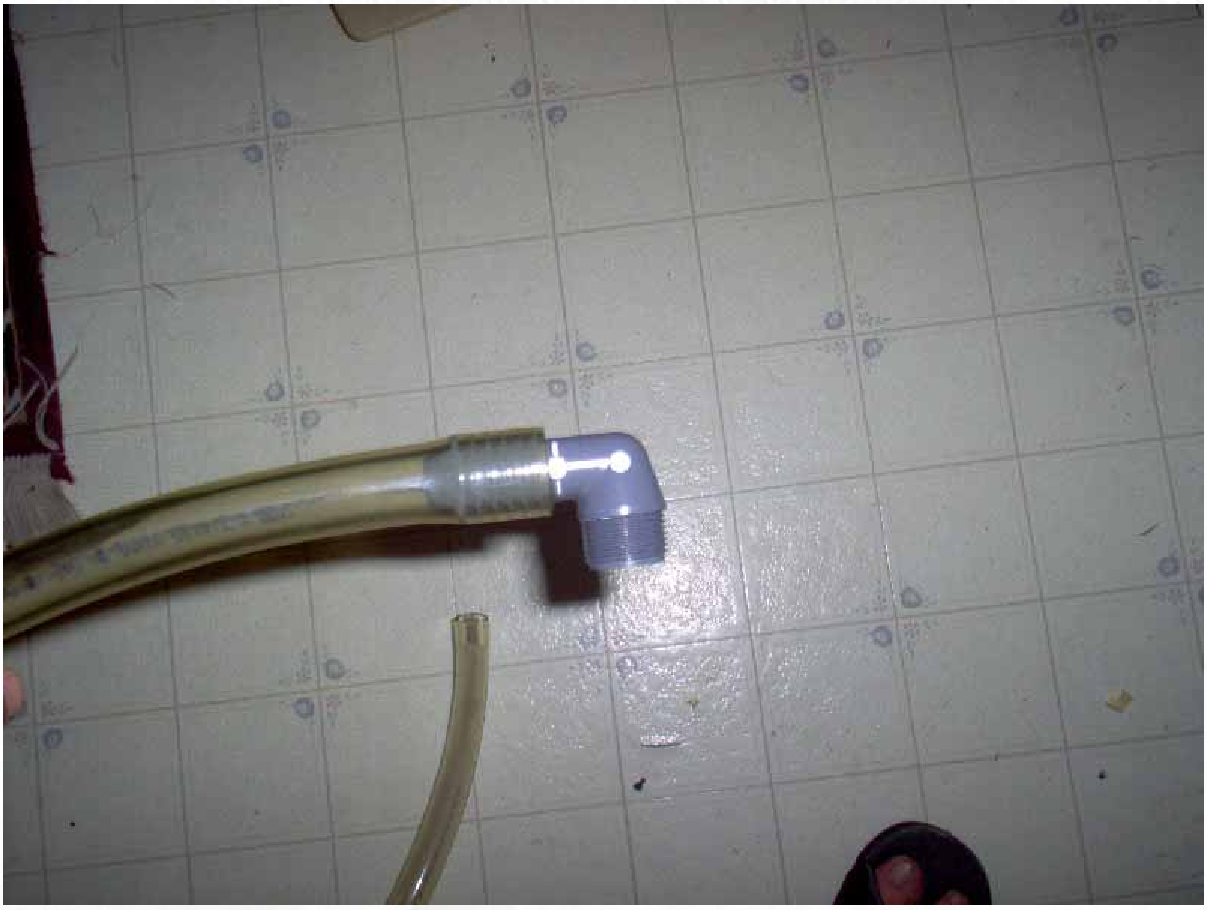
I have my tools and fittings.



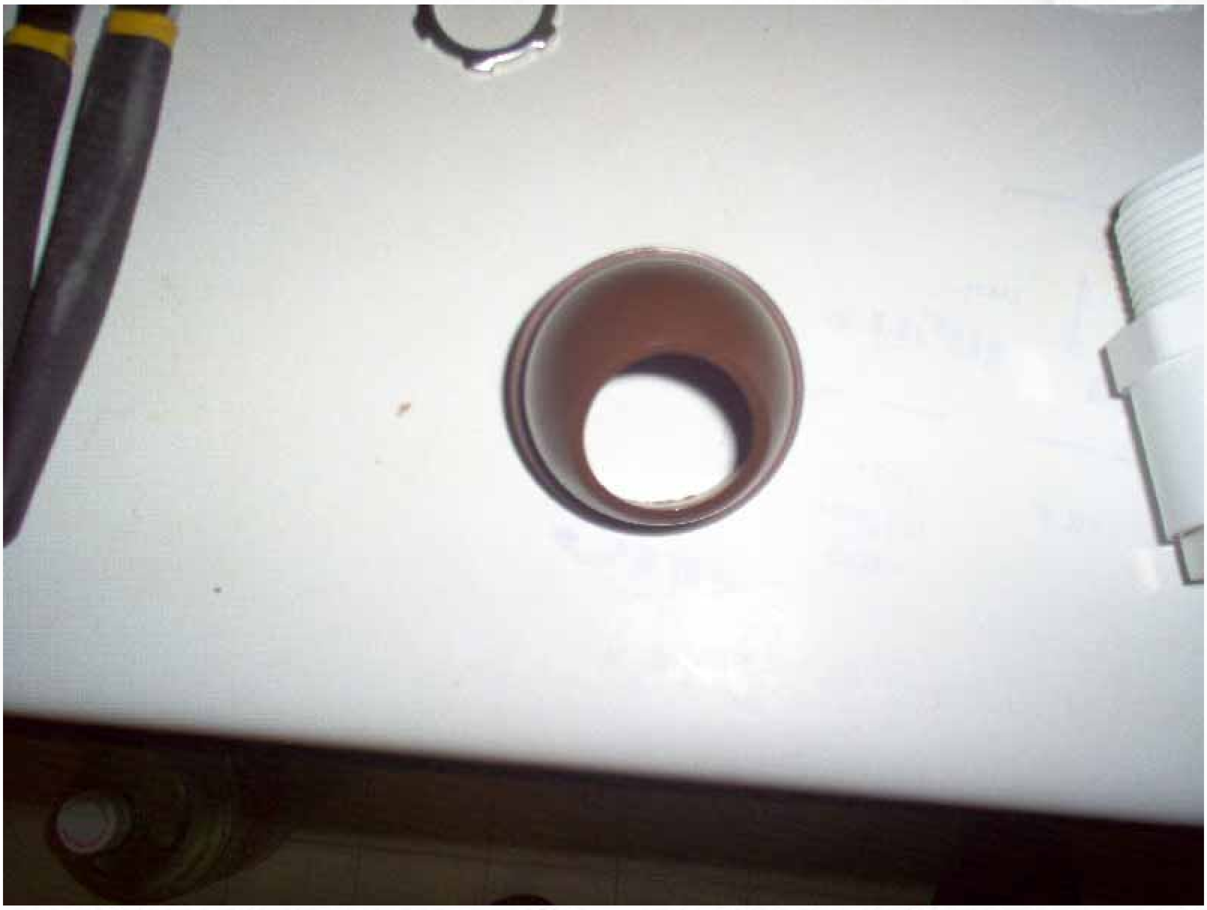
and my hose

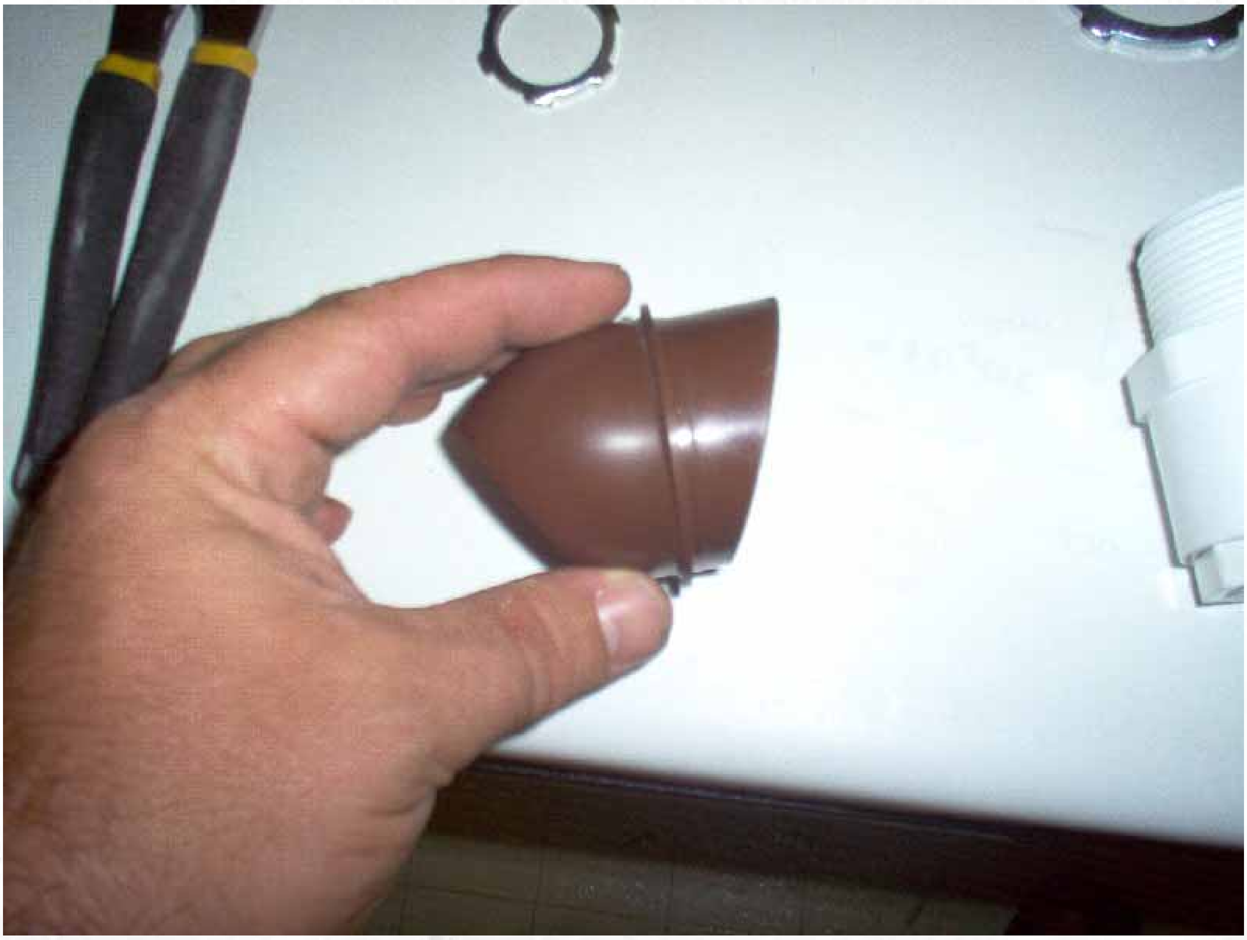
Put the fittings into the hose and get it ready



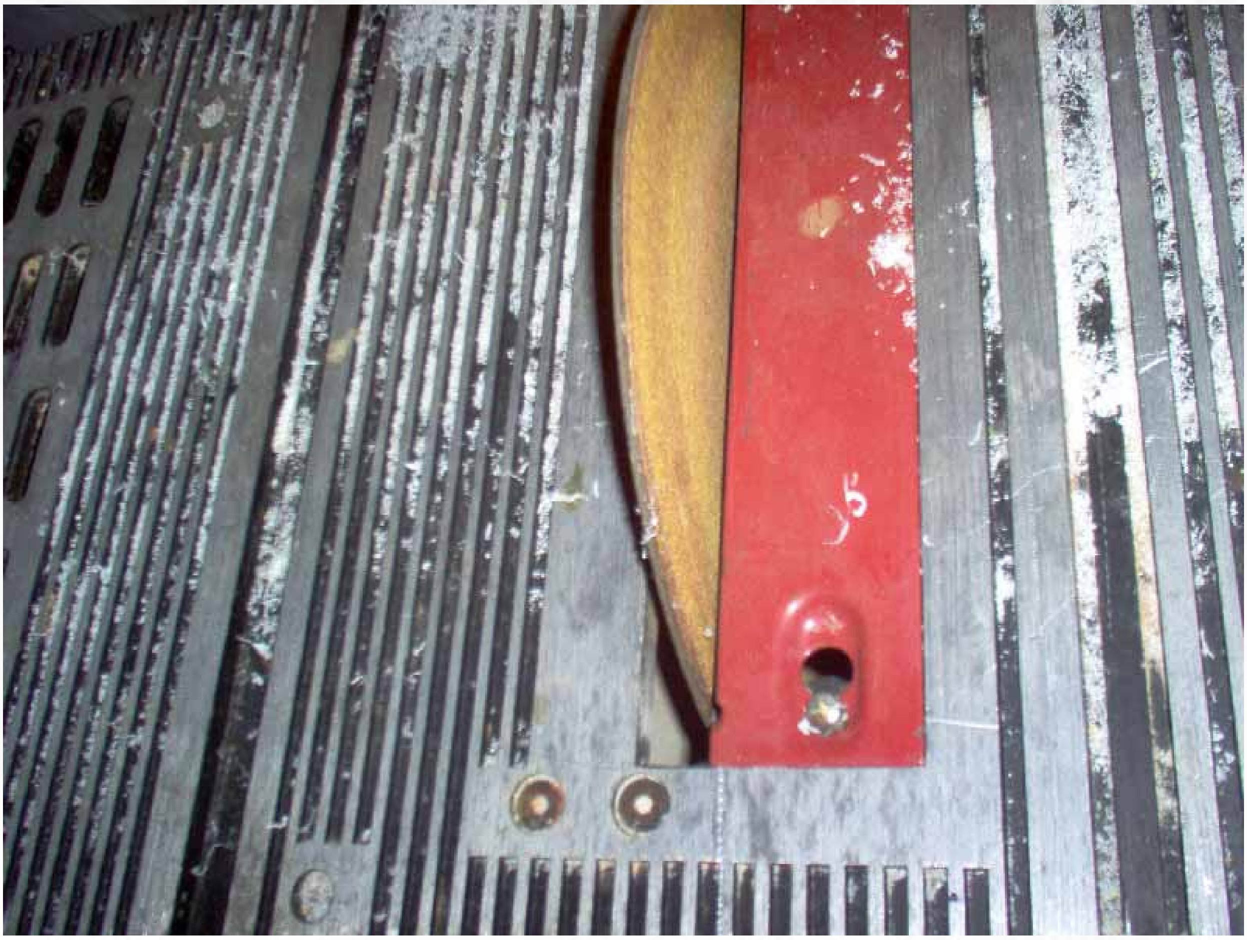


Now that the hose is ready, we move our attention to the largest fitting, I took the nozzle to the hardware store and put together a fitting that would go from the nozzle size to the threaded hose fitting. You will note that the nozzle is not a striate cut on the bottom. This allows it to catch the mist and direct it out the hole. We need to duplicate this on our replacement fitting.

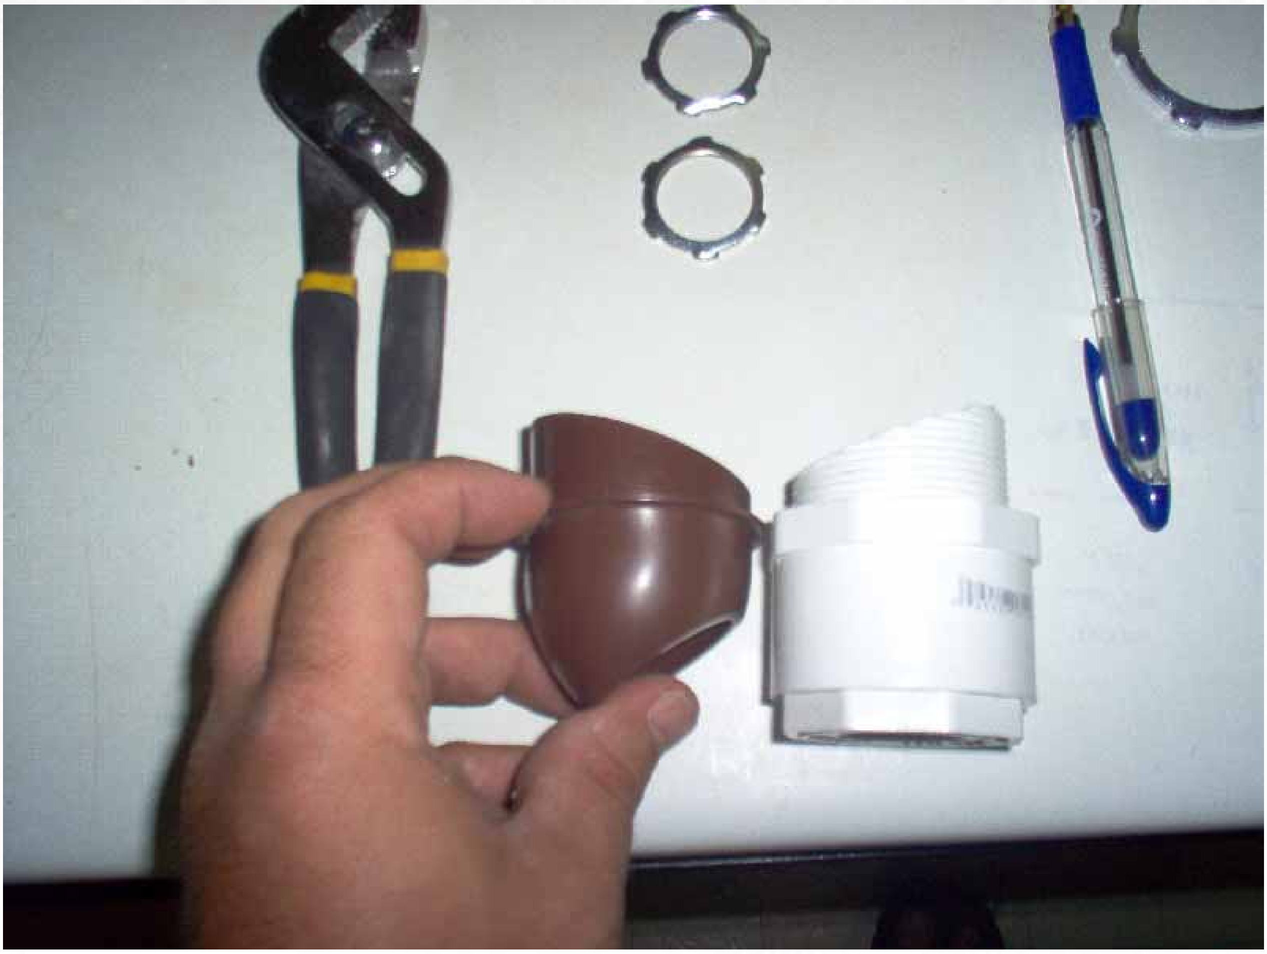




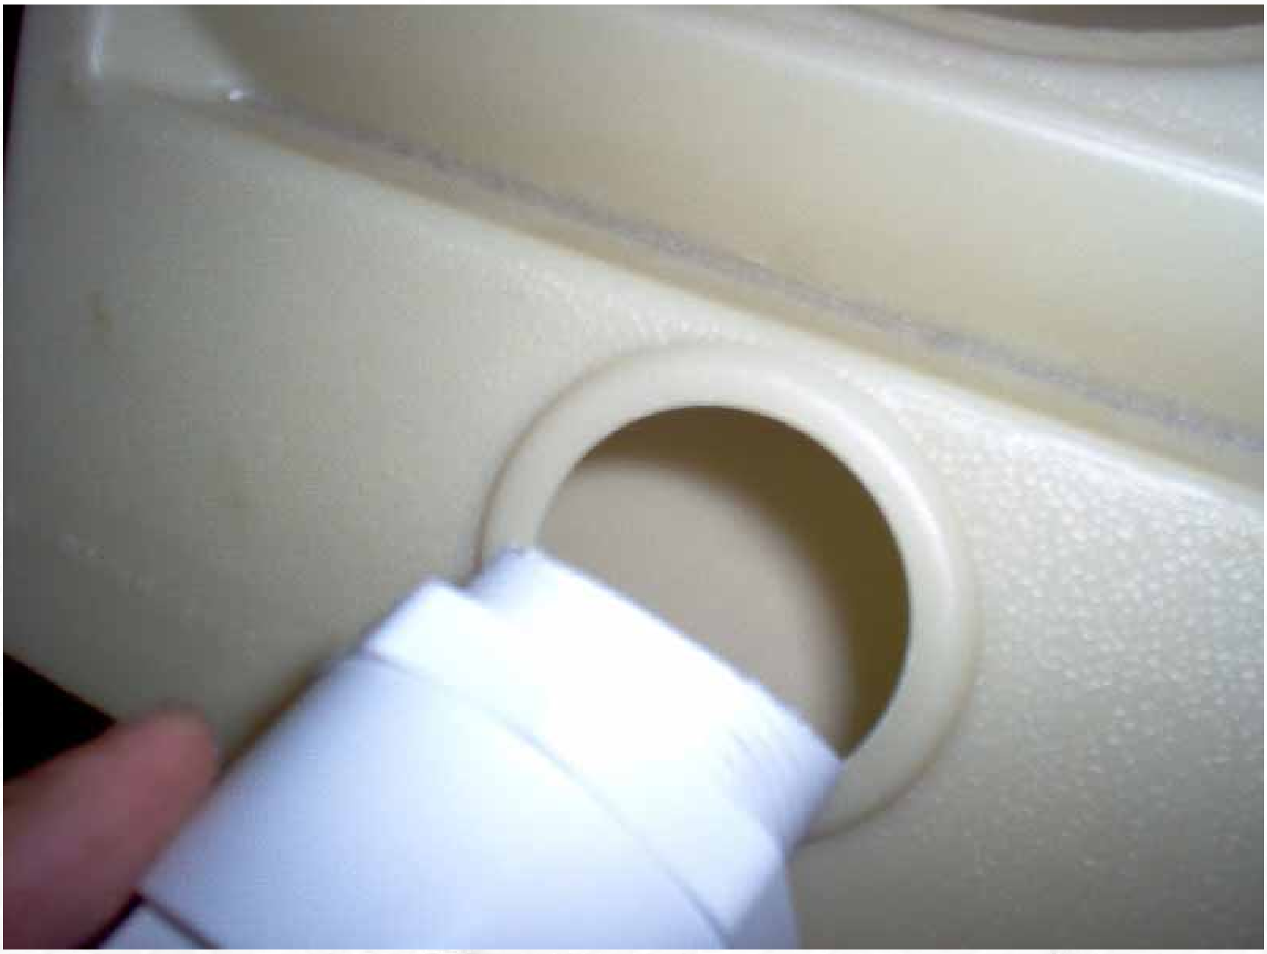
To duplicate this I used an 80 grit sanding disk in my table saw. If you do not have a table saw you can use a saw, drimmel tool, or anything else. (You could even get sandpaper and sand it by hand.)

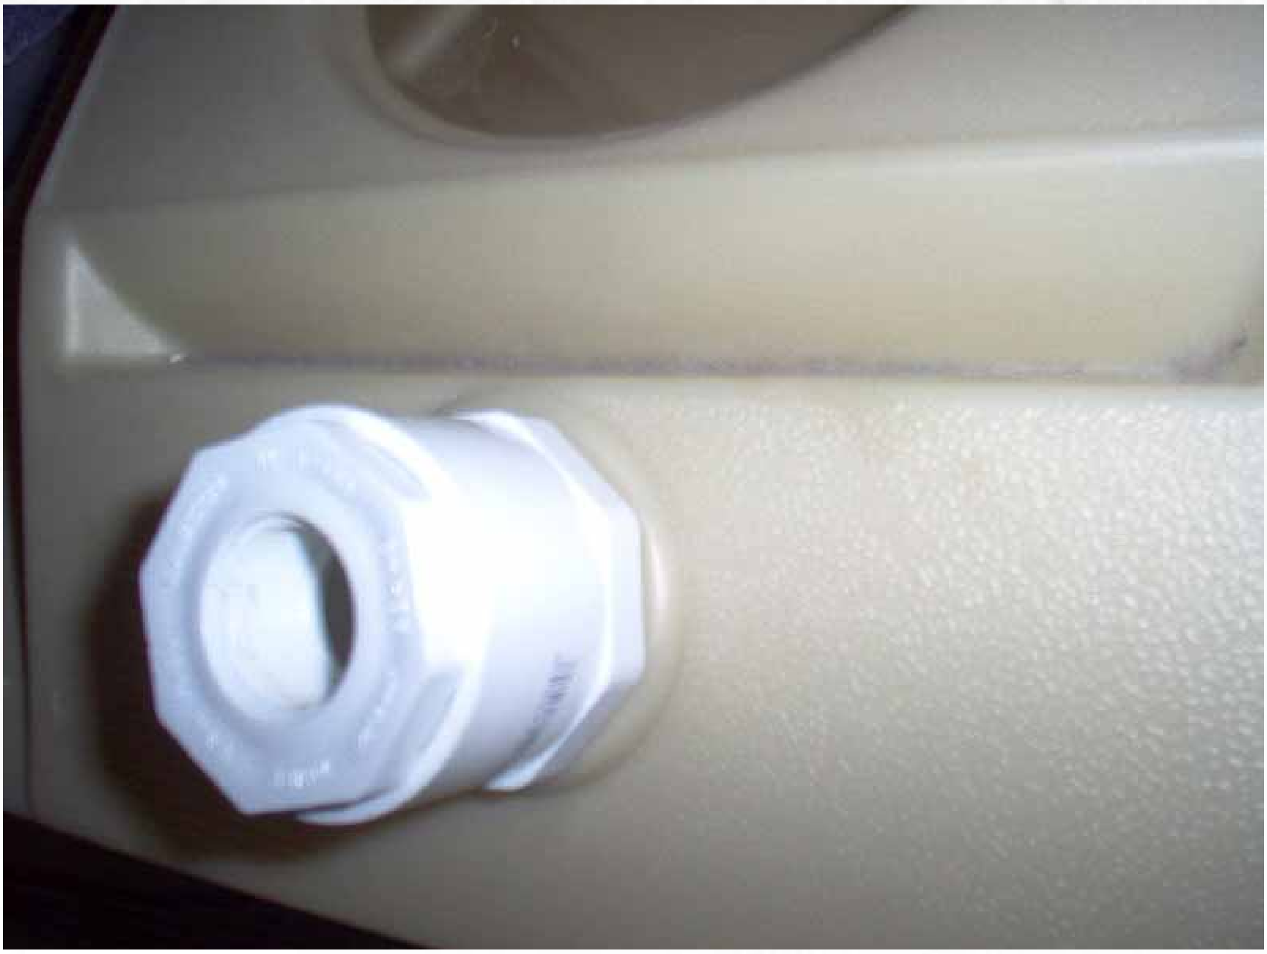


In the end you what it to be as close to the 45deg angle as you can get it.



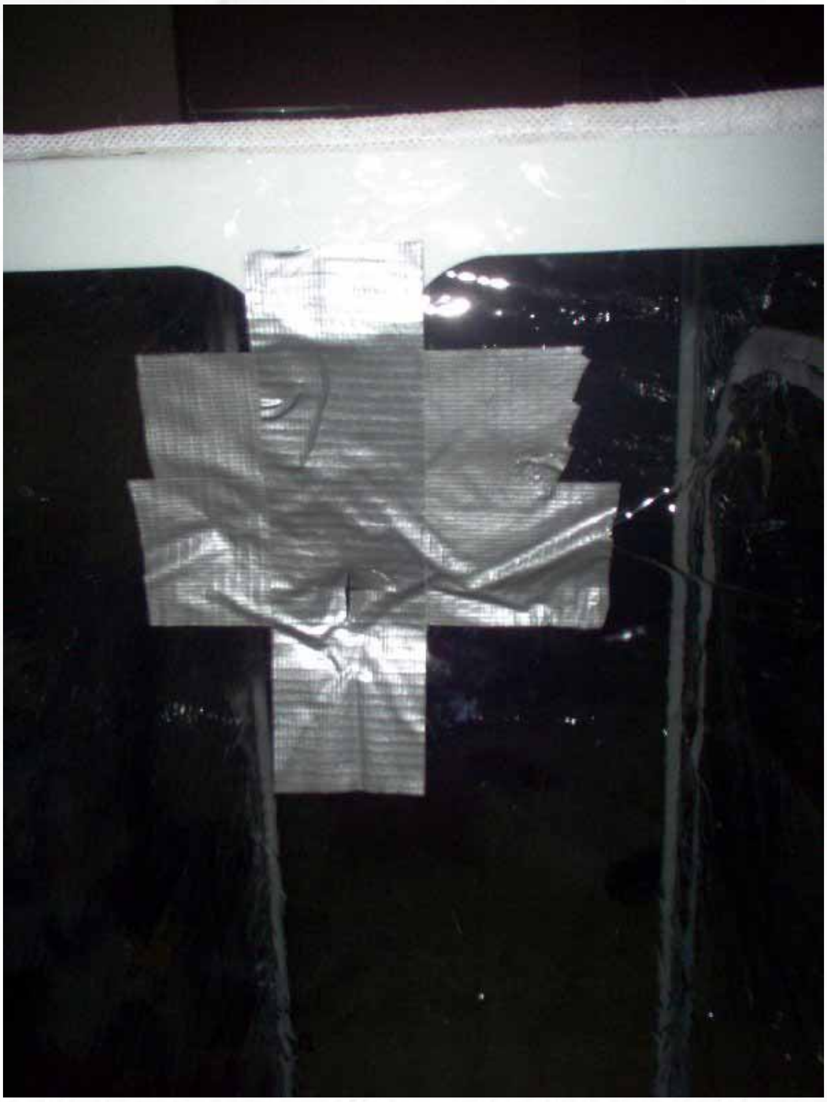
We now put the piece into the hole in the humidifier and use a galvanized nut to hold it in place.





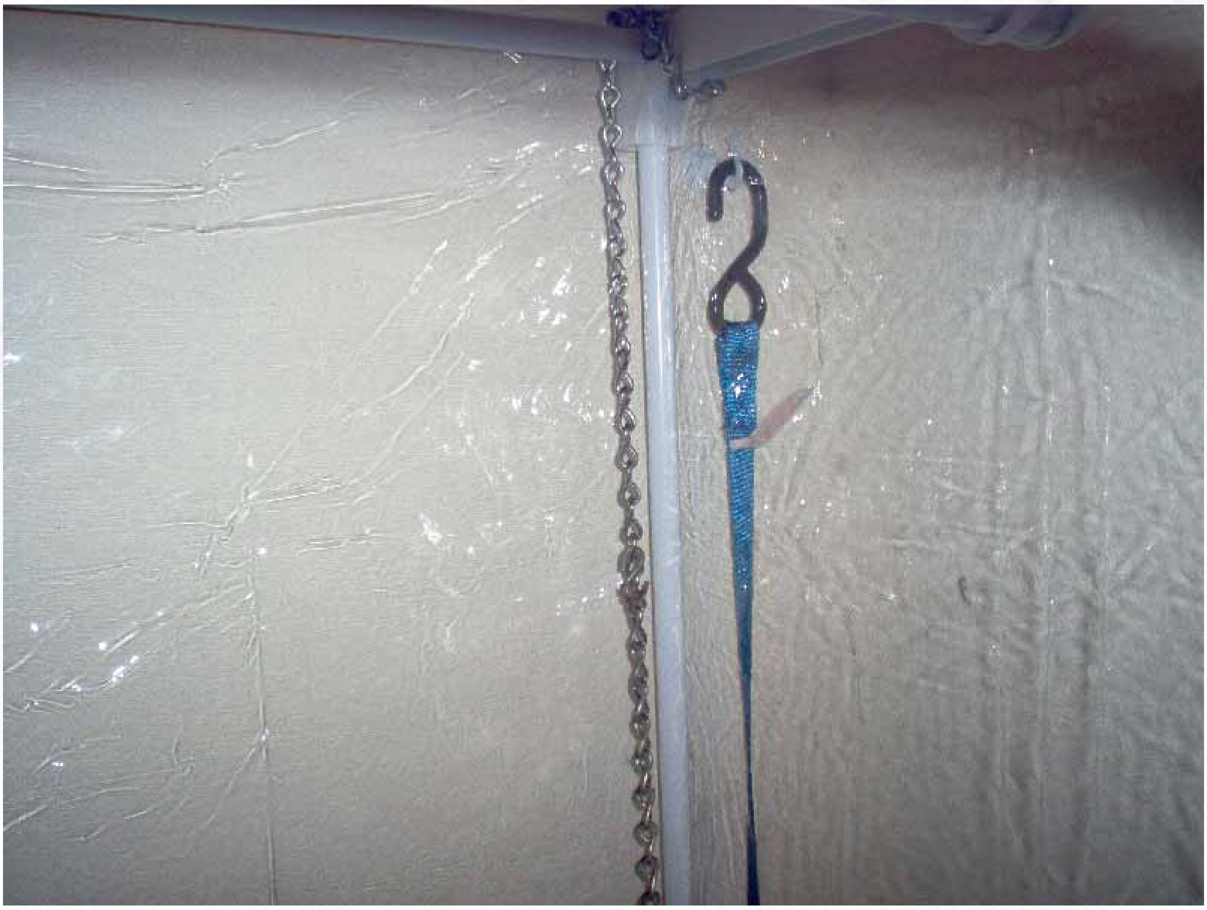
The closet I bought does not have a bottom so I will need to make one. You can use any plastic you can find. I have used plastic drop cloths, tarps, etc. This time I had some leftover black/white plastic from a grow room build so I used it. Just use some duct tape to hold it in place and seal it up.
Most of them have a "Breathable Bottom" on them. This means that the bottom is made of a fabrick. It works better if you can get one like that.

Now in the upper middle of the closet you want to put a couple of layers of duct tape (To re-enforce the plastic) and cut a hole big enough to put the hose fitting through.

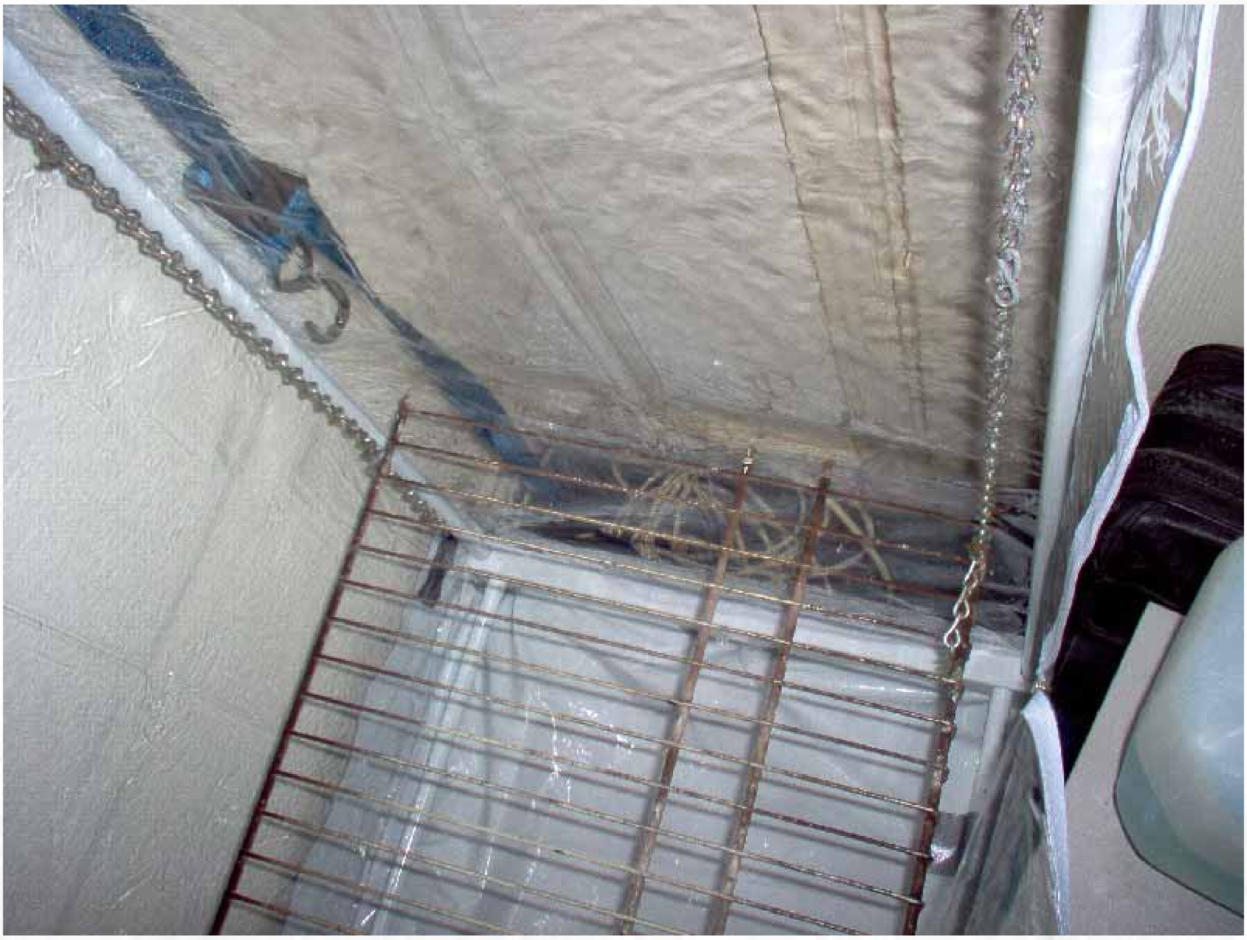


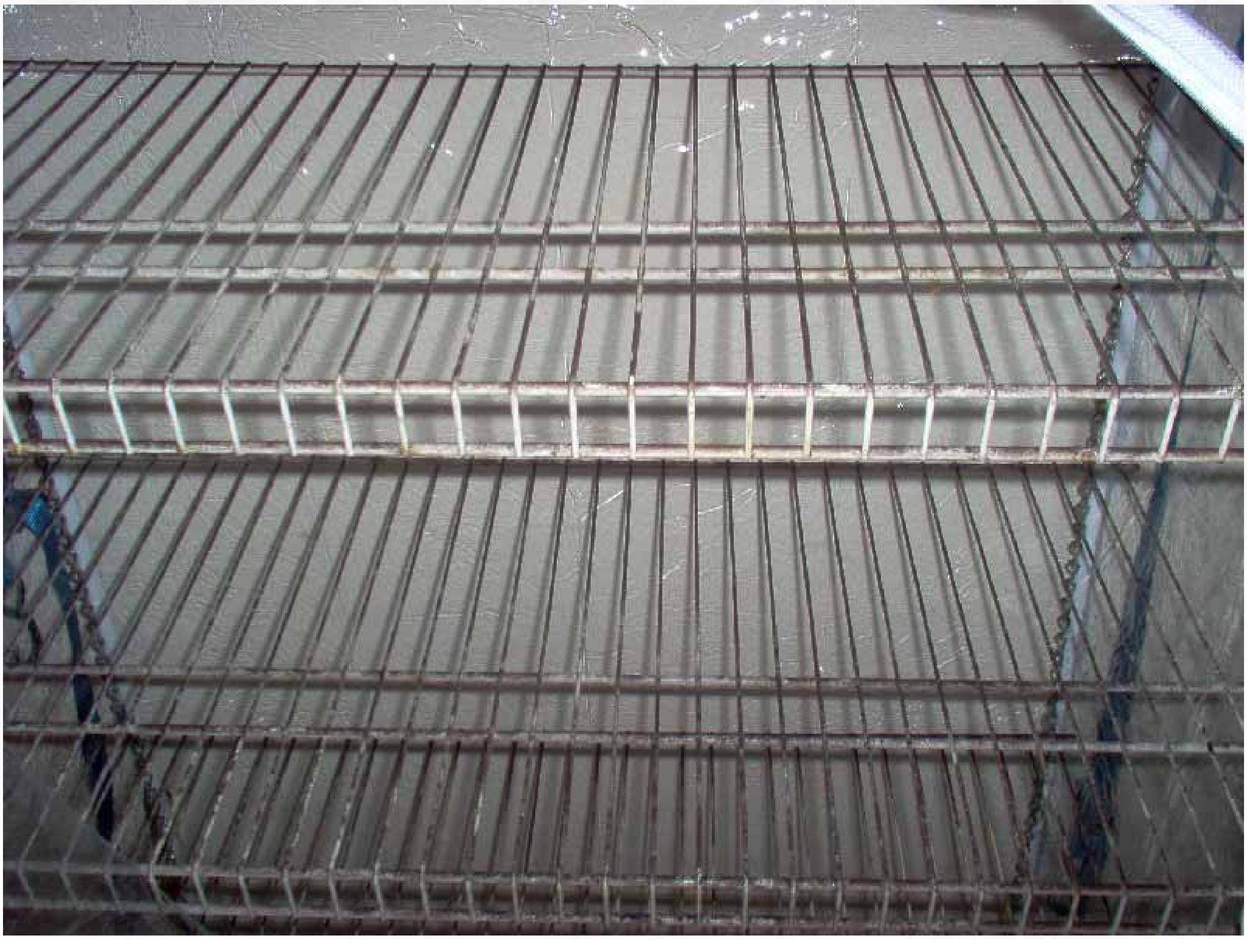
You can then move your Martha into place.

We then use the S-Hooks to hold the chains in the corners of the unit. This will be the points that the shelves connect to it.

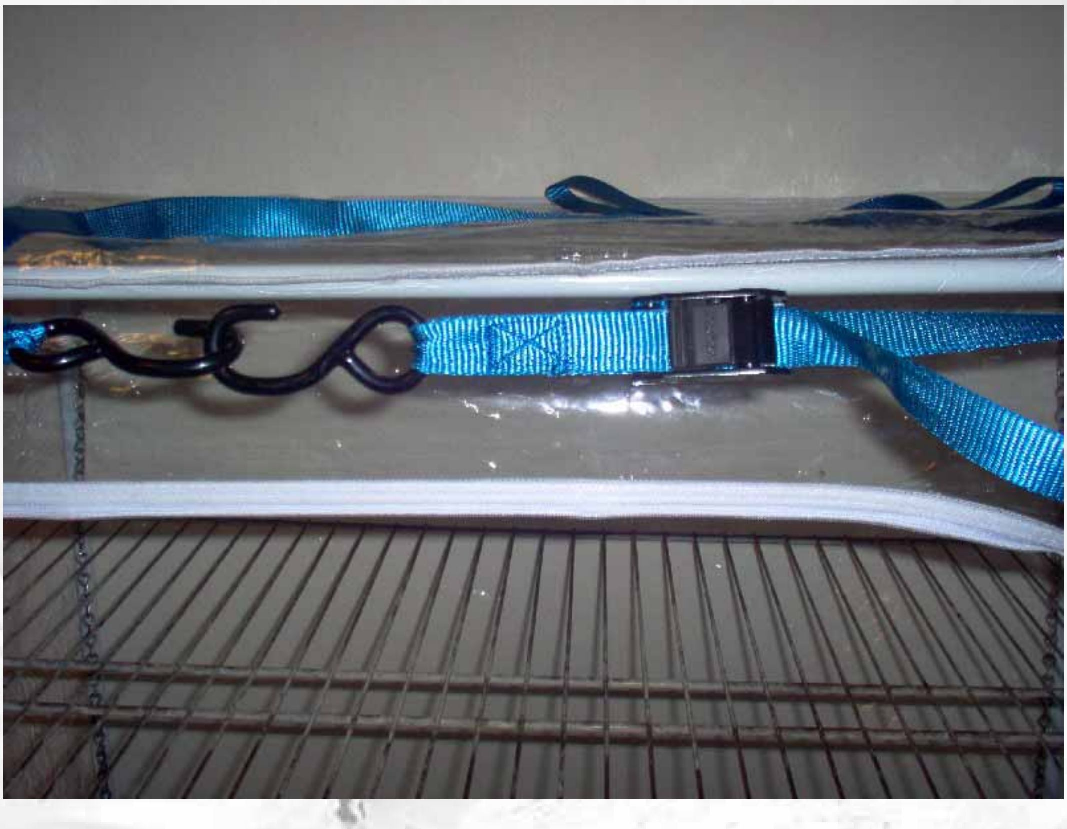


Then use the S-hooks to make hanging points for the shelves and attach the shelves to the chains. I start at the bottom and work my way up.

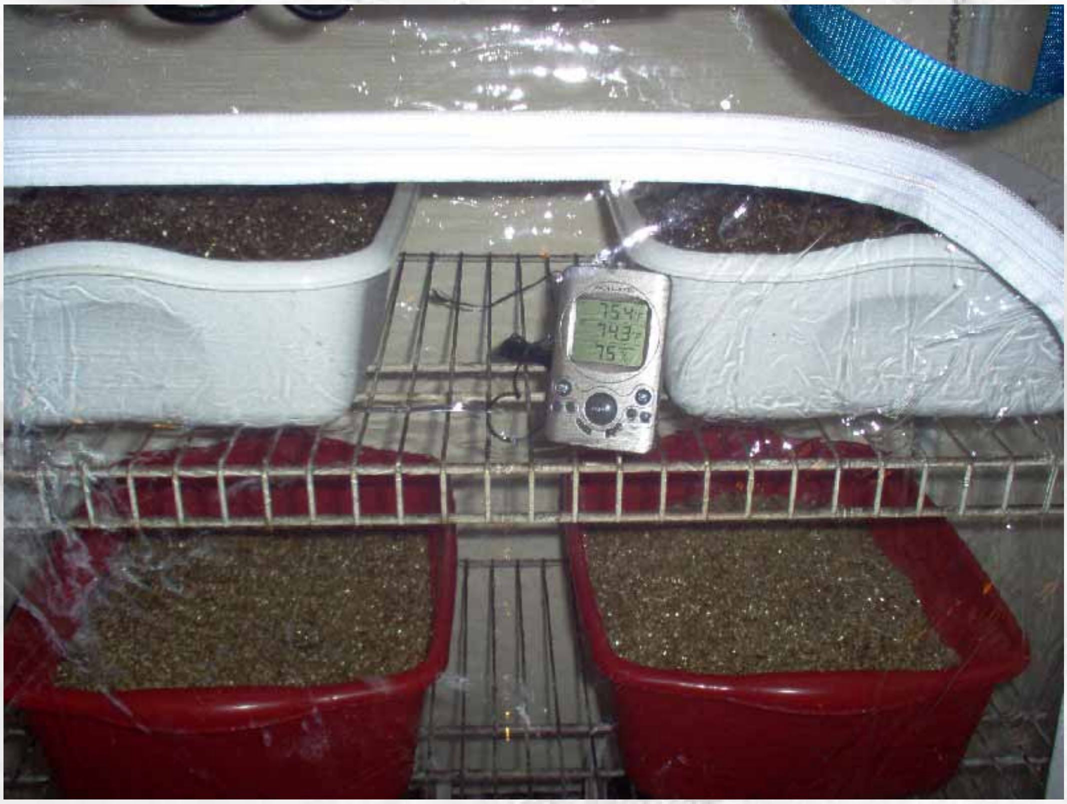




You may have noticed a set of hooks in the wall with straps on them, in the background of the pictures. I use these to hold the unit in place. I tend to load some weight into my and it leans if I do not have it secured to the wall.



Now we load the unit up, hook up the humidifier, and turn it on. Before long the humidity is up.



Some designs call for more than one humidifier on timers. I have found that mine can maintain it's humidity with just one cool mist on 24/7. You should get between 87 and 90% humidity which is perfect for fruiting. This unit, fully loaded, can produce 2lbs of dry mushroom every 35 to 40 days. This is enough for you and 75 of your closest friends to trip every weekend for a month!

A sterile transfer chamber

by

Oldtimer

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/otbox.htm

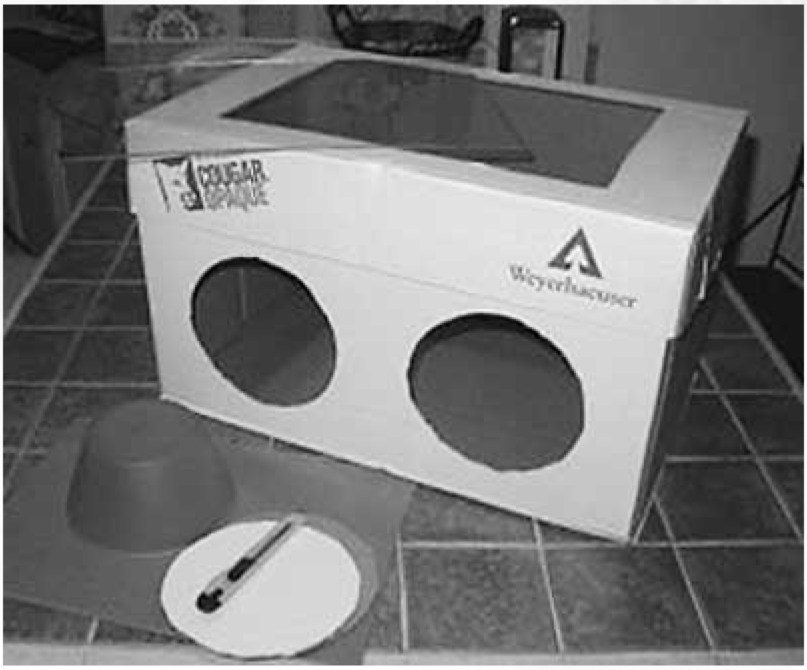
In order to achieve a good success rate when making transfers, you must first construct a transfer chamber or "glove box." This is simply an enclosed area that can be cleaned with disinfectants to keep out contaminants. Such a chamber can be designed in many ways and need not be elaborate to work well. Basically what you are striving for is an enclosure which provides a sterile, draft-free environment to work in while performing sterile culture work.

A good, inexpensive glove box can be constructed from a cardboard box, some aluminum foil and a sheet of plexiglass.

You will need the following materials:

- Clean, sturdy cardboard box.
- Razor knife or box cutter.
- Can of spray adhesive.
- Roll of heavy duty aluminum foil.
- Roll of duct tape.
- A piece of plexiglass cut to approximately 10" x 14".
- Clean dish towel.

Step I



Obtain a good, clean, sturdy cardboard box with a removable lid. The kind paper is shipped in is ideal and can be found at any printing shop or office supply company.

Use a small dish or bowl as a template and draw two circles about 5" in diameter on the front of the box. Cut out the two circular holes in the front side of the box (to allow you to insert your arms while making transfers). Also cut a square hole in the lid of the box slightly smaller than the sheet of plexiglass (approx. 9" x 13"). This hole will be covered with the sheet of plexiglass, effectively forming a "window" in the top of the box.

A razor knife or box cutter makes an ideal tool for cutting these holes in the box. Once you have the holes cut you can proceed to step II and prepare to apply the foil.

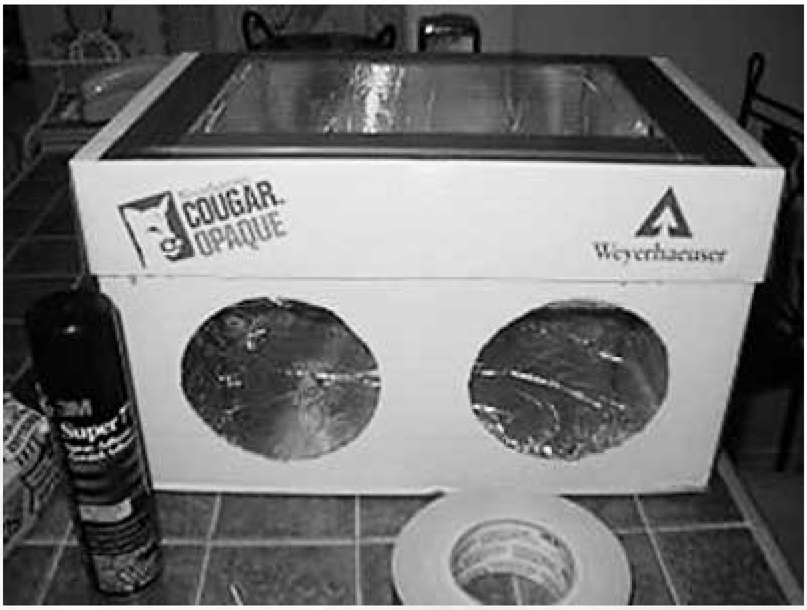
Step II

3M
Super
Spray Adhesive
Aerosol Ad

Wipe the inside of the box with alcohol and allow it to dry. After the alcohol dries liberally spray the entire inner surface of the box (sides, bottom and top) with the supplied Lysol aerosol. This kills any spores that are lying dormant on the surface of the cardboard. Once the Lysol has evaporated, spray a layer of adhesive in the bottom of the box and apply a sheet of aluminum foil to cover. Do not worry if the foil has a few wrinkles or creases. You just want to have a nonporous surface that is easy to clean and sterilize as well as being waterproof. Repeat this process on all sides of the inside of the box.

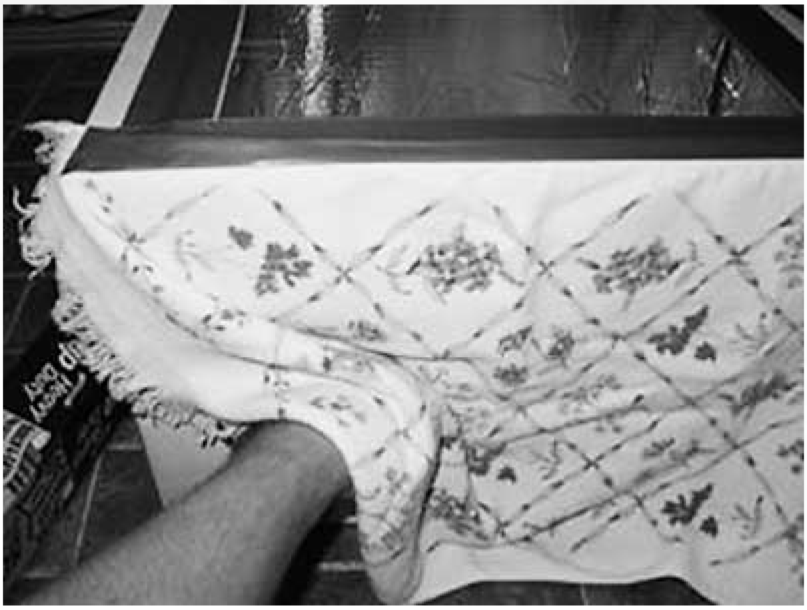
Step III

Fit the lid onto the box. Place the sheet of plexiglass over the hole in the lid of the box and tape each side to the box with duct tape. Be sure to seal each edge as you tape the plexiglass down to the box. This forms a nice, airtight "window" in the top of the box which will allow you see into the cabinet with no risk of contamination from airborne spores and bacteria.
Leave the lid of the box removable (do not tape) to allow easy access for placing your materials inside prior to performing sterile transfer work.



Step IV

Take a small, clean dishtowel and drape it across the top of the box so that it hangs down over the two hand holes in the front.
Run a strip of duct tape along the edge of the towel taping it to the lid of the box along the edge of the plexiglass.
The towel serves as a barrier to prevent drafts from entering the cabinet while you are working, effectively keeping contaminants out.
Do not tape the lid down. Leave the lid removable so it will be easier later when you need to load materials into and out of the sterile cabinet.



Note from Nan - I like a clean plastic sheet instead of cloth.

Congratulations! You now have a completed, fully functional sterile transfer cabinet that only cost a few bucks.... Spray inside of chamber with Lysol before each use but....ALLOW ALCOHOL FROM LYSOL to EVAPORATE COMPLETELY!!! before lighting any burners or lighters inside of box... unless you like the "hairless" look and don't mind your arms stinging like hell for a day or two!

> Note: You can save on the Plexiglas (which must be cut) but substituting some clear plastic film sheet (like a $2 plastic drop cloth) for the window and duct taping the plastic into place securely with no sags. I have done a lot of sterile work under draped plastic hoods and inside cardboard boxes; be clean in and around them and you can do intermediate mycology with only a few contam glitches.

HEPA filter flowhood

original source: http://www.fungifun.org/English/Flowhood

Table of Contents:

- Why you need one
- Getting started
- Sources for HEPA filters
- Match a blower to the filter
- Finding the correct blower
- Construction of the hood
- Some pictures of a similar design

Why you need one

A laminar flow hood is a piece of equipment which makes sterile working procedures in mushroom cultivation easier and reliable.

A flow hood consists of a coarse pre-filter, a blower and a very fine filter (the so called HEPA (High Efficiency Particulate Air) filter which filters particles from the air to a high degree.

This makes the air coming out of the HEPA filter nearly sterile which allows doing transfers in this stream of sterile air without worrying about contaminants entering from the air and contaminating the cultures.

Getting started

You should begin the construction by selecting a HEPA filter and a blower.

The HEPA filter size depends on how big you want to have your working space. The smallest filter size you can reasonably use (for home scale cultivation) is 1ft x 1ft, better though 1ft x 2ft or 2ft x 2ft if you are going to inoculate filter bags.

Match a blower to the filter

Once you decided on the size of the HEPA filter, you have to match a suitable blower to this particular filter. This is a very important step, so make sure to study the directions thoroughly.

Every filter has a "resistance" when air blows through it at a certain speed, this resistance is called the "static pressure".

Press your hand against your mouth. Now try to blow through it. Dependant on how firm you press it against your mouth, you will have some difficulties blowing air out and you will feel some resistance, this is the static pressure.

Every filter has a different static pressure at the working point. The working point is where the amount of the air flowing through the filter is sufficient to meet the requirement of the laminar flow.

The static pressure is expressed in inch of water column in the English units, a typical value would be 1", the SI unit for pressure is Pa(Pascal).

1" water column is around 250 Pa. Each filter has a data sheet (consult the manufacturer if this is not the case with your filter) where the static pressure at the working point is entered. Before the air enters the blower it is usually pre-filtered by a furnace filter around 1"(2.5cm) thick placed in front of the blower to protect it and the HEPA filter from big particles like dust and hairs. It can be assumed that the static pressure for this prefilter at the working point is around 0.2"(50 Pa).

According to Stamets (**Paul Stamets and J.S.Chilton: The Mushroom Cultivator** p. 347 ff) the air speed of the air flowing from the filter surface should be (at least) **100 feet per minute(fpm)**. (around 30 meter per minute or 0.5 meter per second). Determining the correct blower for a filter consists of several steps:

1. Find out the area of your filter by **multiplying the width and the hight** in feet (for instance the smallest reasonably usable filter would be 2ft x 1ft):
2ft x 1ft = 2 ft^2

2. Multiply the required air speed(the one Stamets specifies, 100 ft/min) with the area of your filter:
100 ft/min x 2 ft^2 = 200 ft^3/min

So 200 ft^3/min(= cfm = "cubic feet per minute") is the amount of air your blower must deliver **at the sum of the STATIC PRESSURE of the HEPA filter + prefilter**.

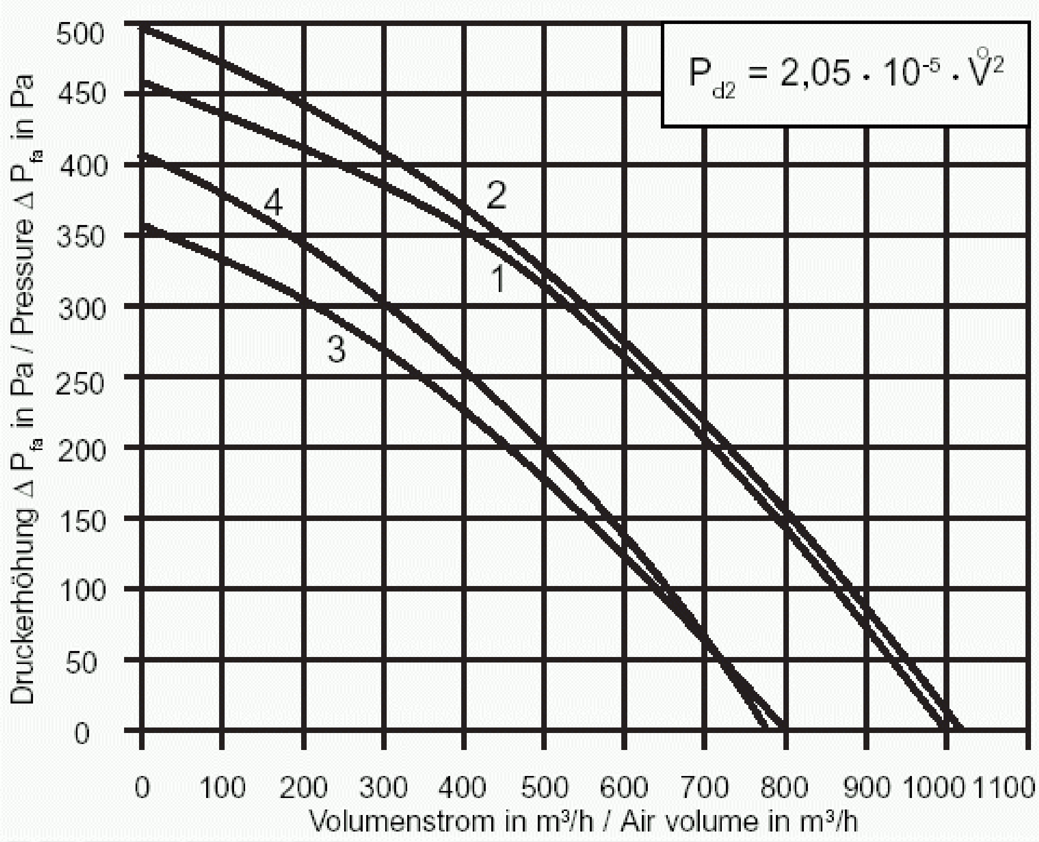
NOTE: 1 cfm= 1.7m^3/h

So if you use the above filter with 1"(250Pa) static pressure and a furnace prefilter with a static pressure of 0.2"(50Pa) your blower must deliver **200 cfm(340m^3/h) of air at a static pressure of 1.2"(300Pa).**

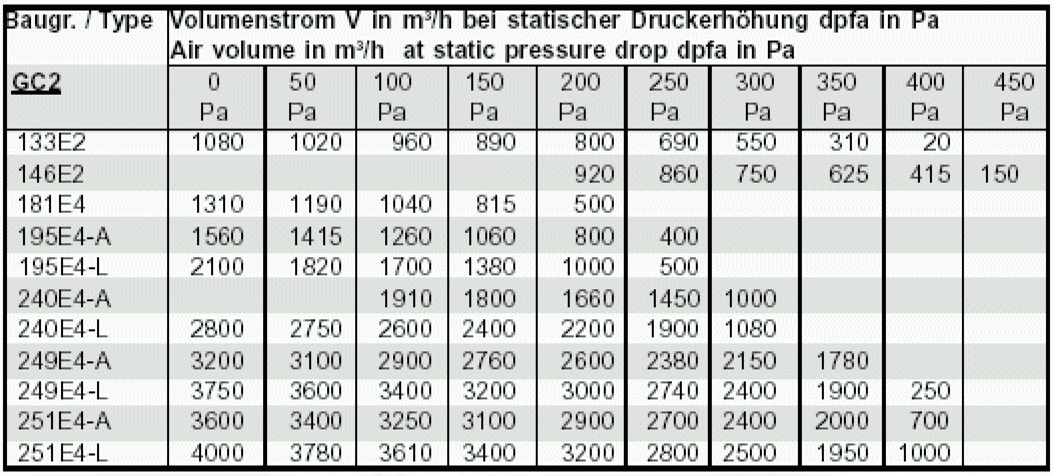
Finding the correct blower

Each blower has a data sheet (consult the manufacturer if this is not the case with your blower) where the correlation between the **volumetric flow** and the **static pressure** is represented by a graph or table.

Here is such a set of curves for 4 blowers (numbered 1-4).
NOTE: Each model of a blower has his own characteristic curve. This chart shows the curves for 4 different particular models of axial duct blowers.
What you can clearly see is that **the bigger the static pressure the less air the blower delivers**, up to the maximum static pressure where the air output is zero.



Sometimes these data are presented in form of a table.



Baugr. / Type	Volumenstrom V in m³/h bei statischer Druckerhöhung dpfa in Pa Air volume in m³/h at static pressure drop dpfa in Pa									
GC2	0 Pa	50 Pa	100 Pa	150 Pa	200 Pa	250 Pa	300 Pa	350 Pa	400 Pa	450 Pa
133E2	1080	1020	960	890	800	690	550	310	20	
146E2					920	860	750	625	415	150
181E4	1310	1190	1040	815	500					
195E4-A	1560	1415	1260	1060	800	400				
195E4-L	2100	1820	1700	1380	1000	500				
240E4-A			1910	1800	1660	1450	1000			
240E4-L	2800	2750	2600	2400	2200	1900	1080			
249E4-A	3200	3100	2900	2760	2600	2380	2150	1780		
249E4-L	3750	3600	3400	3200	3000	2740	2400	1900	250	
251E4-A	3600	3400	3250	3100	2900	2700	2400	2000	700	
251E4-L	4000	3780	3610	3400	3200	2800	2500	1950	1000	

By now you know how much your blower must deliver and at which static pressure. In our example it was $340m^3/h$ at 300Pa.
So what we do now is to go in this chart and find the value of 300Pa(**=1.2"**) at the vertical axis. Then you move to the right until you reach $340m^3/h$ (**=200cfm**).
Now, ideally there should be a curve of a blower going exactly trough this point, but this is not always the case.
So we have to choose a blower that best approximates our requirements.
In most cases we should choose a stronger blower, if it's not too strong.
How strong is too strong? I'd say the blower shouldn't deliver more that 20% more air than we calculated, so in our case the strongest acceptable blower would be around $400m^3/h$.
In this example we have a blower that delivers $300m^3/h$ (according to our calculation it should deliver $340m^3/h$ though). This is a difference of mere 10%. The next stronger blower in this chart delivers $530m^3/h$ at 300Pa, which is way too much.

In this case we go for the smaller(and cheaper) blower (Nr.4) instead of the much bigger one (Nr.1, which delivers 530m^3/h at 300Pa), despite the fact that it's generally recommended to take a stronger one.

NOTE: This chart is only an example for a set of 4 particular blowers. The curves of the blowers available to you may look a bit different, but similar.
Usually, if you search long enough, you will be able to find a blower that exactly matches your HEPA.

The design in this pictorial uses an in-line centrifugal fan, another good option (actually the one most commonly used for flow hoods) is a squirrel cage blower (also called shaded pole blower).

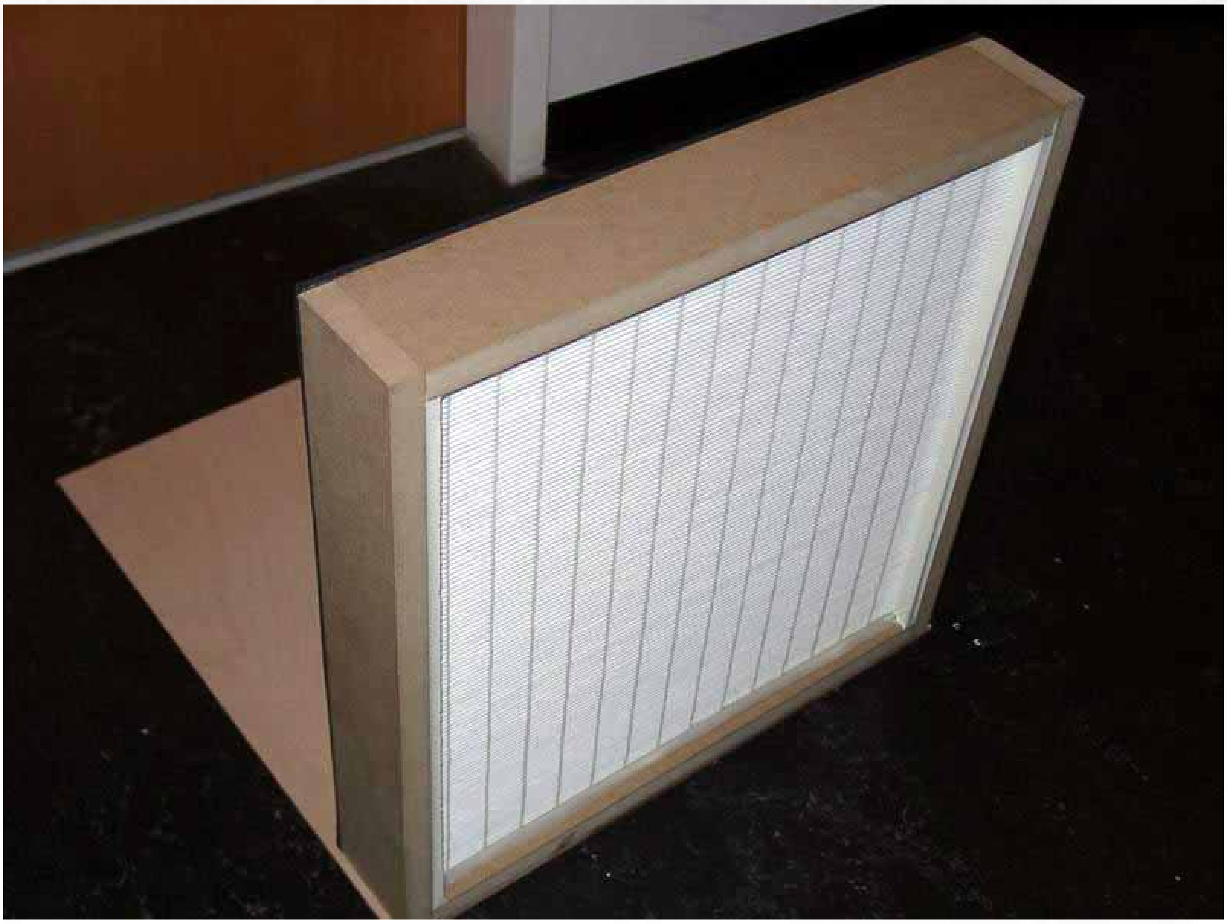
You can get many blowers at ebay.com, often at much cheaper prices than if you bought them directly.

Ebay offers
It is important to contact the seller in advance and inquire about the exact characteristics of the blower beforehand, so you don't end up with a too weak blower.

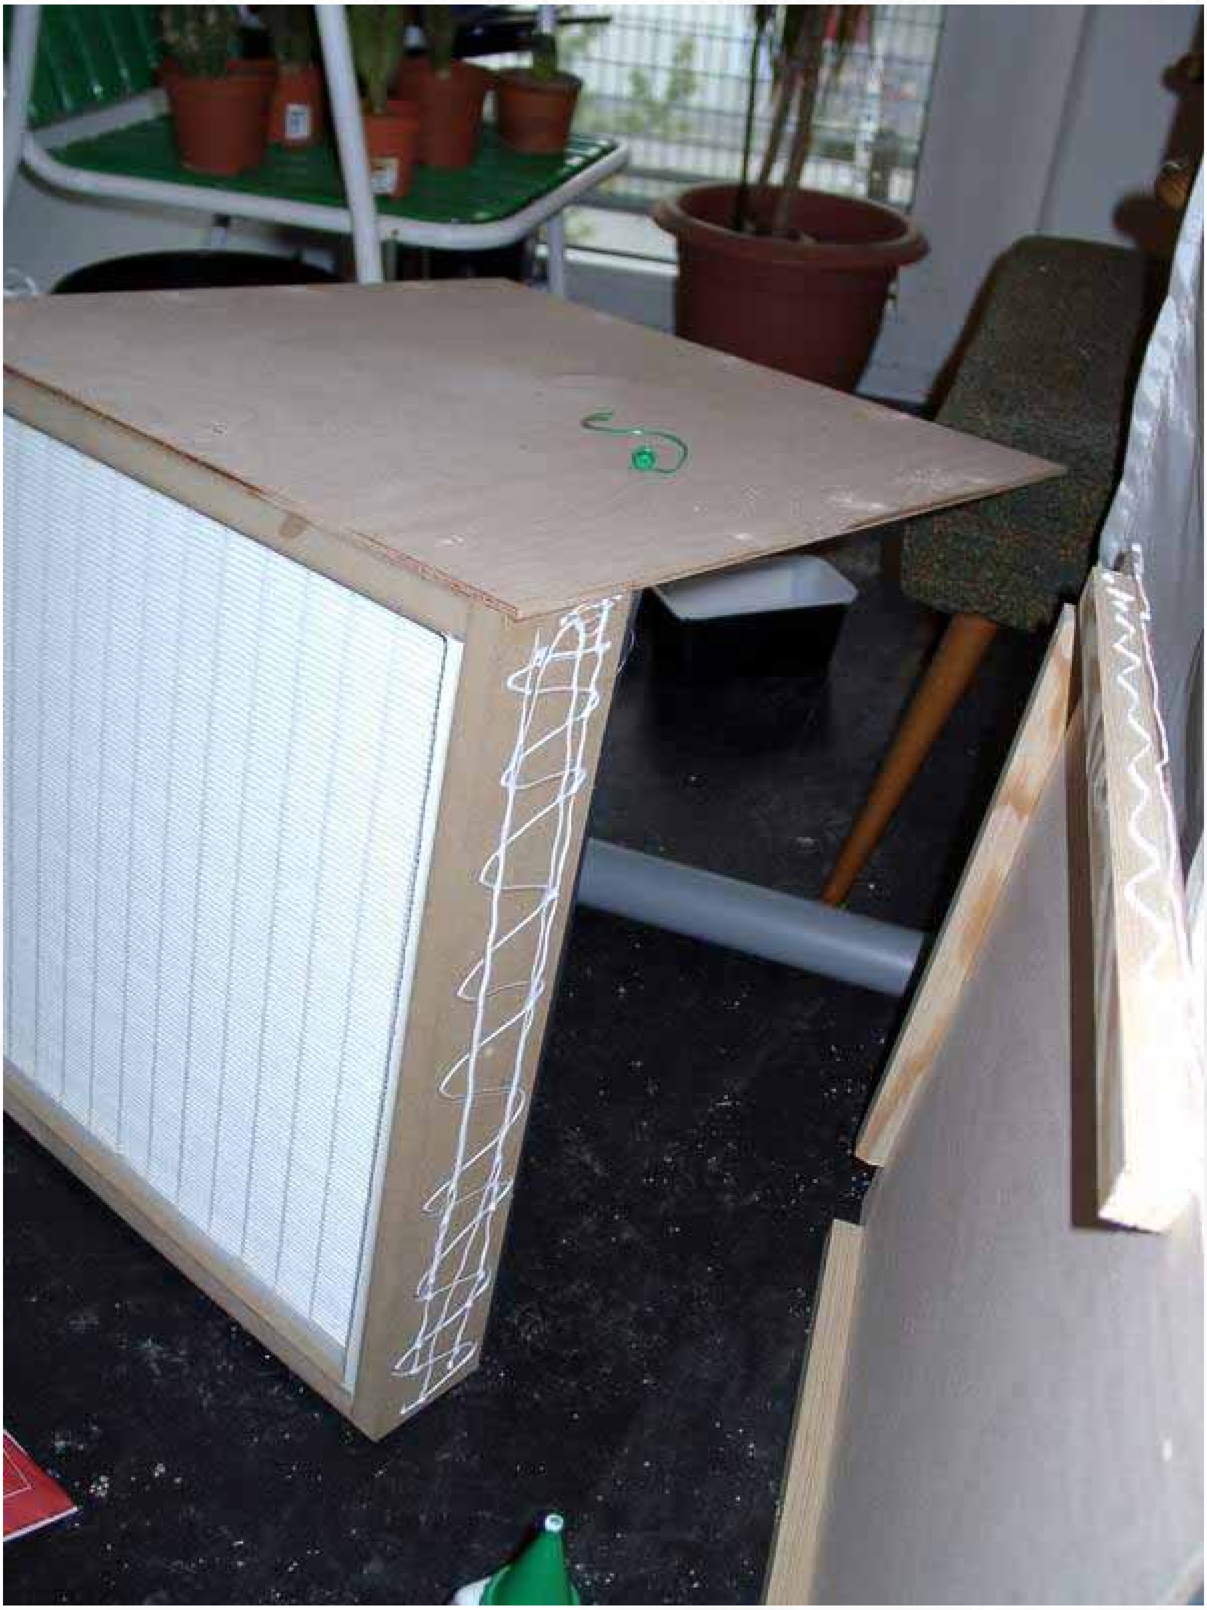
When in doubt, head for the more powerful blower, you can still regulate it down if necessary with a variable speed controller/regulator.

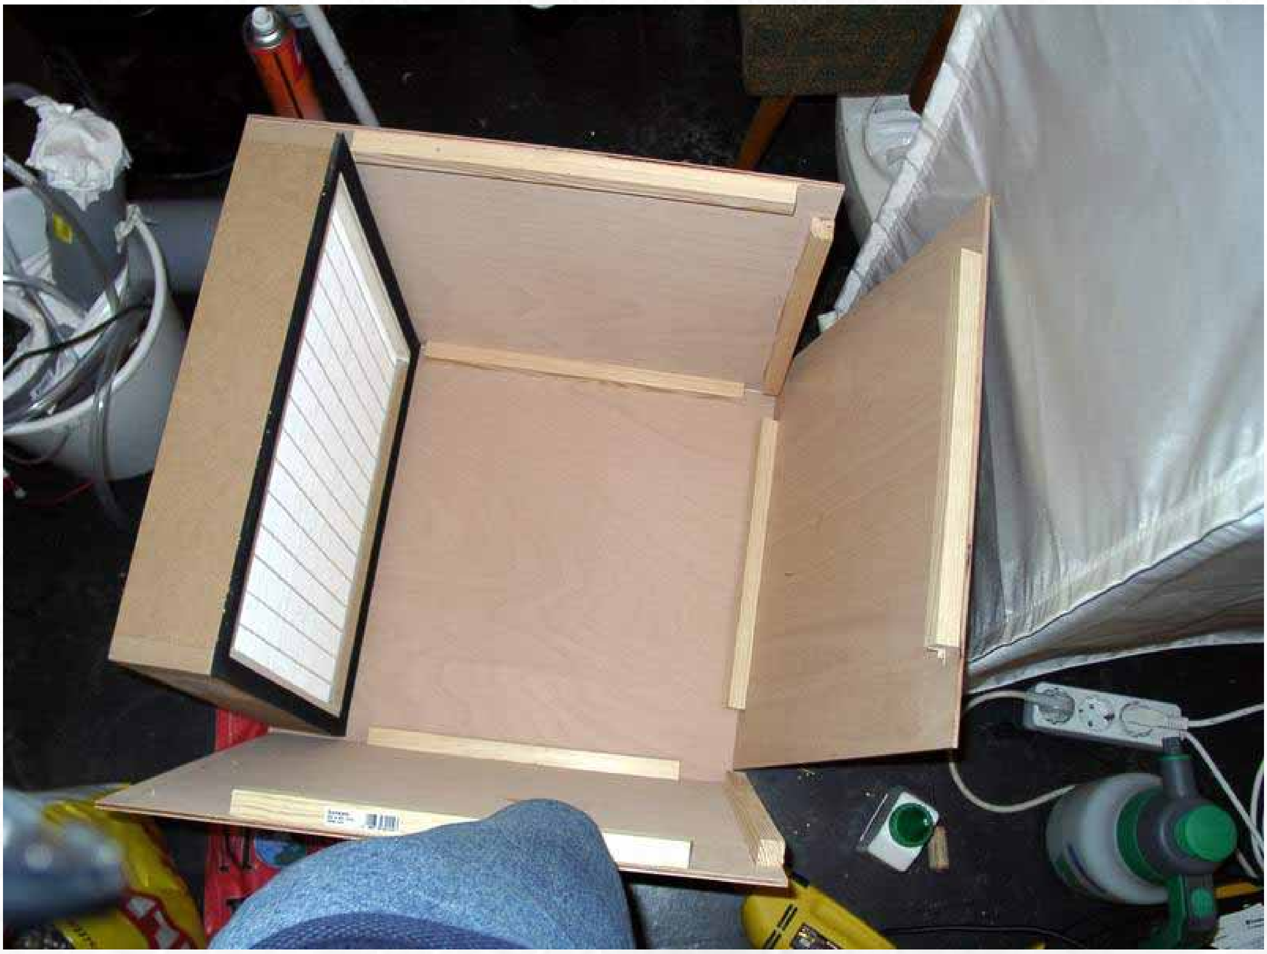
Construction of the hood

After you bought the HEPA filter and a matching blower, you have to get some materials for the construction of the box that will accommodate the above 2 components.
Basically you want to build a box, the front wall of the box will consist of the HEPA filter, and another wall will have the inlet of the blower with the pre-filter mounted. I had the material for the walls already cut to fit the size of the filter and the blower.
I begin by gluing and screwing the filter to the bottom wall.

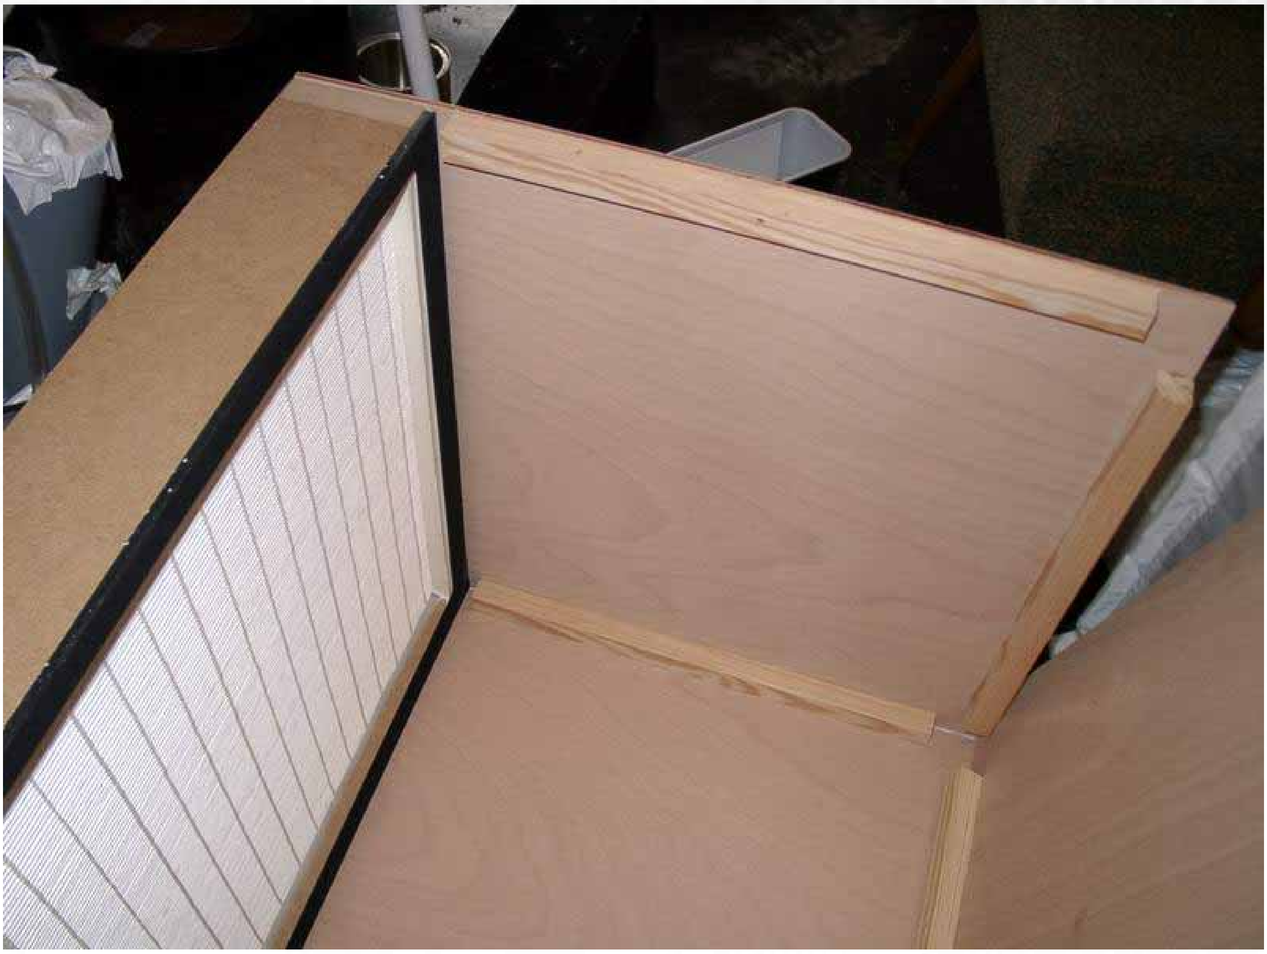


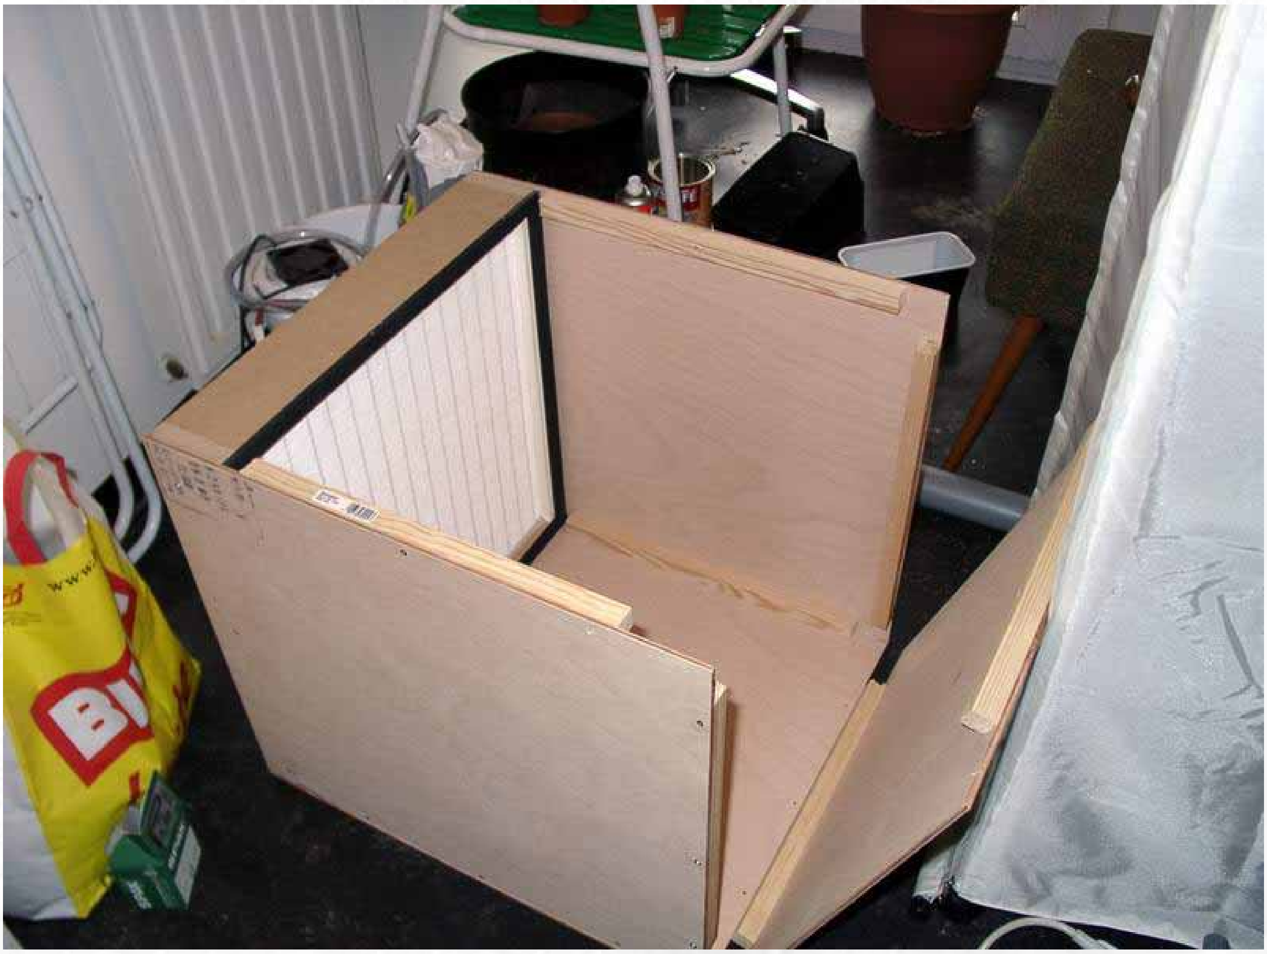
Then I add the side walls...



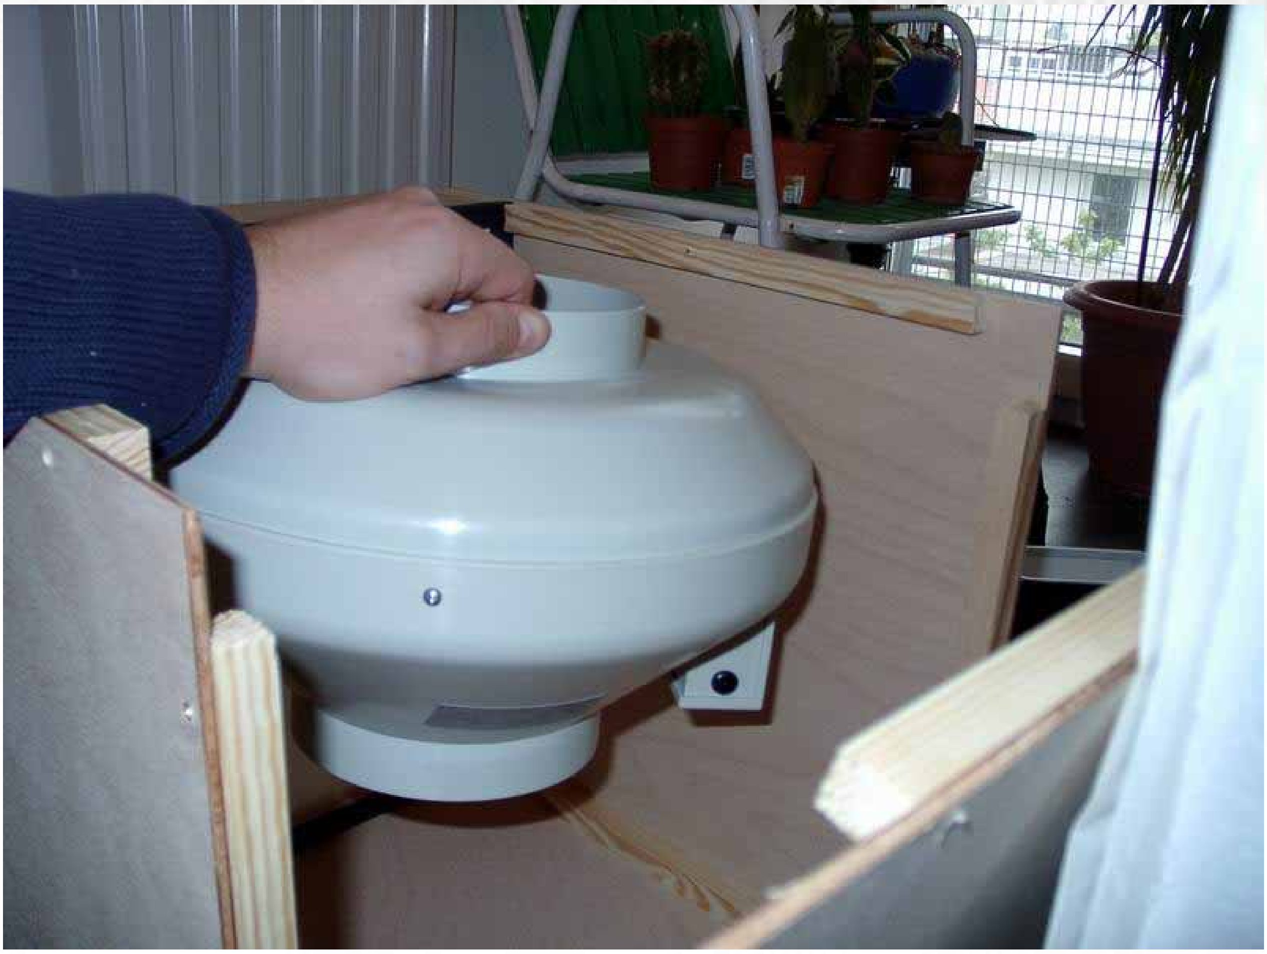


...and the back wall.

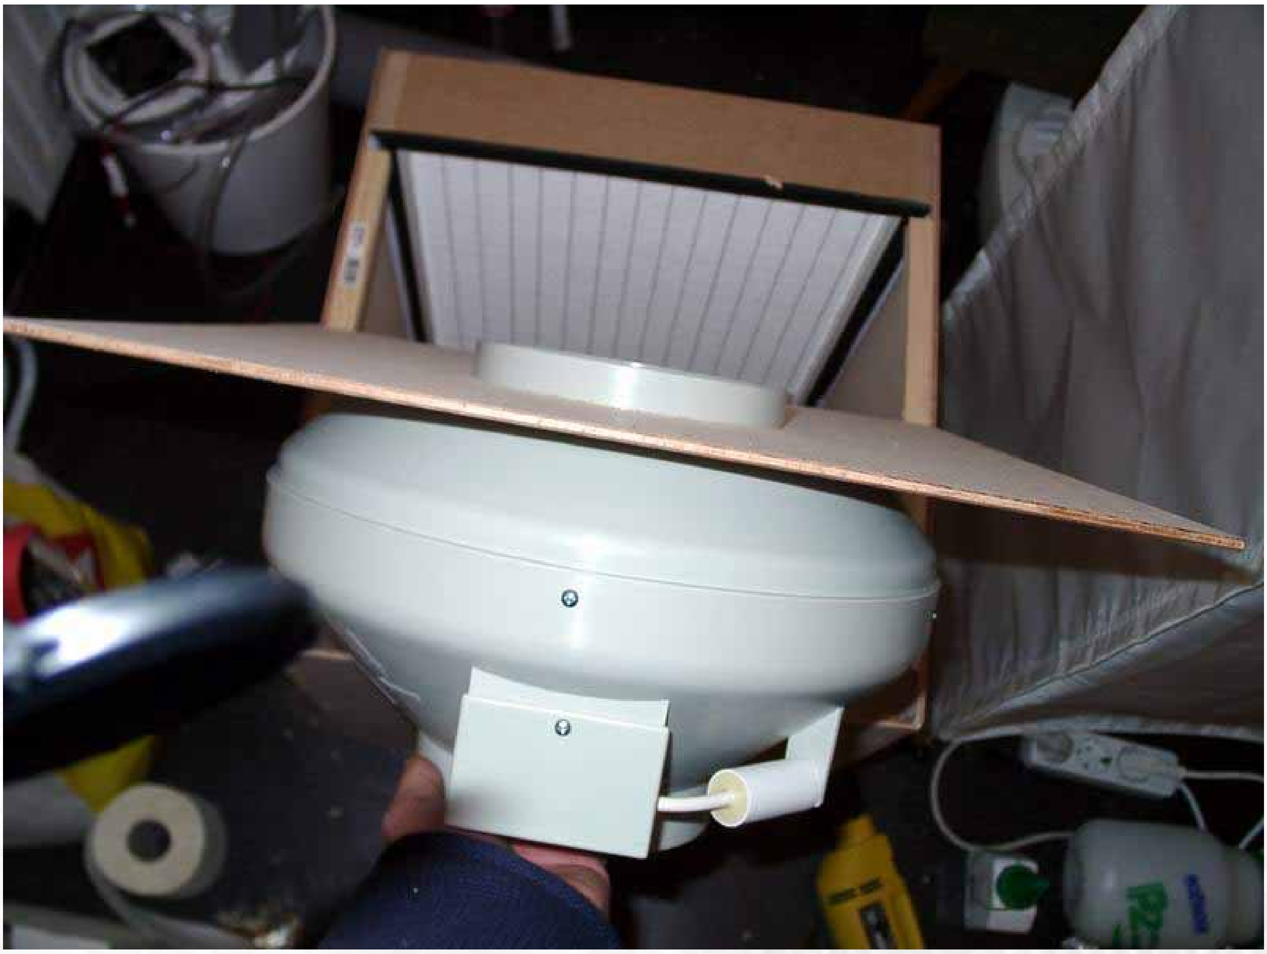


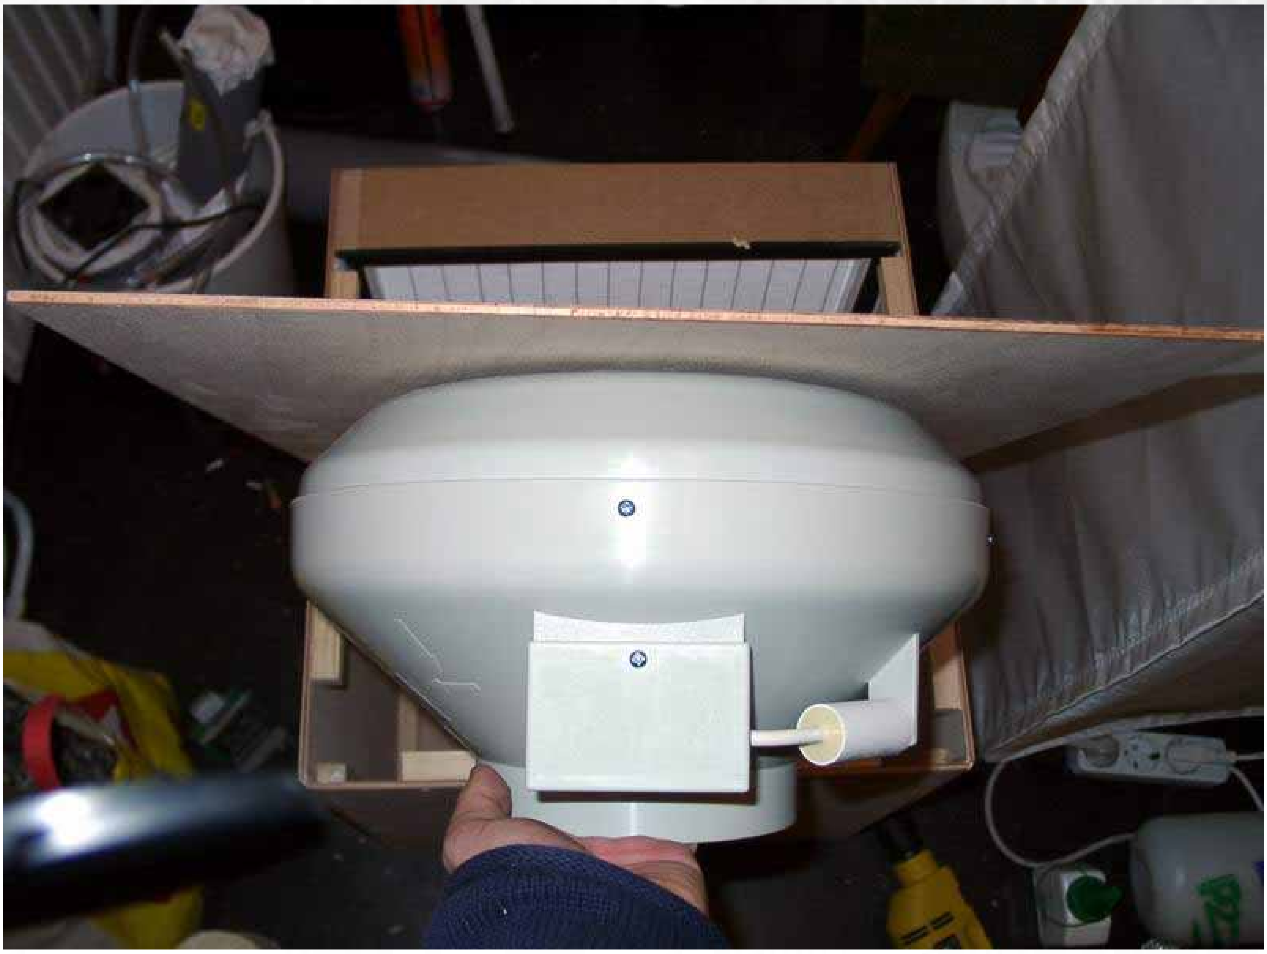


The blower will be mounted so the inlet is at the top.

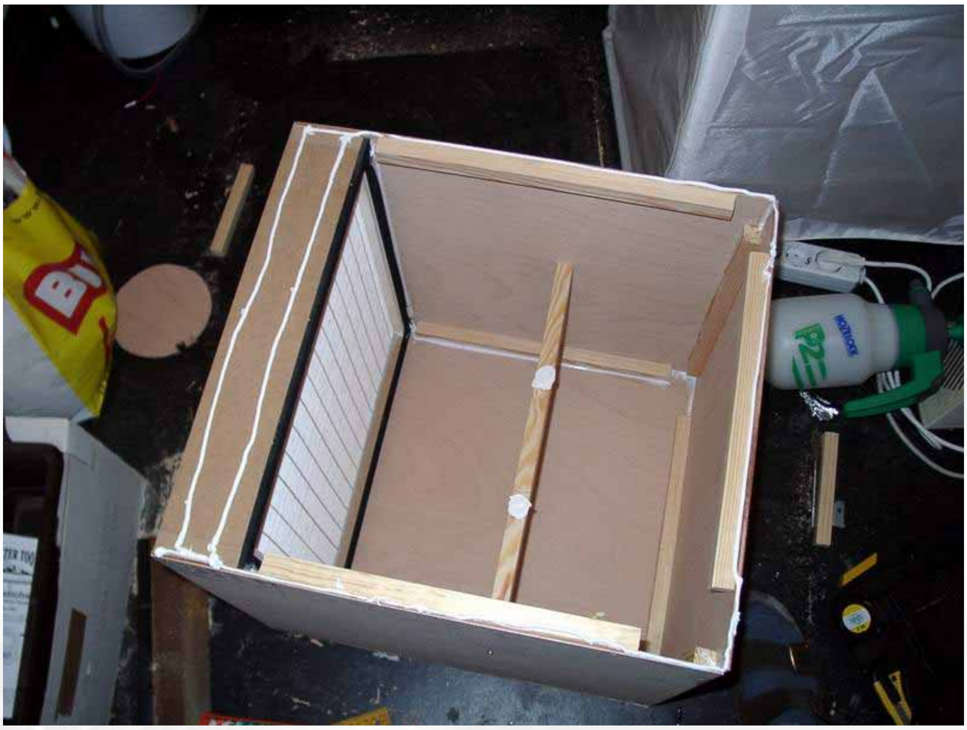


A hole is cut in the wall at the top to accommodate the blower inlet.

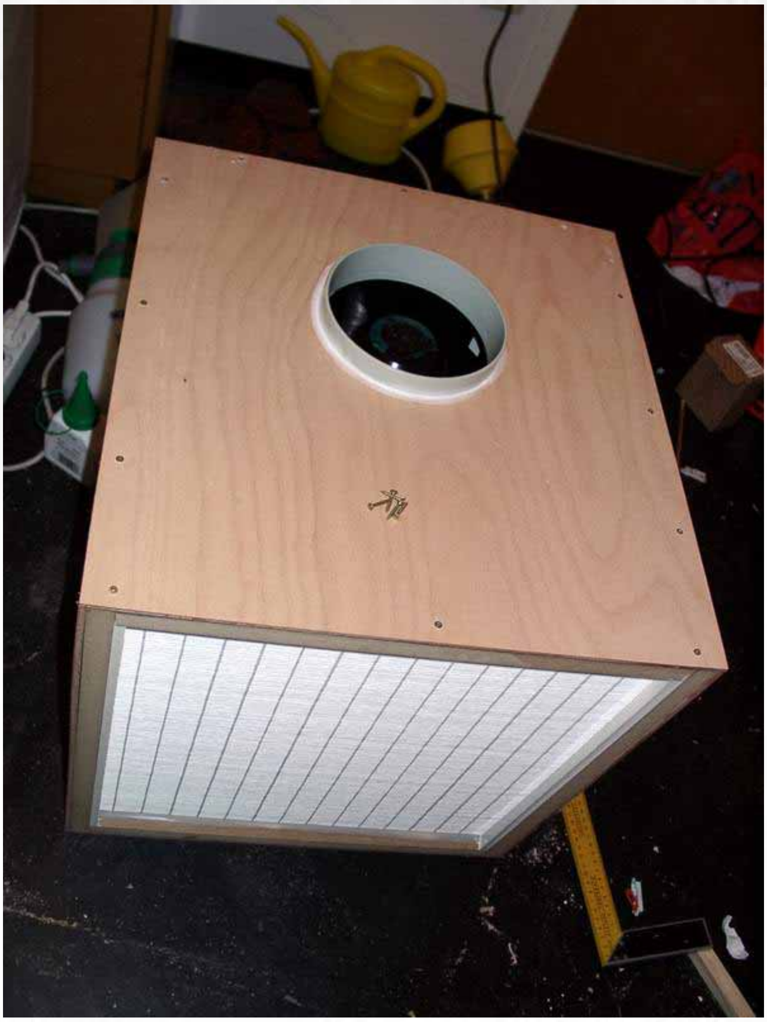




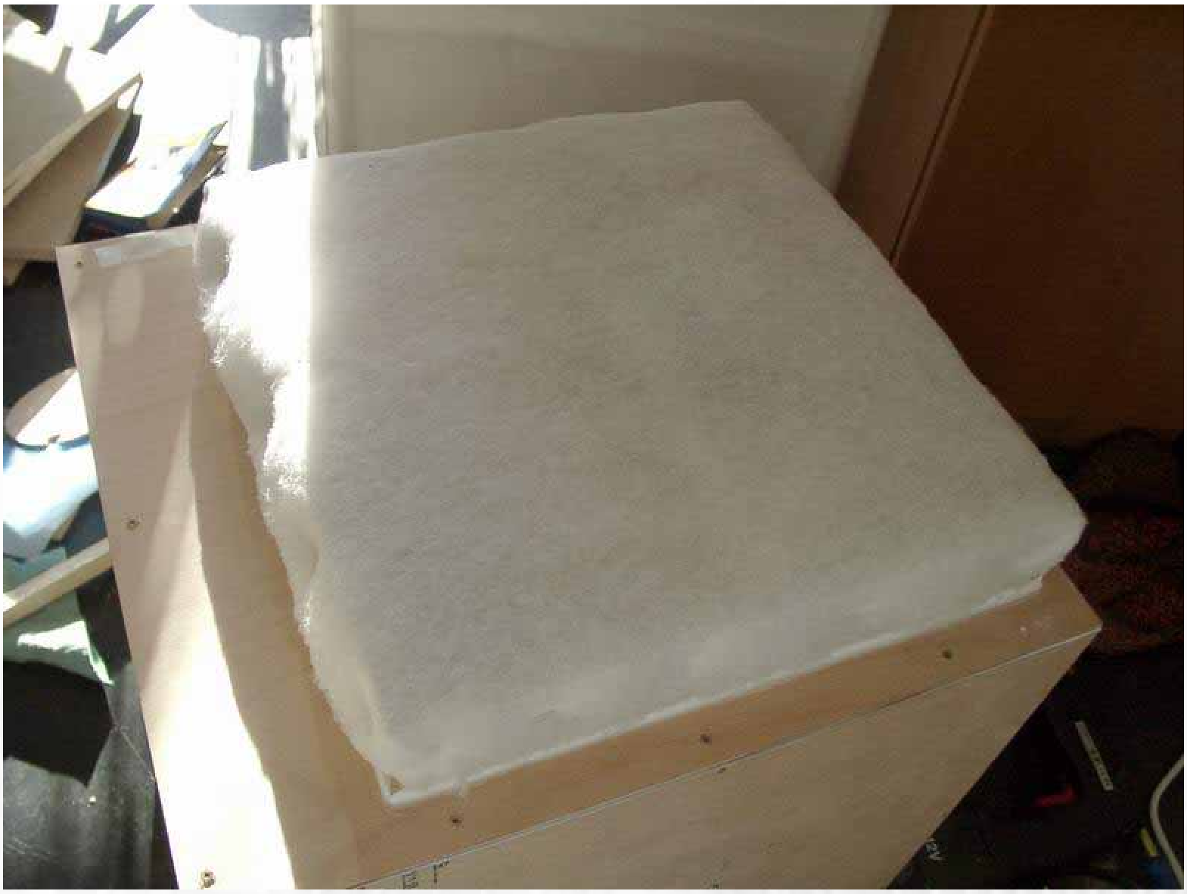
The blower rests on a bar mounted in the box. The white dots on the bar is some (already dried) silicone mass to provide some damping and lessens vibrations. All the joints are filled with silicone mass so the box is airtight.



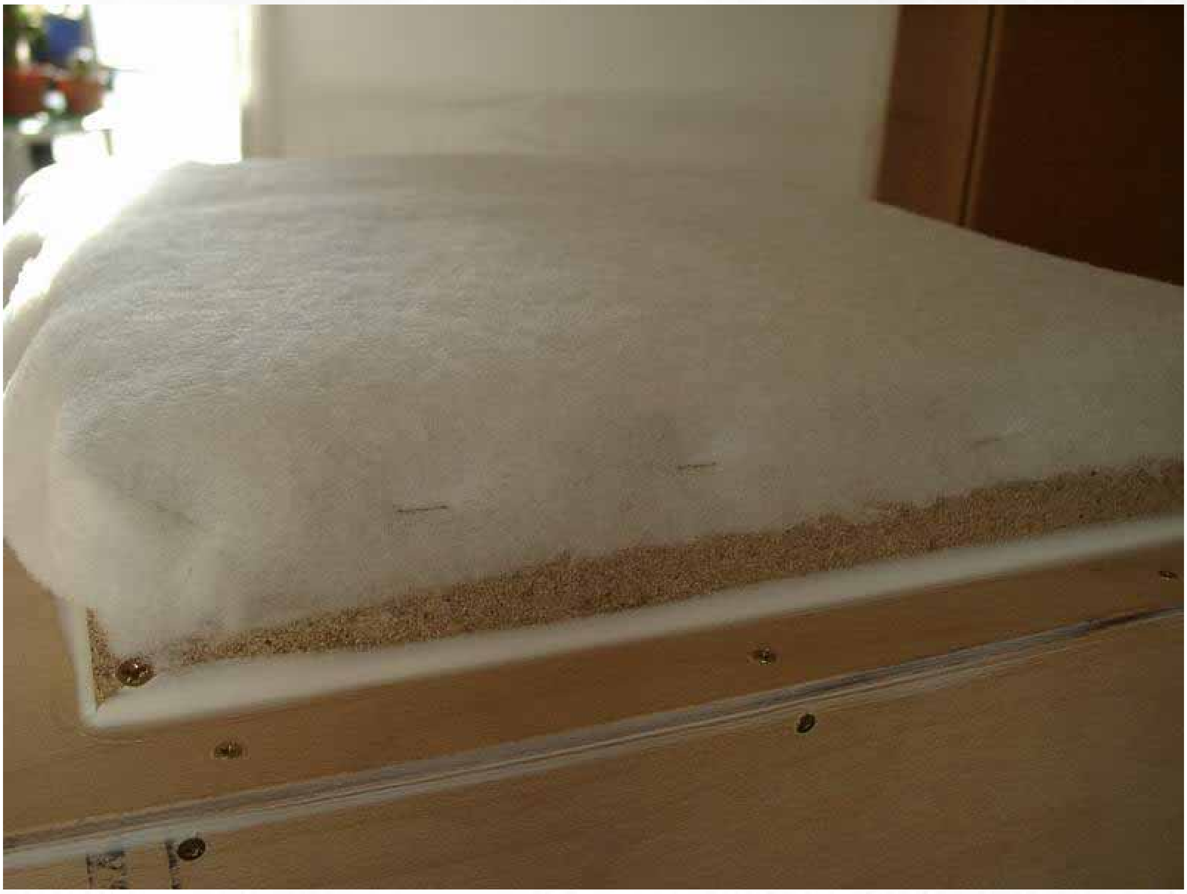
The top with the blower is screwed on the box. The space around the opening and all other cracks in the box are tightened with silicone mass.



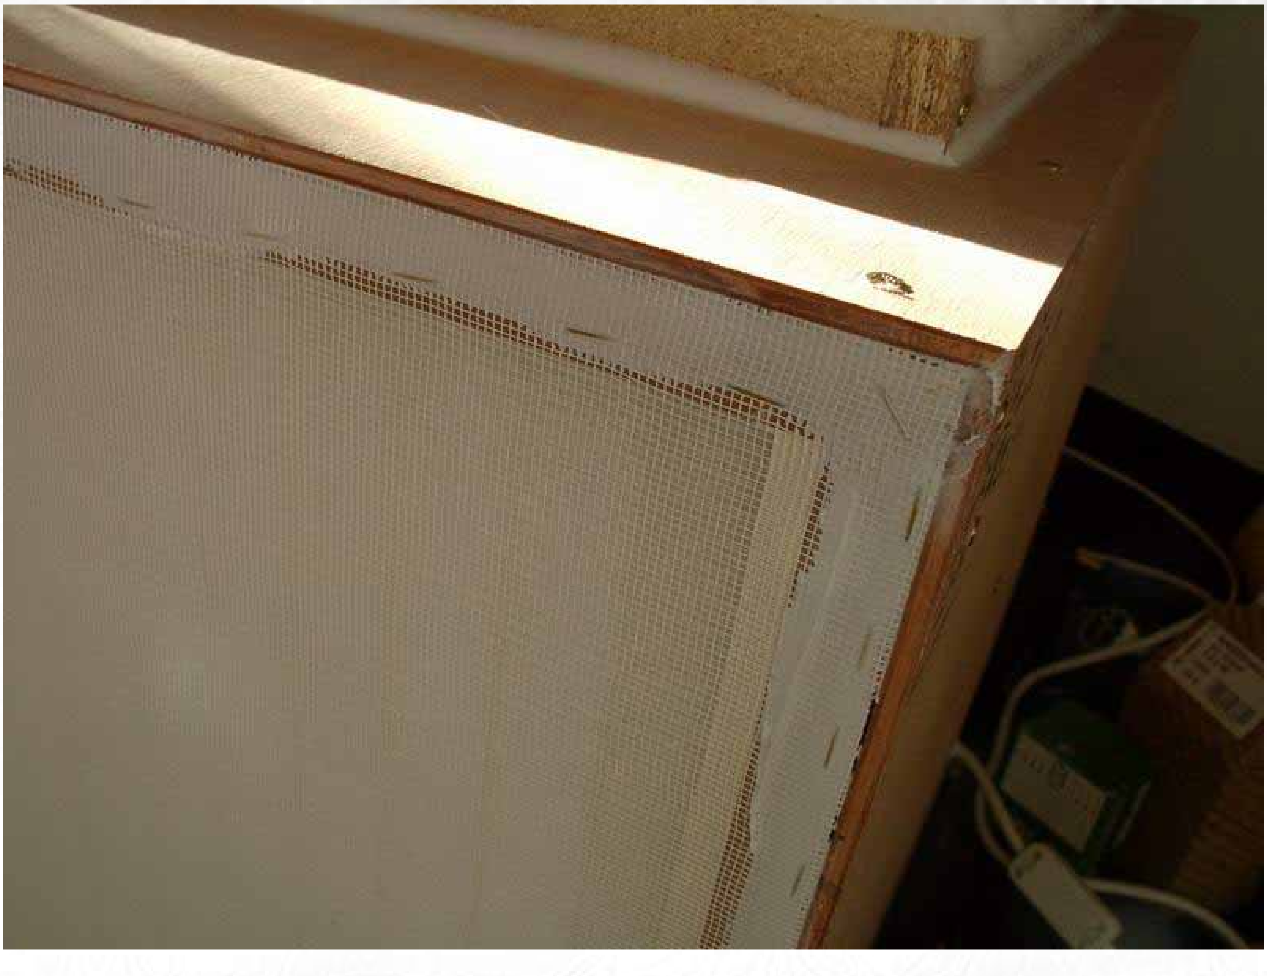
A pre filter is mounted atop of the blower. I use a furnace filter, you can also use other filers, like car air filters, just make sure they are large enough and that they don't have too much air resistance, otherwise you would need a larger blower.



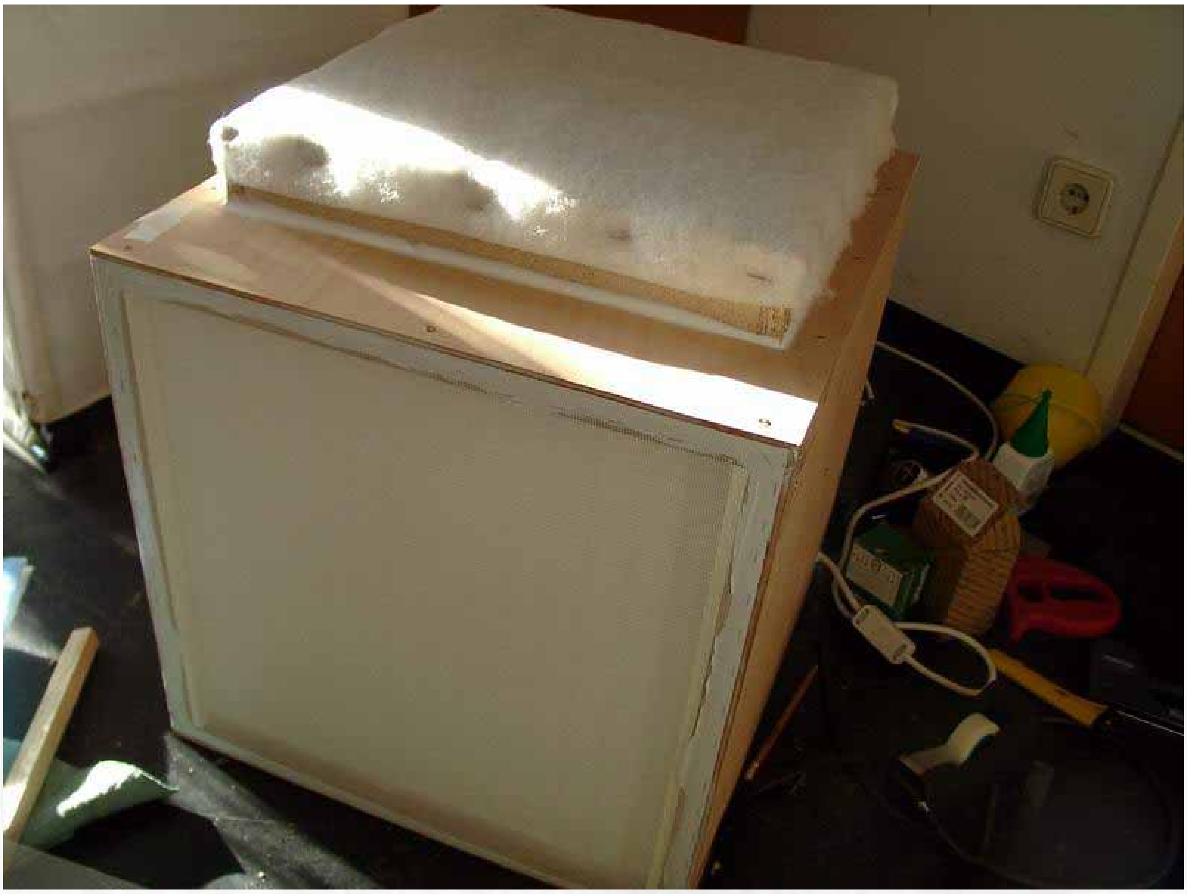
Detail of the pre-filter.



A net is tackered to the frame of the HEPA filter to prevent touching and harming the delicate filter.



The finished flow hood.



Some pictures of a similar design

Some pictures of a similar design, the only difference is that the blower is mounted around 10 cm deeper, so the pre filer is in the same level as the rest of the box. Makes it more visually appealing and more compact this way.

HEPA Case for your Air Pump

by

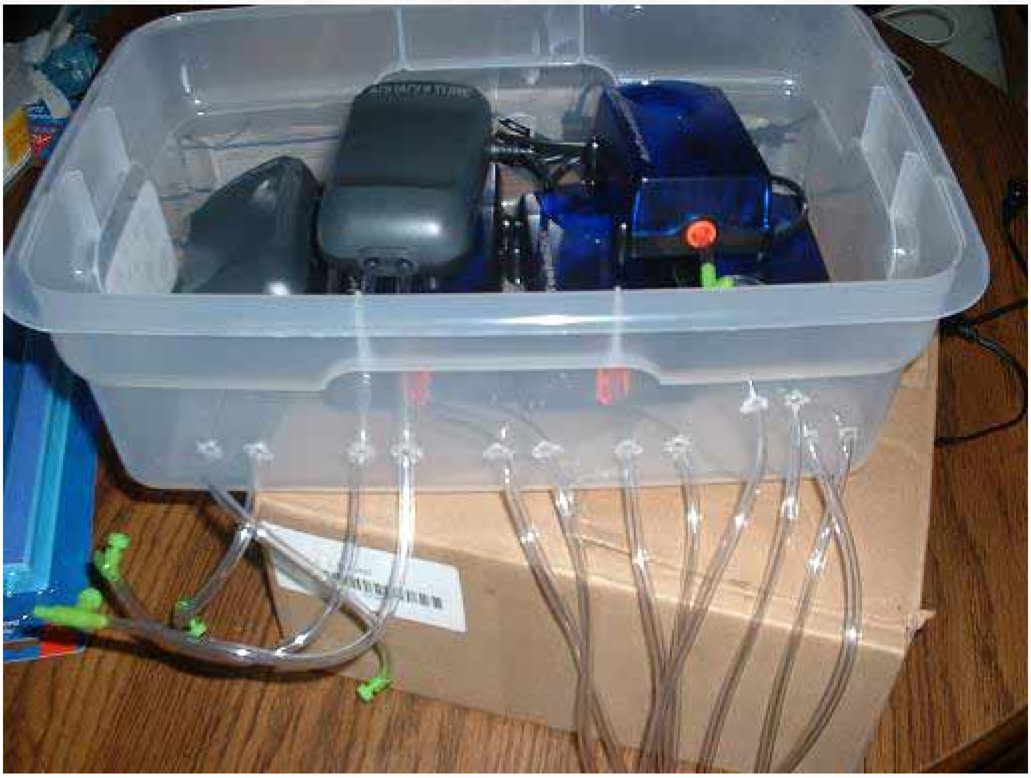
LiL_KuSsH

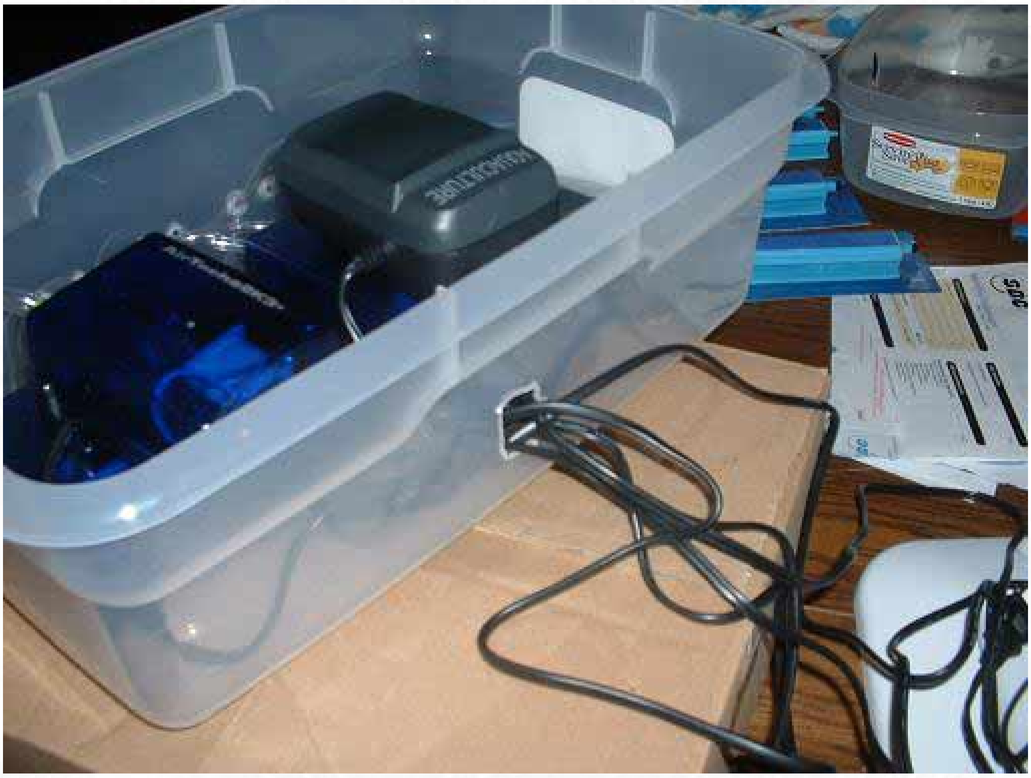
original source:
http://cdn.preterhuman.net/texts/drugs/shroomery_grow_archive_2003_10_14/shroomery_grow/www.shroomery.org/index/par/24205.htm

Materials Needed:

- A HEPA filter (any size, the bigger the better)
- A Tupperware container large enough to fit the pump(s) in Air line Hosing
- Pump (Or cool mist, just requires a larger container. Also I only suggest doing this for a cool mist if you are using it for air exchange and not having to add water to it.)
- A knife
- A heat source
- Silicon (I like duct tape HEHEHE)
- Lysol
- A screwdriver (phillips head large diameter)

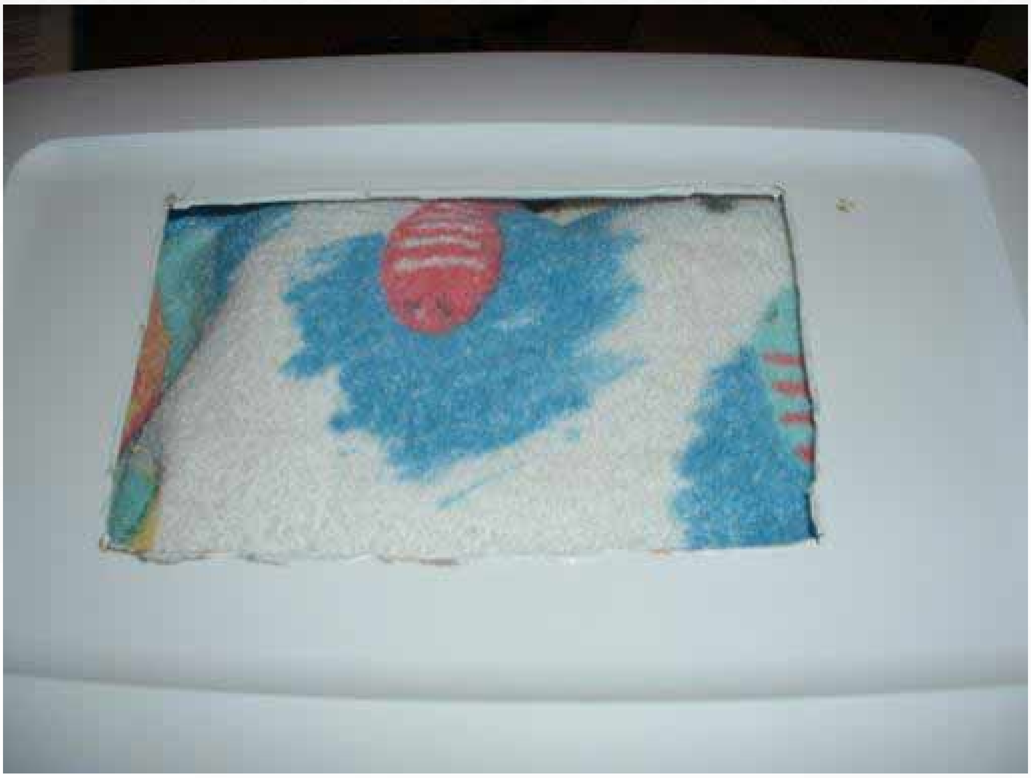
Turn your heat source on and heat the screwdriver till it's extremely hot. Then make two holes in the Tupperware container on the side. This is for the air lines to run through.
Next heat the butter knife till it's red hot. Then make a hole big enough to put the plug for the pump(s) through. Place the pump inside the Tupperware container and put the cord through the large hole. Now cut your desired length of tubing and feed it through the holes and connect it to the pump.
Should look like this :





Then take the knife and get it red hot again. (a utility knife can be substituted but its fun playing with fire). Taking you are knife cut a hole in the lid of the Tupperware container about 1/16th and inch smaller than the HEPA filter.

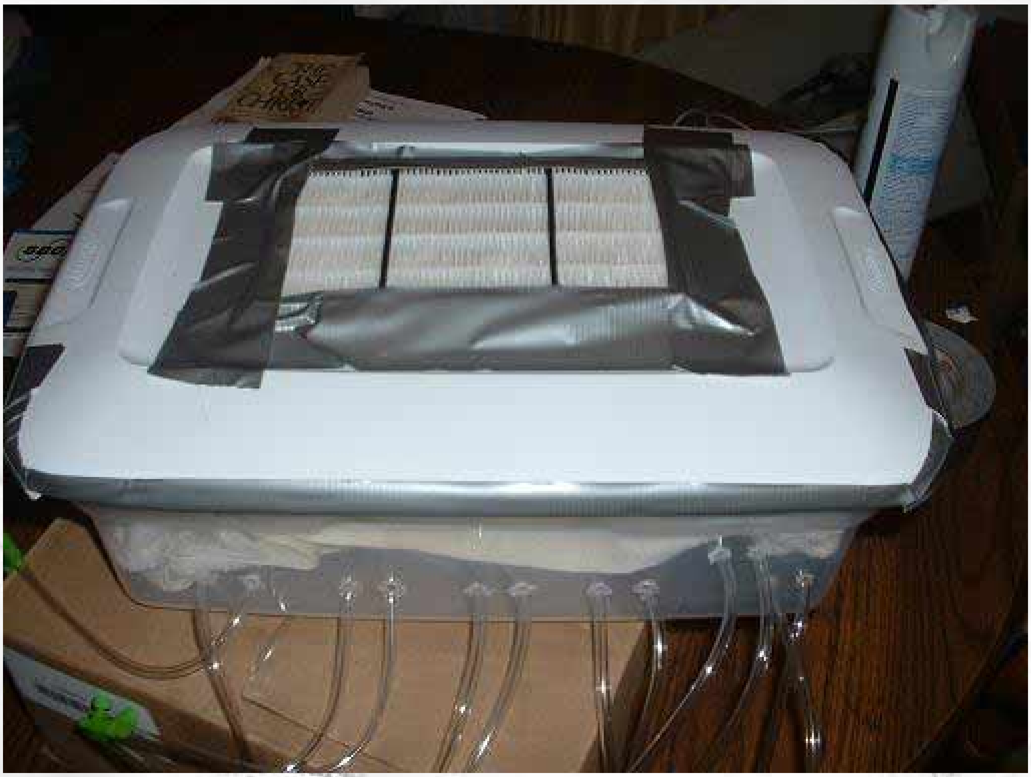
Should look like this...



Using the silicon seal the HEPA filter onto the top of the lid. Some HEPAs have certain sides intake and out put. Make sure the intake is facing up. ... then use your duct tape (I do this... doesn't mean you have to) and tape the sides of the HEPA to the lid.

Now silicon the holes closed that the hose is through. And silicon the hole with the plug through it closed nice and tight. Now place a towel inside the container and spray it down heavily with Lysol. Using the silicone run a bead around the edge of the container and place the lid on it. Now u have a sealed HEPA case. Let the silicon set in a ventilated area for 24 hours.

After its set run the unit for 12~24 hours to make sure the silicon vapors are completely out. BAM! Hepa Casing!



Have Fun and Be Safe!

Double Tub Pictorial

by

Carlito

original source: http://www.shroomery.org/9107/Double-Tub-Pictorial

Foreword:
I would like to first say that this tek is not mine. I am taking the time to document this for the benefit of our fellow members. Credit must be given to those that have pioneered this technique. Primary credit goes to Eatualive who had the courage to try this and bring it to light. There are others out there who have used this tek, Iamthewalrus, Mushroommark, many others and me of course.

Okay let's get started.

This tek will be written as a 'How to' manual. I will attempt to cover every facet of the growth and make references to those people who have coinciding information to aid in the final product.

First Things First:
The first phase in any tek is the planning. When using the Double Tub tek you must plan ahead. Failure to plan properly will result in wasted material. When assessing the needs of your grow there are a few key measures that must be taken into account before you do anything. These are:
1. The amount of colonized substrate you will use.
2. The amount of substrate after the spawn is mixed.
3. Having enough substrate to fill the area needed.
4. Leaving room for the casing layer.

Failure to address these key measures may result in too much spawn, too little, lack of height for CO2 expulsion, and finally no room for your casing layer.

Preparation does not have to be exact, but must account for the medium in which you are going to be growing in, in this case Double Tubs. For the purpose of this tek I will be referring to horse manure and WBS as the spawn mediums.

There are a couple of things to keep in mind. Do not to get wrapped up in exact specifications. This is not an exact science and a little imagination can go a long way.

There is no exact formula for mixing spawn. The difference between 2 quarts of WBS and 5 when spawning is time. The Double Tubs will keep the spawn contained in a contaminate free environment, as long as you keep the conditions reasonably clean. Allowing time to properly clean and sterilize all surfaces will go a long way and may mean the difference between 1 flush and 5.

Okay, now that we have those key points out of the way, let's move on.

Tools List:
The following are recommended tools for this tek, but are not required:
1. Drill (cordless or corded)
2. Hole-saw 1-1 1/2 inch
3. Tape measure

If you do not posses these tools, its okay, you can make your holes with a knife.

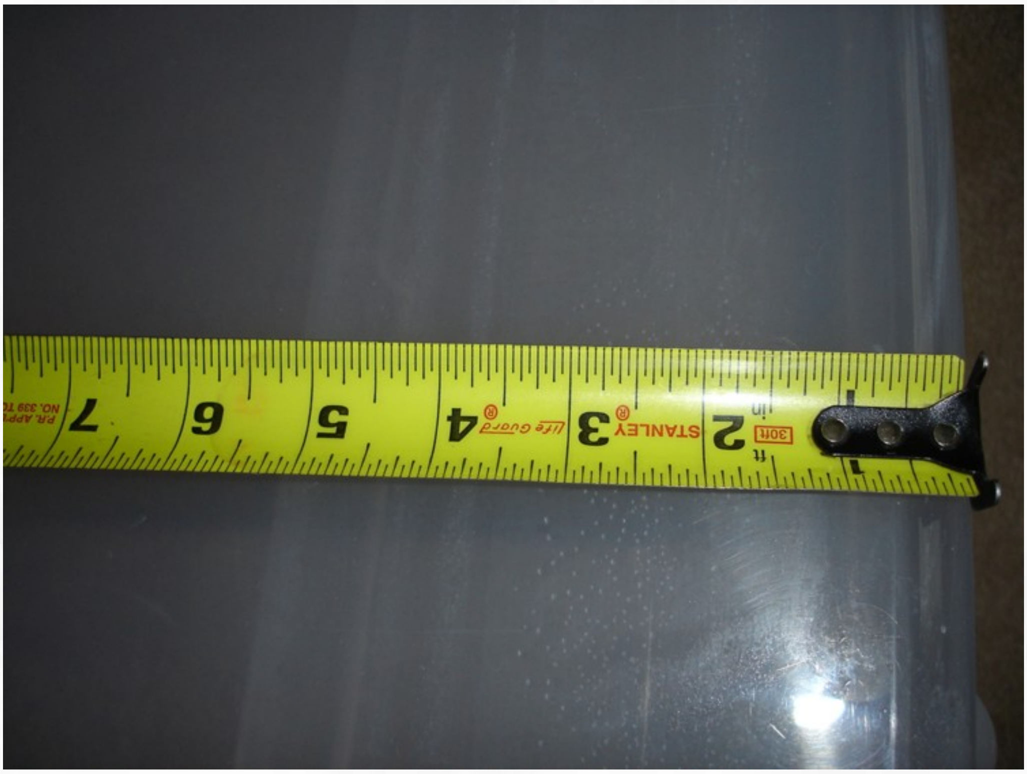
Materials List:
1. Sterlite or Rubbermaid tubs (19 qt minimum to 64 qt maximum) Qty. 2
2. Poly-fill 20 oz. Qty. 1 bag
3. Duct tape Qty. 1 roll
4. Black trash bags 30 gallon Qty. 2 bags
5. Alcohol Qty. 1 bottle

Now that we have our materials and tools in hand, it's time to start planning our hole placement. A total of 8 holes will be drilled for these containers (4 holes per container). 2 holes will be drilled approximately 4-5 inches from the bottom of the tub on each side, while the other tub will be drilled exactly the same.

When you are drilling the holes, place them semi-equally apart from one another by selecting the holes about 3-4 inches from the end of the sides. If you decide to use say 3 inches from the side and 4 inches up, do the same on the other side. Height placement is more important than side placement, as the holes should be fairly close to the substrate level.

Tip 1:
Remember to leave room for the casing layer. If you are going to have 4 inches of substrate and a 1/2 inch casing layer, it does you know good to have your holes drilled at exactly 4 inches. Where would the casing layer go? The bottom of the holes is where the measurement needs to take place.

As seen here:

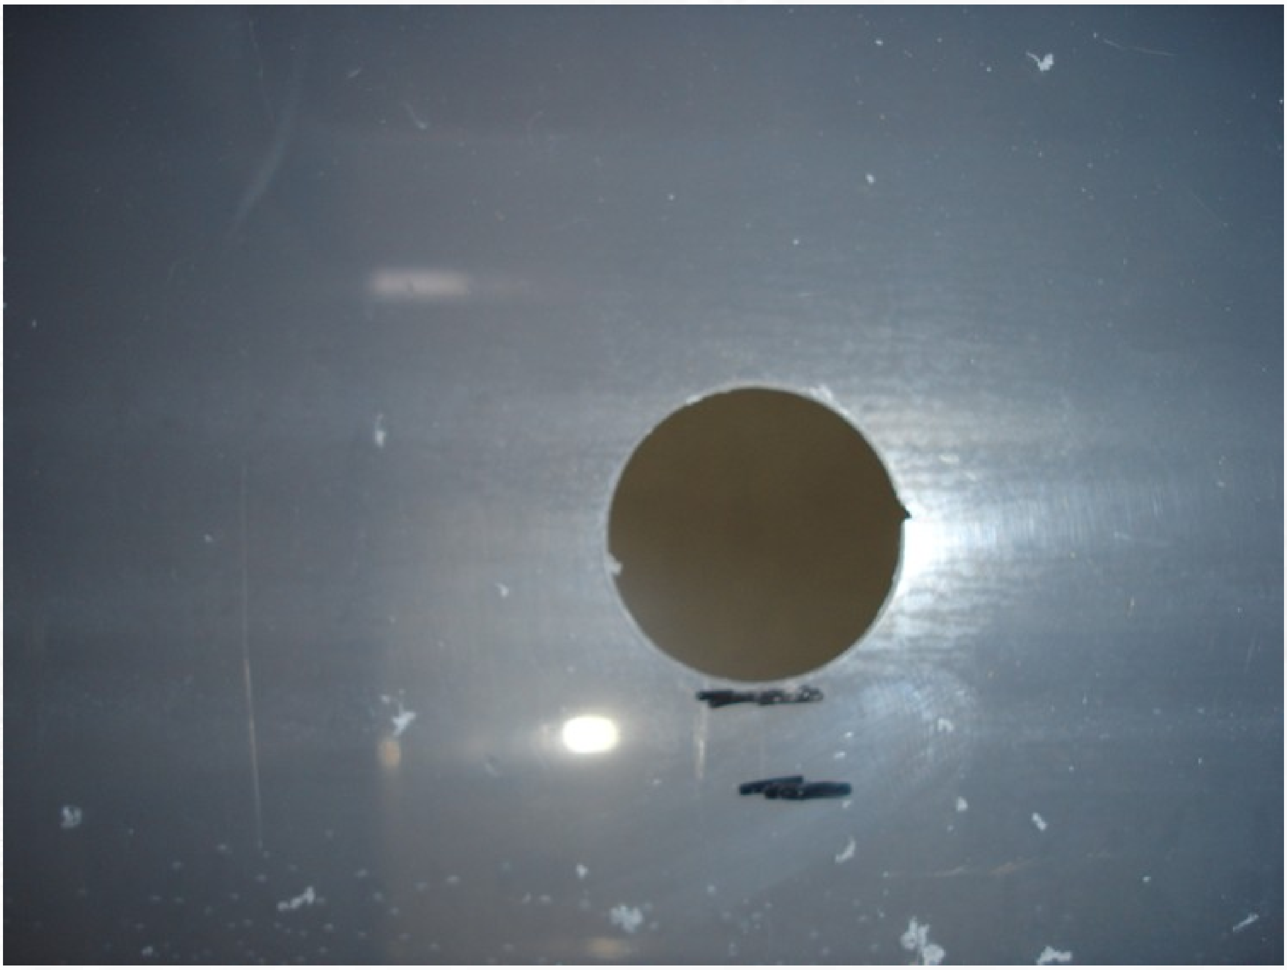


The reason why the two tubs will be drilled in the exact place is to avoid confusion on which tub is the top and which is the bottom. Remember that the tubs will be placed on top of each other, so the top tub, after it has been inverted, will be a considerable distance from the bottom holes.

What is the purpose of having holes at 4-5 inches on the bottom and way at the top for the top tub? I'm glad you asked. The lower holes, or holes at the substrate level, will aid in CO2 expulsion. The top holes will allow filtered air, filtered from the poly-fill, to enter the tub and provide air exchange.

The poly-fill is non-organic and not prone to habiting contaminates.

Now that that you have drilled your holes the container should look like this.

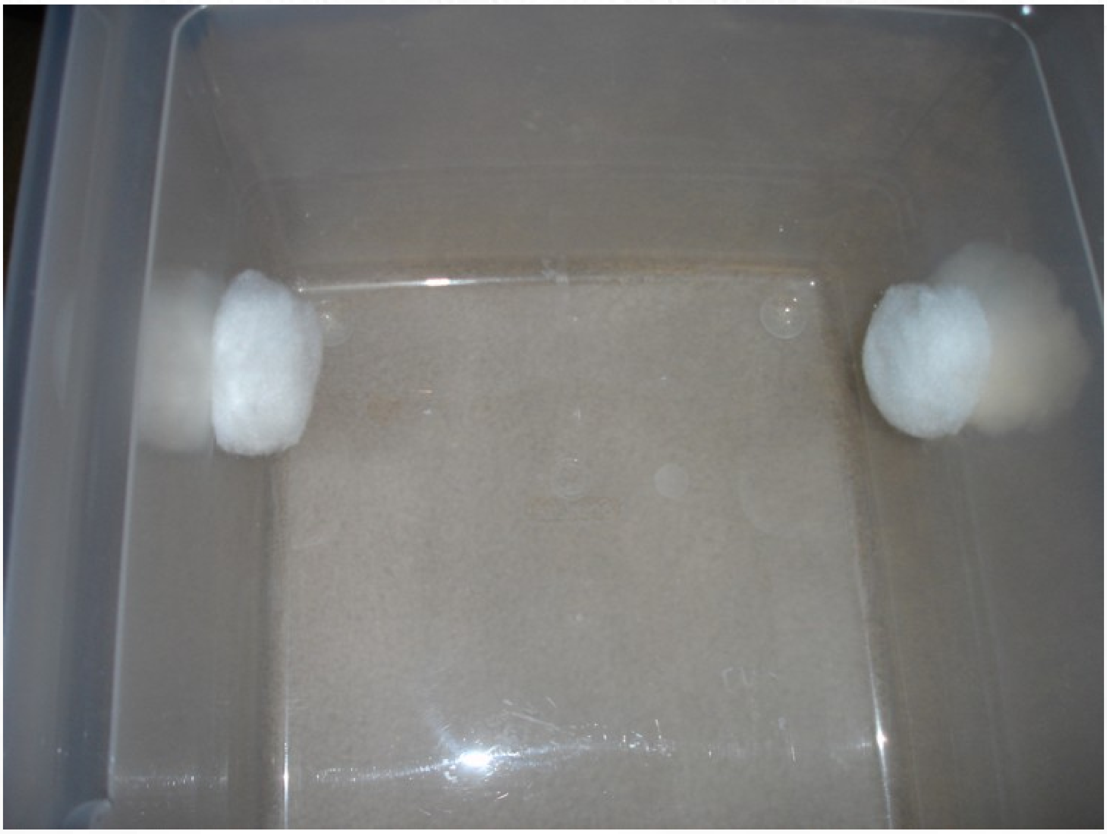


Notice how I planned my holes around where I want my substrate and final casing layer to be. I have plenty of room to even add a half inch of substrate if I choose, but I won't.

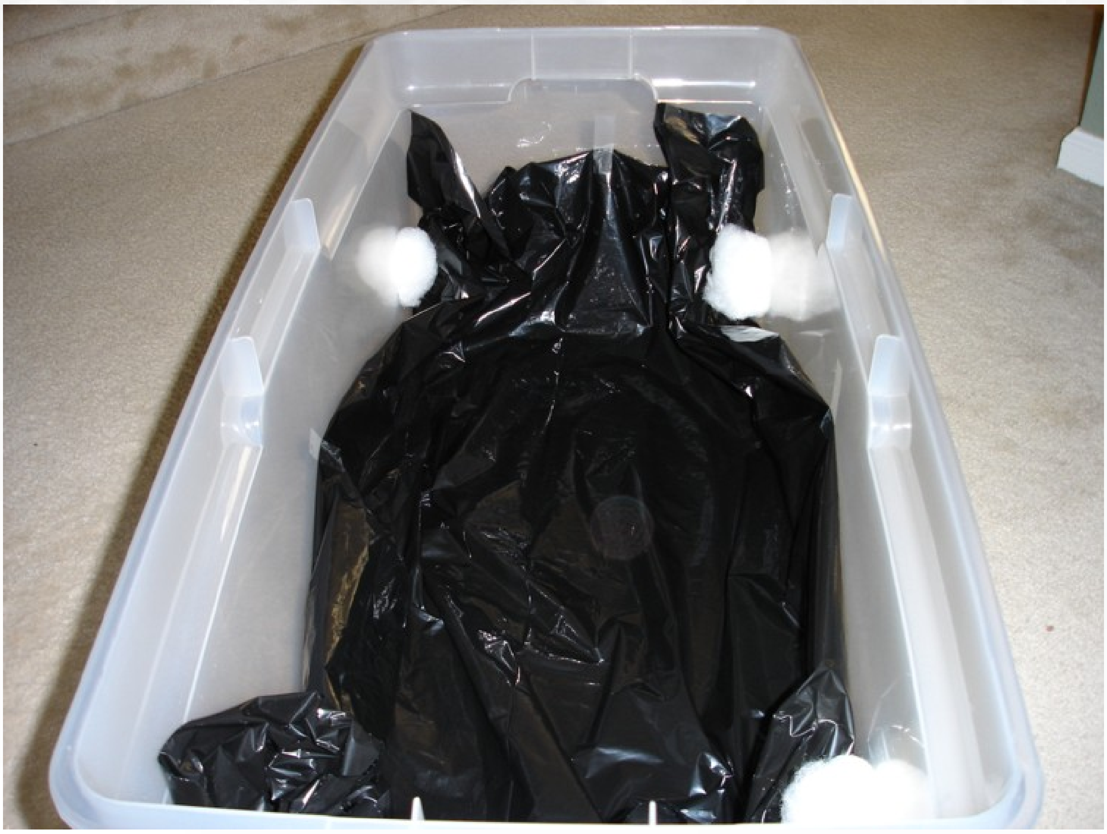
Tip 2:
Collect your horse manure and place in to the container dry. See how much you need to get up the holes, leaving room for a casing layer, and even it out. Now pull out the horse manure and weigh it. This is now the dry weight you need to grow every time for that container.

What about when you hydrate it and the weight changes? Good question. The answer is it doesn't matter. Hydrating horse manure increases the weight not the volume. In other words, the same horse manure dry, will take up roughly the same space wet. The wet horse manure simply weighs more than the dry.

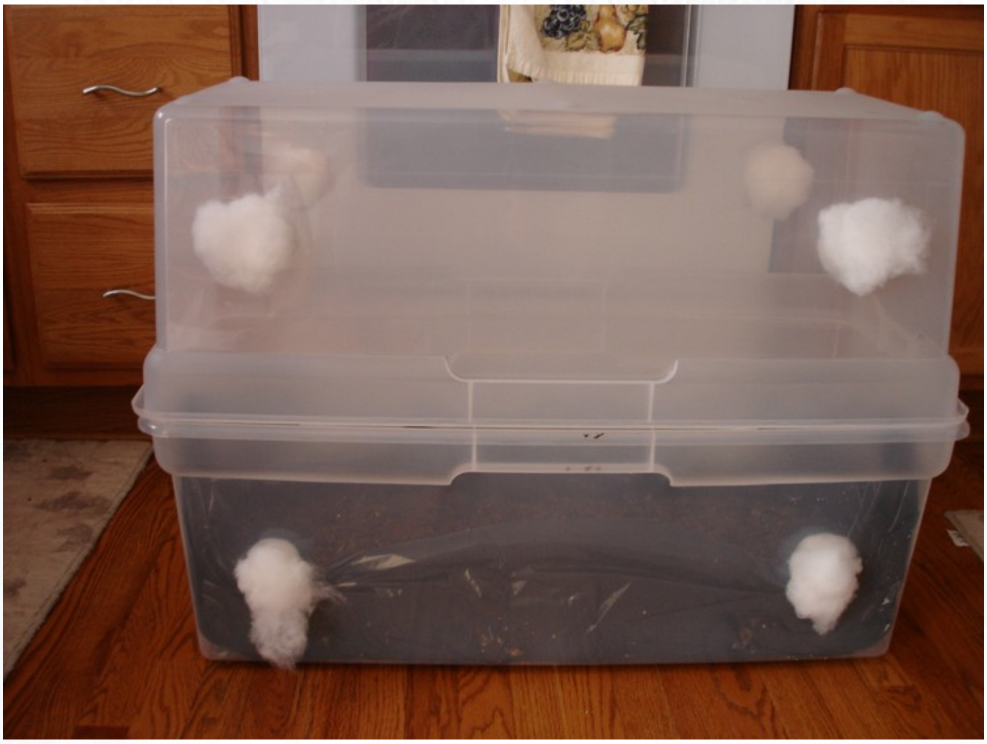
Once you have your holes drilled its time to pull some poly-fill out of the bag and stuff the holes. This does not need to be complicated. The best method for stuffing the poly-fill is to take a nice size wad and begin stuffing from the outside in. You want the poly-fill from the interior of the tub to look like large round cotton balls. This will avoid contact with the mushrooms during growth and looks neater. The poly-fill needs to be snug, but not so tight that the tub is deforming on you.



Okay, so we've stuffed all of our holes in both containers and now need to sterilize the containers. This can be accomplished by spraying some alcohol in the tub and thoroughly wiping the sides, rim, and bottom. Do not take your sweet time doing this. Get it done as quickly as possible. Place a trash bag or two on the bottom of the container that you are choosing to be the bottom. The trash bags should come up slightly higher than the poly-fill, by about a 1/2 inch, but not so high as to interfere with the fruiting.



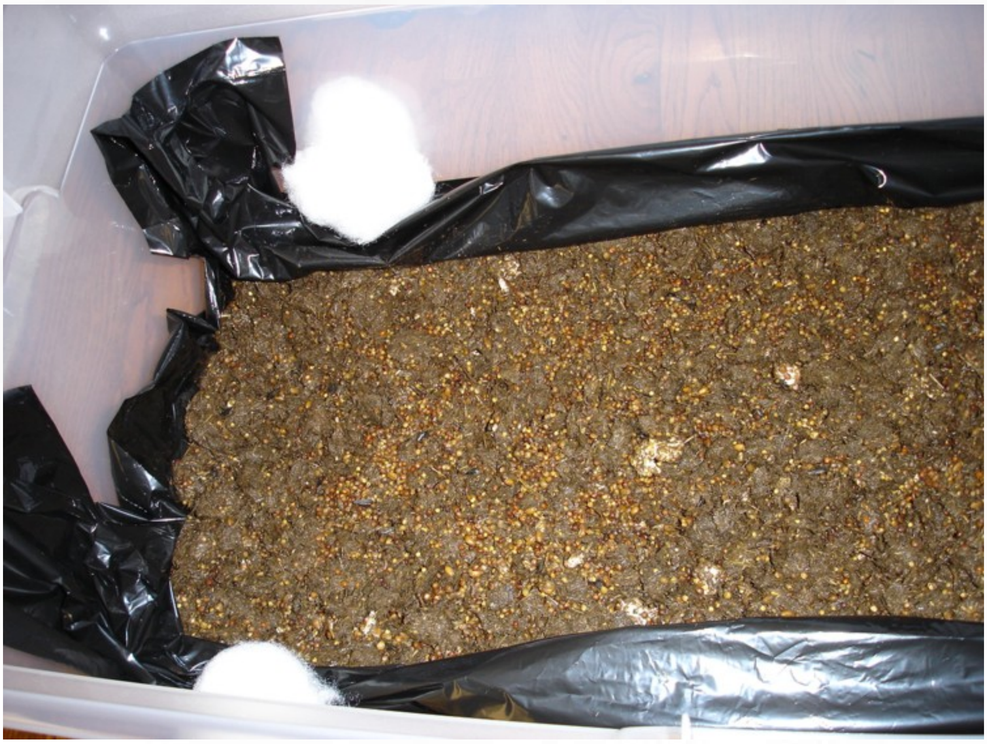
Once this is done, invert the chosen top tub and place on top of the bottom tub. Make sure the container lips are aligned with one another so you don't have anything floating in there from the open air.

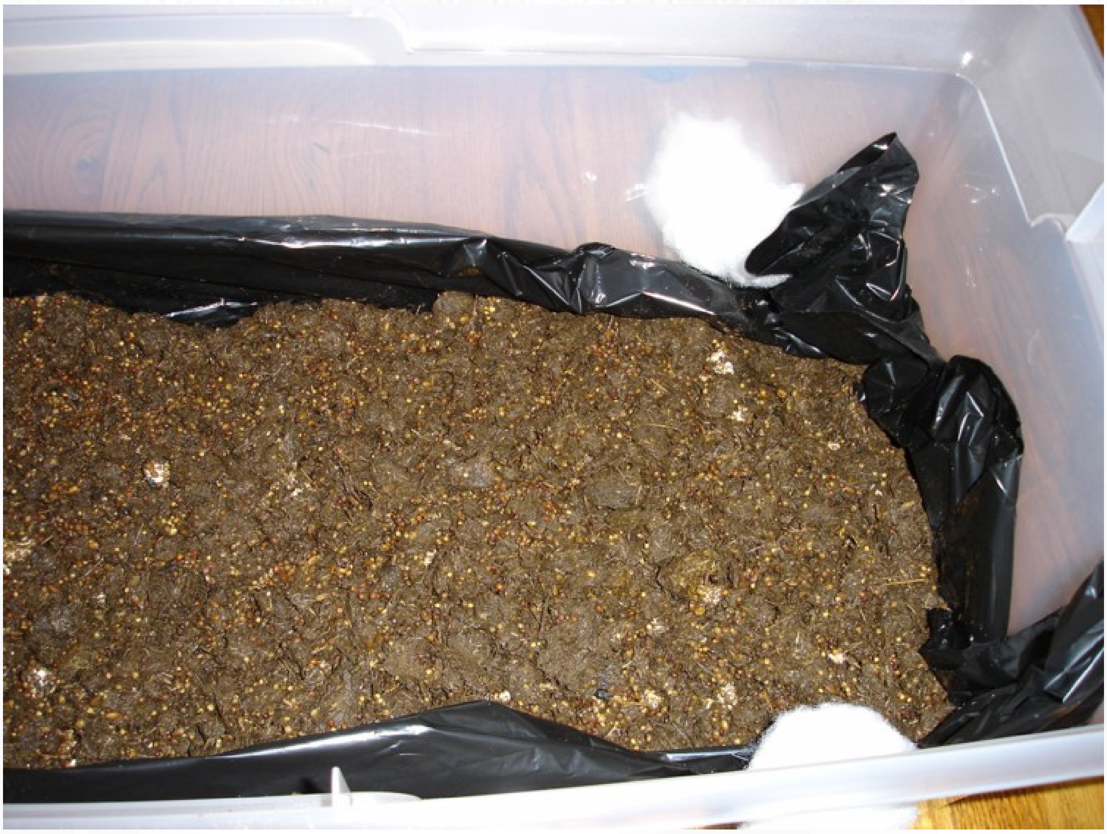


The next step is to take the materials for your spawn medium. You can use either Roadkill's horse manure tek or Agar's. Both work great.

In this case, I am using 7 quarts of PR WBS to about 12-15 lbs of dried horse manure in a 64 qt container. Place the horse manure into a sterilized container, preferably lined with a trash bag, and put your colonized substrate on top. In this case, I'm using WBS. Break up the WBS and begin mixing thoroughly. Once you have mixed up your spawn, place a lid onto the container with the spawn. Spray some Lysol into the air around the Double Tubs and wait for 10 minutes.

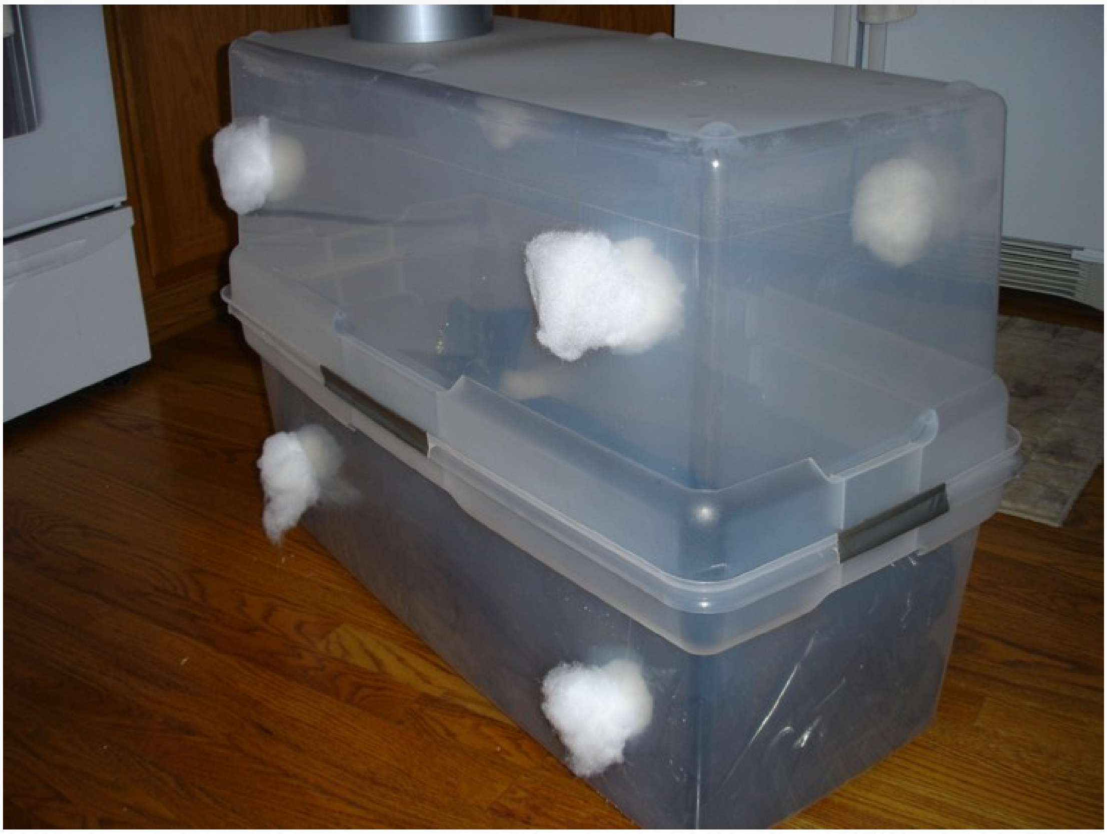
Now that I have mixed my spawn, I'm ready to place it into the bottom tub lined with the trash bag. Remember that your double tub should have closed during your spawn mix. Carefully place your mixed spawn into the bottom tub on top of the trash bag. You need to do this slowly, as you do not want the spawn to go down the sides of the trash bag, only inside the lined tub.





Now that you have your spawn in the tub, remove the tape you used to tack the trash bag in place and begin moving the bag so it is not covering the bottom holes. It may sag a little, but this is okay. Try and fold the sides of the bag towards the outside of the tub so they shorten in length. Remember, the water will drain down the sides, not onto the substrate.

Now that this is completed, you need to set the top tub onto the bottom tub, as seen below. To avoid knocking the top tub off the bottom, place duct tape between the lips of both tubs and seal in 4 places. If you want to be really cautious, you can seal the entire lip instead.



Place the double tub in your chosen room for incubation. A closet works very well for this, as the air does not circulate significantly, and the temps stay about the same. Ideal temps for the entire double tub grow are 68-74 degrees. Now that you have the container in your chosen room, place a black trash bag over the top of the tub so only the interior trash bag is visible. The bottom holes stuffed with poly-fill should be visible also.

The spawn needs to run for at least 5 days undisturbed. That means no peeking. After 5 days has passed, inspect your spawn by looking into the container, not opening it. If you are 100% colonized, prepare your casing mix. If you are not 100% colonized, leave the container in place and check every 2-3 days until you are complete.

Once you are complete, case the colonized substrate. I prefer the 50/50 mix. This can be found here.

It is very important to note that the tubs should only be opened to case and to harvest. There will be no misting or manually fanning. The only exception to this rule is when the double tubs are placed in a room that has stagnant air during the fruiting phase. If this is the case, you can use a personal size, oscillating fan to move air around the room. Do not point the fan directly at the tub, as you will dry out the casing and/or your growing mushrooms.

Once you have cased the substrate, it is time to incubate again for 5 days by placing back into the room where it began and placing the trash bag back on top. You will do no patching during the incubation phase for the casing. The substrate will colonize the casing layer evenly and you're ready to fruit.

You will see a bit of condensation on the sides of the container after the incubation of the casing layer. This is desired and will help in later flushes.

Depending on where you have your containers, you may need to place them in an area that has indirect sunlight. I place my tubs in my bathtub and crack my blinds. The course of the sun's natural rotation takes care of my lighting needs and affords about 12-14 hours of light. I also use a small personal size, oscillating fan in the room to move air around, but it is not required if air is coming in from an adjacent room.

At no time will you open the tubs, until the harvest. If you want to see the mushrooms growing, look through the top container. In about a week, you will start to see pins.

Once the mushrooms have completely matured and are ready for harvest, begin planning ahead. Set some time aside to complete the harvest. Have some Lysol on hand, alcohol, trays for mushroom collection, and pre-sterilized casing mix for patching. Before you remove the top tub, spray some Lysol into the air around the container and allow 5-10 minutes for everything to settle.

Spray some alcohol onto your hands and rub in thoroughly. Remove the duct tape from the lip of the two containers and have you collection tray/container ready for the mushrooms. This will be a monster flush, so try to avoid taking too much time doing the harvest. Once you have picked all of your mushrooms, grab your casing mix and lightly patch the areas you just pulled from.

Tip 3:
Avoid allowing the mushrooms to mature too much. Overly mature mushrooms will drop their spores and cause a big mess on you casing layer. You also want to keep printing in mind during your harvest planning. All mushrooms should be picked within 24 hours of each other. During the next 24 hours of the harvest, you will pick all of the mushrooms, including the aborts. Nothing will be left behind.

After you have completed the harvest and patched, place the top back onto the bottom container and seal with duct tape again. Very important: Do not mist the casing after you have patched or you will disturb the environment.

There it is. Eatualive's Double Tub tek revisited. I have made some modifications to this tek, namely the sealing of the tubs, details on hole placement, recommendations for temperatures, and tips to avoid trouble along the way.

Additional photos will follow as things progress so there is no confusion.

Thank you.

Carlito

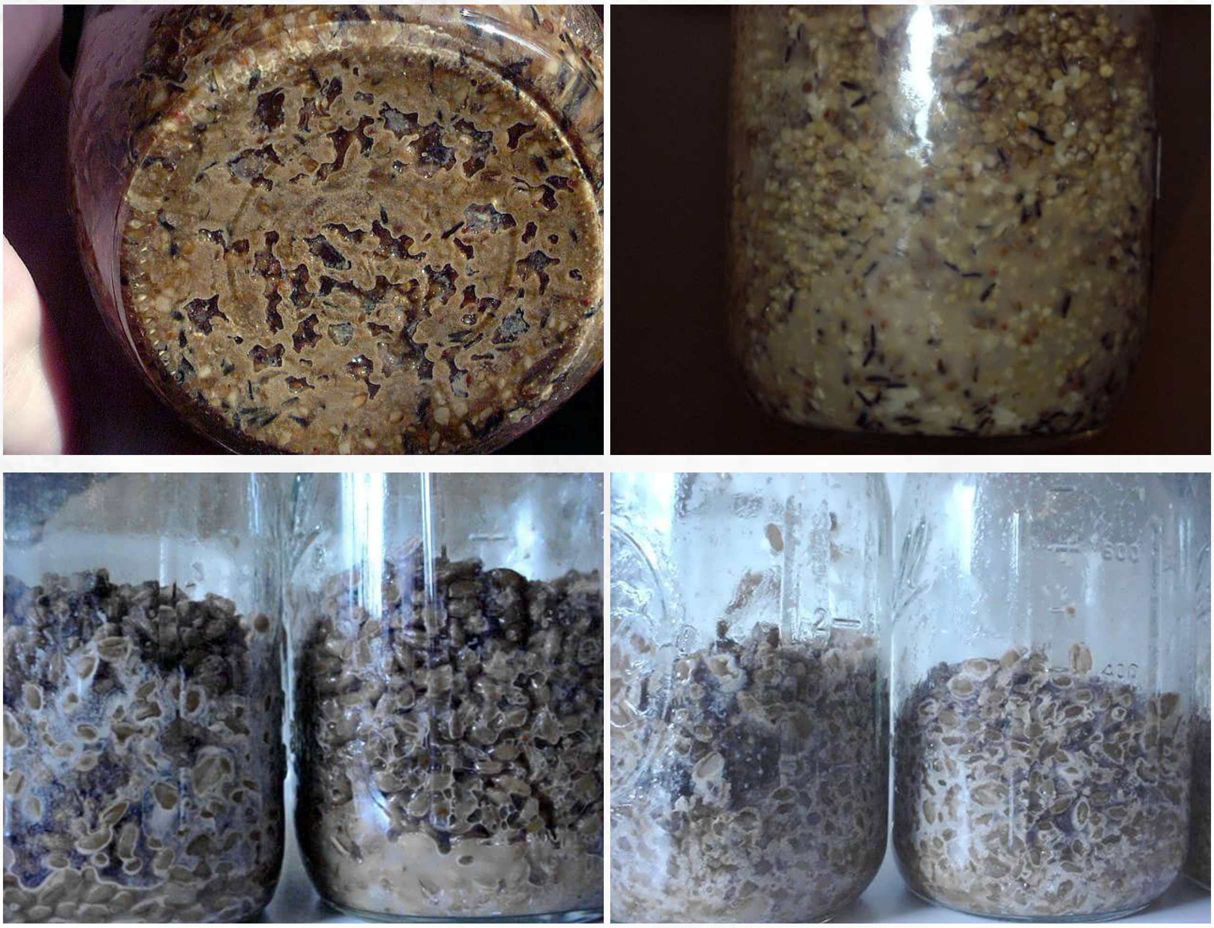
What are common contaminants of the mushroom culture?

original source: http://www.shroomery.org/5276/What-are-common-contaminants-of-the-mushroom-culture

Most specialty mushrooms are grown on sterilized substrates, and once a contaminant gets a foothold, it flourishes in the absence of competition from other contaminants. In nature, complex interactions among hundreds of other fungi, bacteria, nematodes, etc. maintain an ecological equilibrium. In a sterilized medium, the grower provides ideal conditions for the contaminant to prosper. In sawdust bags, contamination usually involves another fungus living off the waste products or on the remains of the cultivated fungus, or sometimes on the living mycelium or fruiting body of the cultivated fungus. The only competition for these contaminants is the cultivated fungus itself.

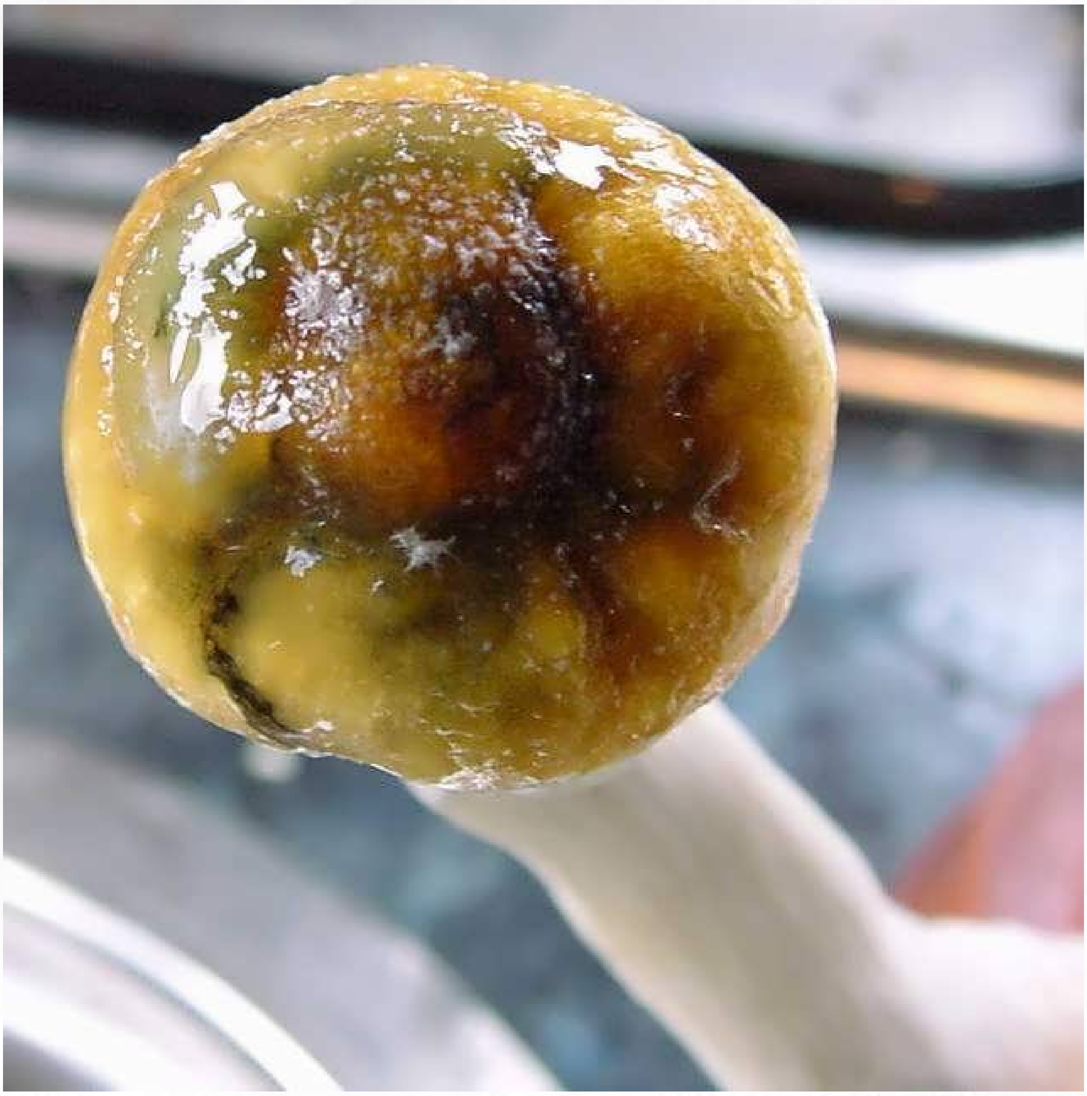
Wet Spot, Sour Rot - *Bacillus sp*

In grain spawn jars, one commonly encounters *Bacillus*, which sometimes survives the sterilization process as heat resistant endospores. A dull gray to mucus-like brownish slime characterized by a strong but foul odor variously described as smelling like rotting apples, dirty socks or burnt bacon. *Bacillus* makes uncolonized grain appear excessively wet, hence the name "Wet Spot". Pallid to whitish ridges along the margins of individual grain kernels characterize this contaminant. *Bacillus* primarily reproduces through simple cell division. In times of adverse environmental conditions, especially heat, a single hardened spore forms within each parent cell body - bacterial endospores, which can survive high temperatures for prolonged time.
The most practical method for eliminating bacterial endospores involves soaking the grain at room temperature 12 - 24 hours prior to sterilization. Endospores, if viable, will germinate within that time frame and then be susceptible to standard sterilization procedures. And, new endospores won't form in the moist environment of the resting jar of grain.



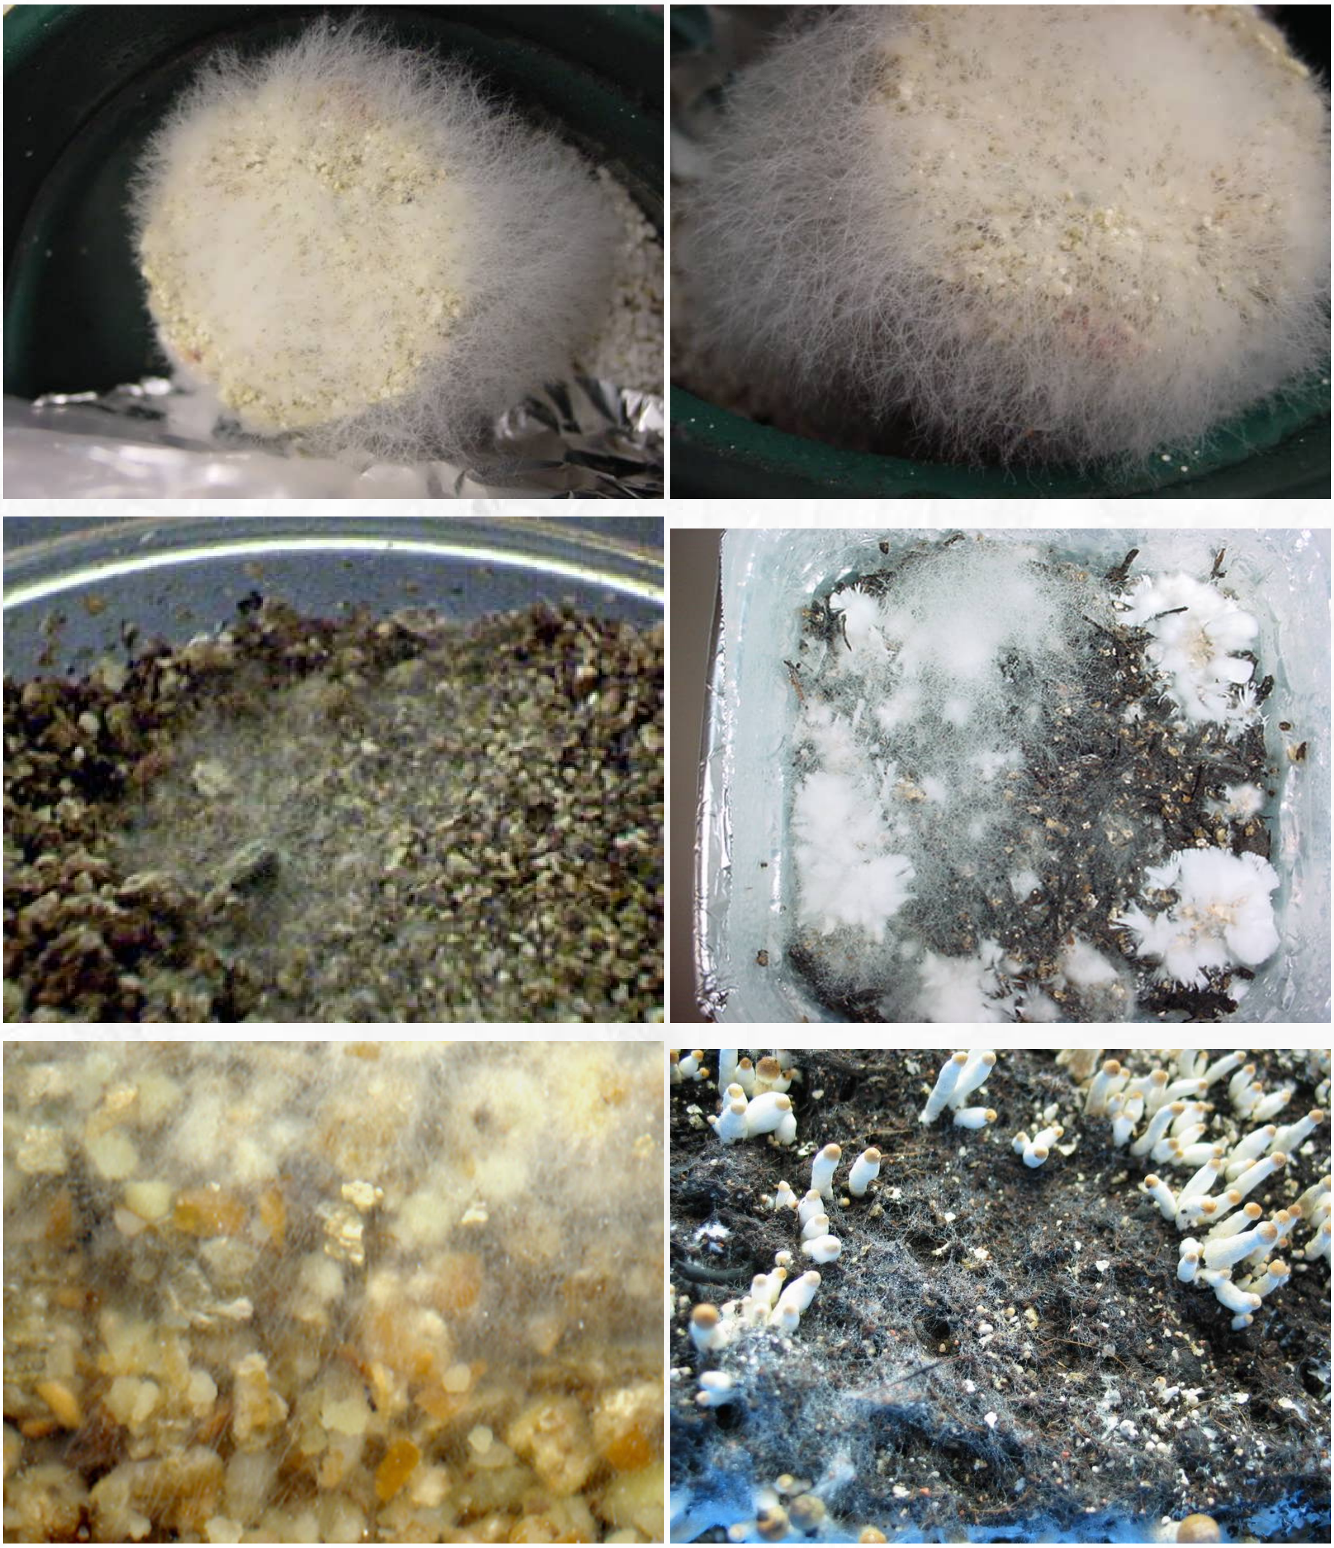
Bacterial Blotch - *Pseudomonas tolaasii (P. fluorescens)*

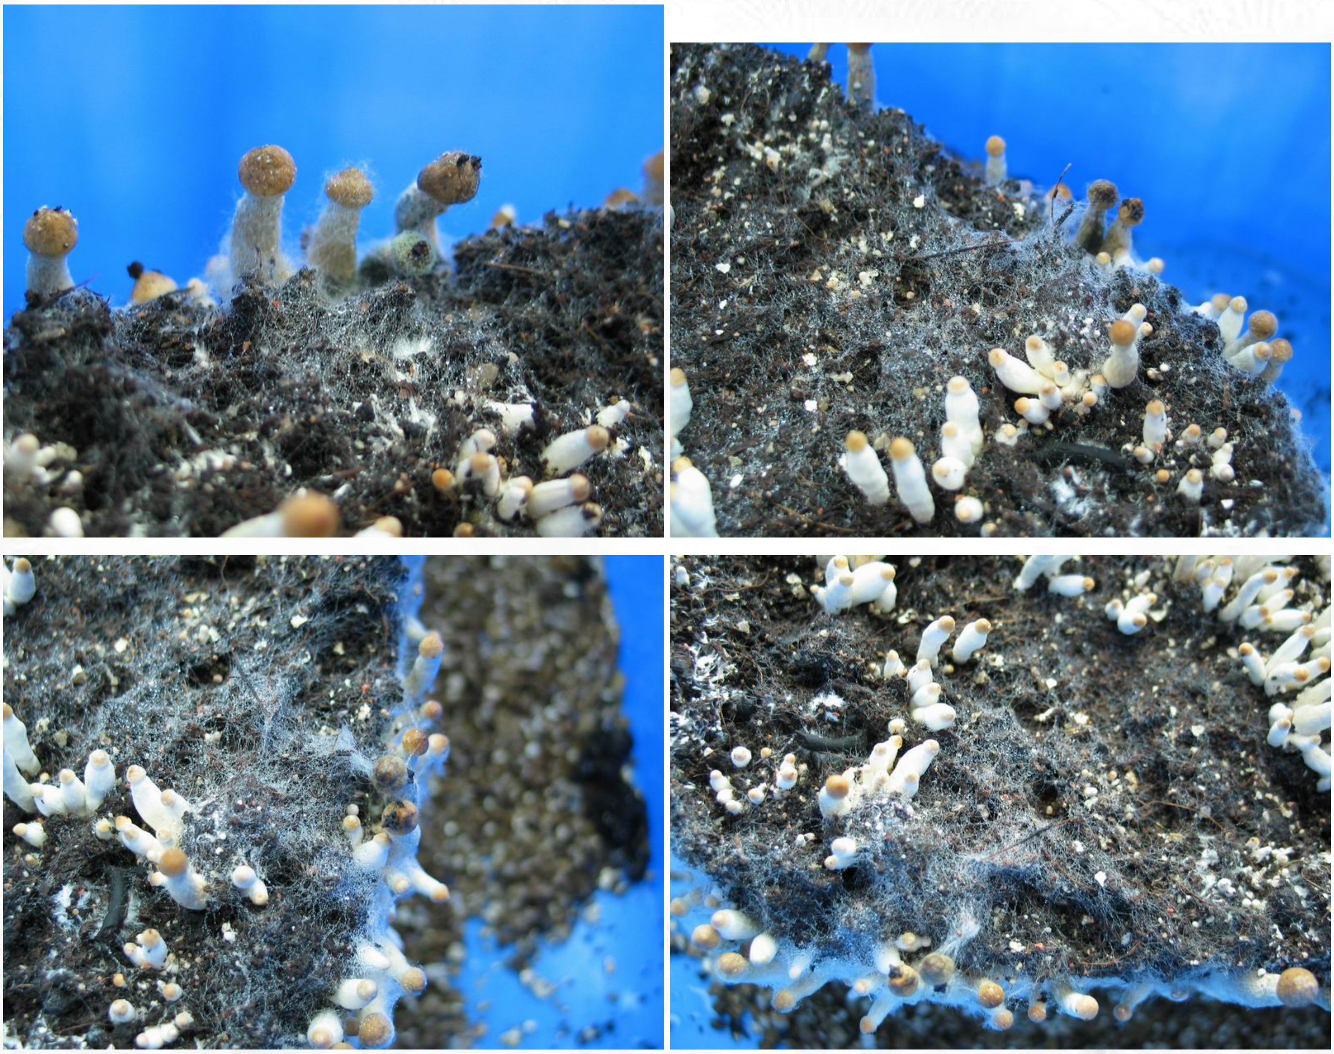
Yellow to brown lesions form on mushrooms. Typically, spotting occurs at or near the edge of mushroom caps. Blotch occurs when mushrooms remain wet for a period of 4 to 6 hours or longer after water has been applied. The bacterium is spread in air-borne soil particles. Controls include lowering humidity and watering with a 150 ppm chlorine solution (calcium hypochlorite products are used since sodium hypochlorite products may burn caps). If the mushroom stays wet, however, chlorine has little effect since the bacterial population reproduces at a rate that neutralizes the effect of the oxidizing agent. Shiitake caps are affected by a bacterial disease caused by *Pseudomonas gladioli* (*Burkholderia gladioli*). Sanitation is a critical component of control measures.



Cobweb mold or Dactylium Mildew - (*Hypomyces sp.*)

A cottony mycelium grows over casing. When it contacts a mushroom, the mycelium soon envelopes the mushroom with a soft mildewy mycelium and causes a soft rot. It is also a parasite of wild mushrooms.
Cobweb mold is darker than mycelium... almost grey as compared to white. The difference in color is sometimes hard to tell for somebody that hasn't seen them side by side before. Cobweb has several other indicators... the one that sticks out is the speed of growth. A small patch the size of a dime will spread to cover an entire jar/casing in just a day or two. Cobweb is also very very fine strands, while mycelium tends to be thicker ropes.
Cobweb mold is favored by high humidity. Control strategies include lowering humidity and /or increasing air circulation.





Green Mold - *Trichoderma harzianum, T. viride, T. koningii*

Green mold caused by *Trichoderma harzianum* is characterized by an aggressive, white mycelium that grows over the casing and onto mushrooms, causing a soft decay. Masses of spores that eventually form are emerald green. Heavily infested patches of compost are barren. This is currently the most important disease in the U.S. Agaricus industry. Many farms spread salt on the compost in affected areas when green mold is first recognized. Strict sanitation is essential. Shelving, trays, walls, floors, etc. may be surface disinfected as a matter of routine, but it is done with a sense of urgency following an outbreak of a disease. Many commercial products are available for cleaning surfaces. The base ingredients in these materials include chlorine, iodine, phenol, or quaternary ammonium, among others. Surface disinfectants are used farm-wide, from equipment sanitation to room washdowns to foot-dip solutions to picking basket pre-wash. Other Green Molds may be better defined as indicators since they don't seem to be as aggressive as *T. harzianum*. These species of *Trichoderma* also sporulate on the casing surface and may sporulate on infected mushrooms. These fungi indicate that carbohydrates are available, possibly due to inadequate nitrogen supplementation during Phase I or undercomposting. *T. viride* reportedly produce toxins that dissolve mushroom cells walls. A wet compost low in ammonia prior to pasteurization, flies, poor sanitation, anaerobiosis, and other factors influence green mold. These fungi are common in sawdust and commonly occur in the production of specialty mushrooms.
Trichoderma is often mistaken for Penicillium or Aspergillus molds (and vice versa), being that all three look very similar and are not easy to tell apart without the use of a microscope.
Some pictures underneath possibly show any of the three genuses out of the aforementioned reason.

More:

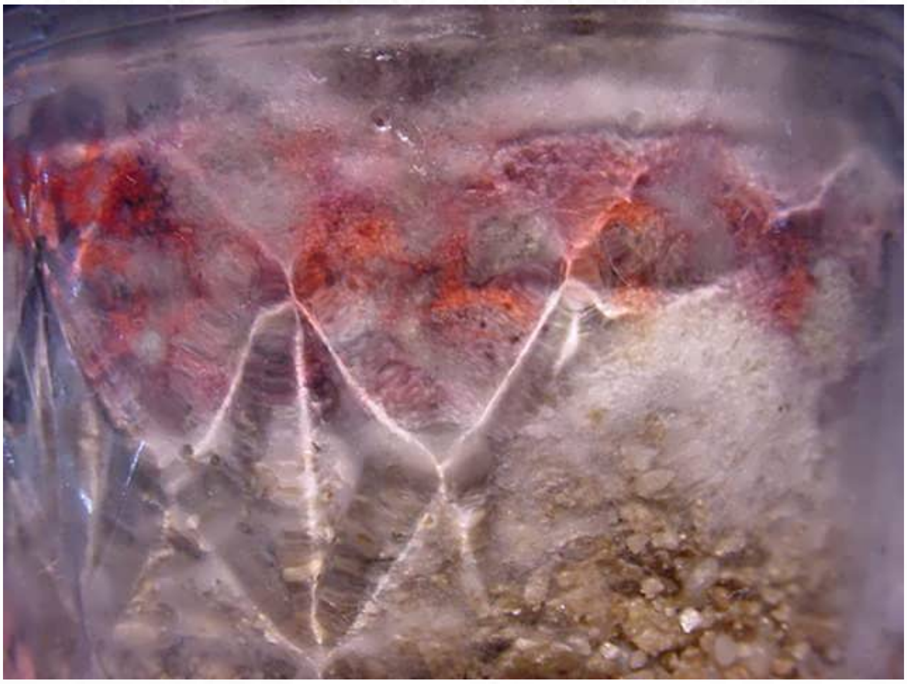
http://www.ppath.cas.psu.edu/MushGrowInfo/Trichoderma%20Green%20Mold.html

Cinnamon Brown Mold - *Chromelosporium fulva (Peziza ostrachoderma)*

The color of this mold ranges from yellow gold to golden brown to cinnamon brown. It grows rapidly in circular patches. It is very common in soil, and flourishes on damp wood. Areas in compost overheated during spawn run may be colonized. Improperly conditioned compost will also support growth, but it is most commonly known as a re-colonizer of overly pasteurized casing, possibly living on dead microorganisms. It often occurs on sterilized soil. Sexual fruiting bodies may appear several weeks after the first appearance of the mold. Spores are airborne.

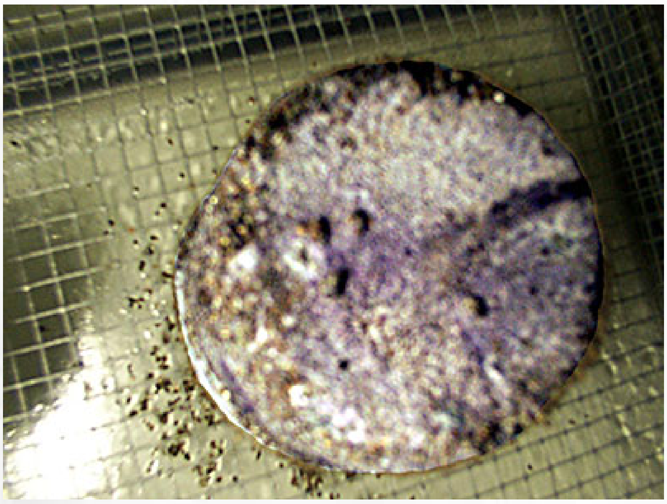
Lipstick Mold - *Sporendonema purpurescens (Geotrichum candidium)*

This fungus colonizes compost or casing. As spores mature, the color of the mold changes from white to pink, to cherry red, and finally to dull orange. It is slow growing. Spores spread in air, during watering, and on pickers. The lipstick mold utilizes certain fats in the compost. It is an uncommon problem. Control is centered around sanitation.



Pink Mold, Red Bread Mold - *Neurospora*

Commonly to occasionally seen on agar and grain. *Neurospora* is fast growing, sometimes taking only 24 four hours to totally colonize a media filled Petri dish. It is ubiquitous in nature, occurring on dung, in soils and on decaying plant matter. Since this fungus grows through cotton stoppers or filter discs, a single contaminated jar, though sealed, can spread spores to adjacent spawn jars within the laboratory. This condition is more likely if the filter discs or cotton plugs are the least bit damp; or if the external humidity is high. Furthermore, *Neurospora* spores germinate more readily at elevated temperatures. The pink mold seen in mushroom culture is most frequently *Neurospora sitophila*, a pernicious contaminant that is difficult to eliminate. All infected cultures should be removed as soon as possible from the laboratory and destroyed. A thorough cleaning of the laboratory is absolutely necessary. If contamination persists, remove all spawn and start anew.



Sepedonium Yellow Mold - *Sepedonium spp.*

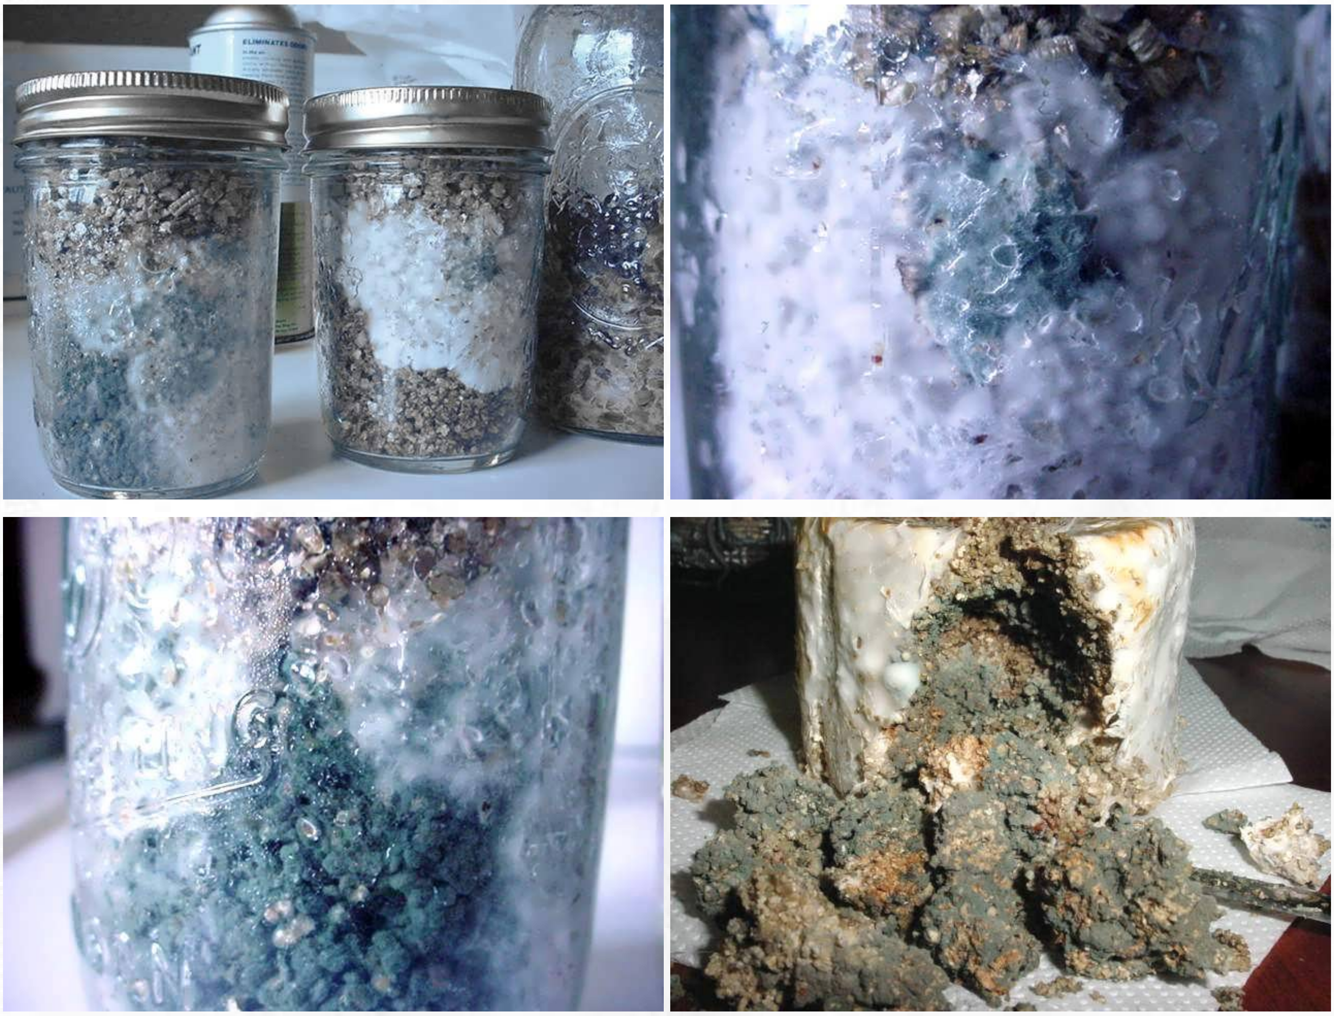
This white, sparse mold grows in the compost during spawn run. With age, it turns dull yellow to tan. Spores are airborne. Thick-walled spores may survive peak heat. The mold colonizes compost considered ideal for spawn growth.

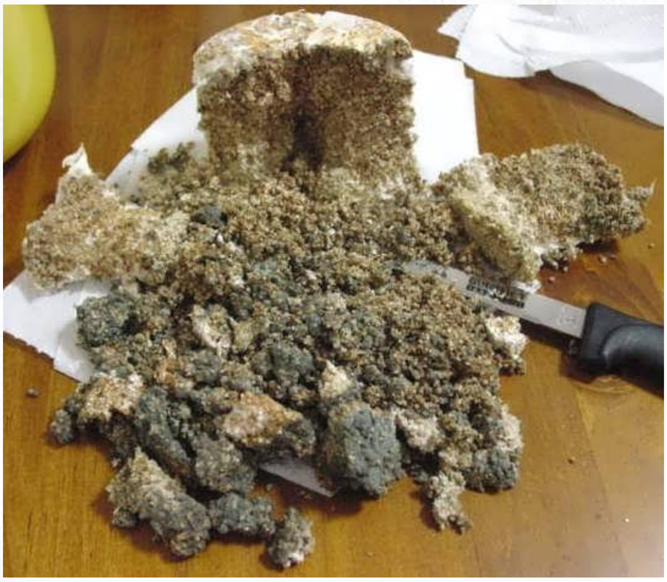
Black Whisker Mold - *Doratomyces spp.*

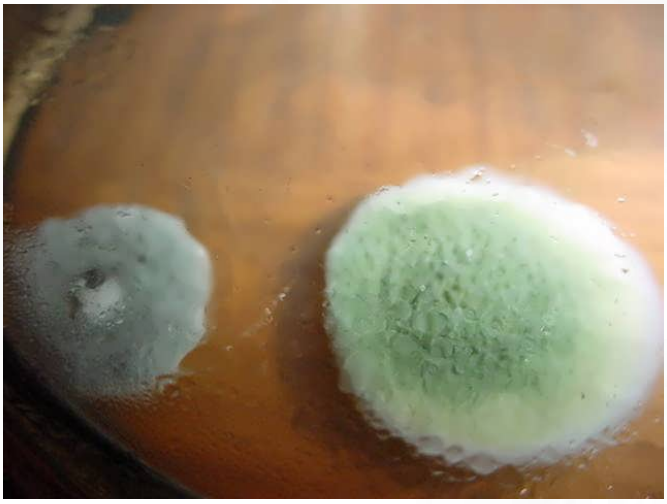
This fungus produces black powdery spores that appear as smoke when disturbed. This mold indicates the presence of certain carbohydrates in the compost at spawning time. It also indicates that the straw has been incompletely caramelized or underheated in Phase I (therefore, carbohydrates are in a form easily utilized). The proportion of carbohydrates, particularly cellulose, may be too high. The black whisker mold is also present in compost that overheated during spawn run. Simple carbohydrates are utilized by this fungus but it can also utilize lignin. *Doratomyces*, *Aspergillus*, and *Penicillium* produce copious numbers of spores and may cause respiratory problems (nasal and throat irritation, chest congestion, breathing difficulty, etc.).

Blue-green Molds - *Penicillium spp.*

Abundant blue-green spores are produced on the surface of the substrate. Similar to Aspergillus. Favorable conditions parallel those for the black whisker mold. *Penicillium spp*. utilize simple carbohydrates, as well as cellulose, starch, fat, and lignin. These fungi are very common on specialty mushrooms and are one of the chief concerns in agar and grain culture. Spores are airborne and ubiquitous.







Black Mold (also Yellow Mold and others) - *Aspergillus sp.*

Very common in agar and grain culture, and in compost making. Found on most any organic substrate, *Aspergillus* prefers a near neutral to slightly basic pH. Well used wooden trays and shelves for holding compost are frequent habitats for this contaminant in the growing house. Species range in color from yellow to green to black. Most frequently, *Aspergillus* species are greenish and similar to *Penicillium*.

Aspergillus niger, as its name implies, is black; *Aspergillus flavus* is yellow; *Aspergillus clavatus* is blue-green; *Aspergillus fumigatus* is grayish green; and *Aspergillus veriscolor* exhibits a variety of colors (greenish to pinkish to yellowish). These molds, like many others, change in color and appearance according to the medium on which they occur. Several species are thermophilic.

Some *Aspergillus* species are toxic. *Aspergillus flavus*, a yellow to yellowish green species, produces the deadly aflatoxins. *A. flavus* attacks cottonseed meals, peanuts and other seeds high in oil that have been stored in hot, damp environments. Of all the biologically produced toxins, the aflatoxins are the most potent hepatocarcinogens yet found. The toxicity of this species was largely unknown until, in 1960, 100,000 turkeys mysteriously died from an outbreak of this disease in Great Britain.

Since *A. flavus* grows on practically all types of grain, this species is of serious concern to mushroom spawn producers. Careful handling of any molds, particularly those of the genus *Aspergillus*, should be a primary responsibility of all managers and workers in mushroom farms.

Aspergillus fumigatus and *Aspergillus niger*, two thermotolerant mesophiles, are also pathogenic to humans in concentrated quantities. The affliction is called aspergilliosis or "Mushroom Worker's Lung Disease". Spent compost is the most frequent source of *Aspergillus fumigatus*.

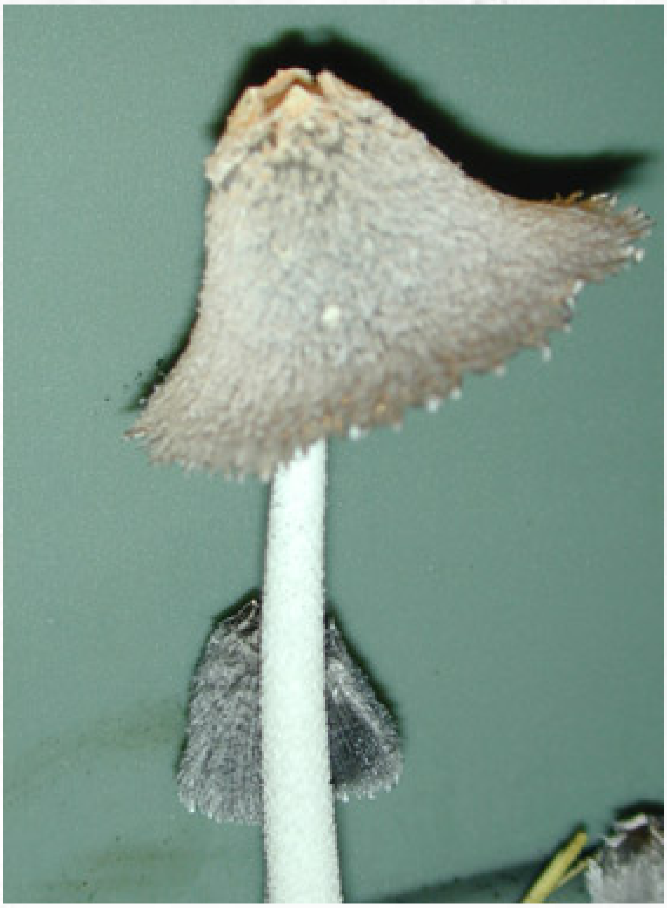
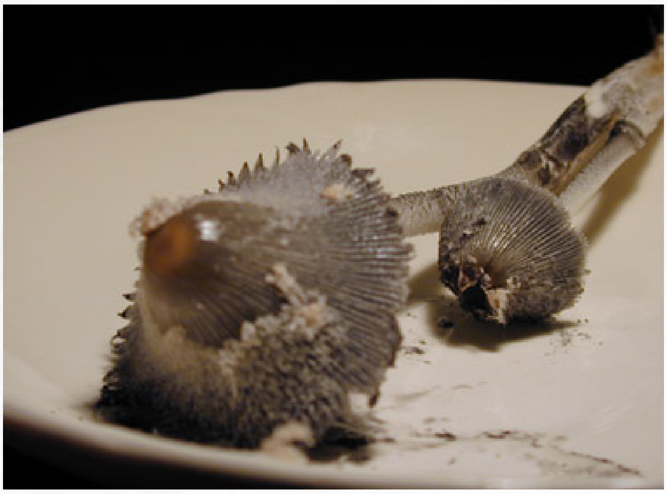
Inky Cap - *Coprinus spp.*

These are evidence of free ammonia in the compost. Ammonia seems to be a nitrogen source. Their delicate gray caps autodigest quickly. Inky caps are indicators of nitrogen over-supplementation or a poorly managed Phase II compost. If there is too much residual ammonia, Phase II thermophilic microflora may be unable to convert all the ammonia into microbial protein. In addition, areas in the compost that did not remain within the range of 115 to 135 F from 72 to 96 hours after pasteurization may contain residual ammonia. This fungus is strongly cellulolytic.





Oedocephalum (Brown) Mold - *Oedocephalum spp.*

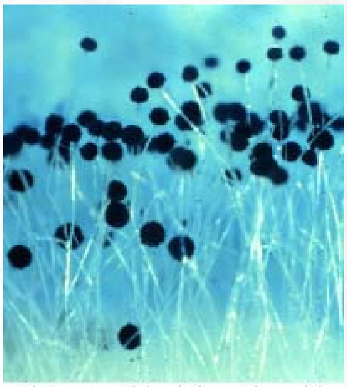
This mold makes light gray growth on compost surface, later becoming brown as the spores mature. It forms erect spore-bearing structures with spherical clusters of large spores at its top end. This mold indicates that ammonia and amines were not completely eliminated during Phase II (which might be the case when carbon sources are limiting and nitrogen can't all be converted into microbial protein). Its ecology is similar to *Coprinus*, and often occurs with it.

Olive Green Mold - *Chaetomium spp.*

Fruiting structures of this mold look like olive-green cockleburs - 1/16 inch in diameter - that develop on compost. Although its heat tolerant spores survive 140 F for 6 hours, the mold appears only in compost improperly managed during Phase II, especially where Phase II ventilation is inadequate. Lack of oxygen when compost temperatures are greater than 142 F permits formation of compounds produced in anaerobic conditions. These compounds are toxic to spawn growth but are utilized by the olive green mold. It is highly cellulolytic.

Pin Molds - *Rhizopus spp.*

A very fast growing fungus. Once it sporulates, it forms many tall aerial hyphae adorned with black-headed pins. It grows on readily available carbohydrates. Along with *Aspergillus* and *Penicillium*, species of this genus are the primary contaminants of grain spawn. It is also very common on straw.



Rhizopus -black bread mold

Plaster Molds and Flour Molds - *Papulaspora byssina, Thielavia thermophila, Botryotrichum piluiliferum, Trichothecium spp.*, and others

These molds develop when nitrogen sources (ammonical compounds and amines) from Phase I are not completely utilized by the microbes during Phase II and when the nitrogen is not converted into microbial protein. They are often seen in raw compost. Aerial hyphae aggregate on compost surface, resembling plaster of paris. White plaster mold (*Botryotrichum piluiliferum*) forms dense white colonies. *T. thermophila* is thermophilic (unique among the indicator molds), and may grow rapidly during the last days of Phase II. It indicates hot spots during spawn run, inhibiting spawn growth (resulting in black areas). Brown plaster mold (*Papulaspora byssina*) forms dense brown colonies on compost.

La France Disease - an isometric virus

Symptoms of this disease include a degeneration of the mycelium, suppression of fruiting, and rapid dying of mushrooms. In time, the mushroom mycelium disappears. Infected mushrooms are off-white and drum-stick shaped. Other fruitbody symptoms include dwarfing, premature opening of veil, development of an elongated spindly stem with a small cap, formation of a thickened stem with a thin flat cap, and malformed or absent gills. Mushrooms should be picked before the veil opens since spores may carry virus particles (75% infection rate of spores from infected mushrooms). Pasteurization of wood after the compost has been removed is essential. Initial sources include infected spores or mycelium in or on wood, compost, casing, people, and equipment. Wood should be cleaned, disinfected, and steamed. The virus may enter a mushroom farm from neighboring farms and from wild mushrooms. Controls include pasteurization (145 F for 6 or more hours) of compost, spawn, equipment and empty rooms), cleaning HEPA filters, and general sanitation. In 1962, Hollings first identified viruses in mushrooms, also the first report that fungi had viruses. Another virus with a lipid membrane is found in all hybrid spawn; its effect is unknown. PCR is now used by makers of spawn for early detection of viruses. An outbreak of viruses on a farm can be devastating.

More:
http://www.hri.ac.uk/isms/article4.htm

Mummy Disease - *Pseudomonas aeruginosa*

Symptoms of infected Button mushrooms include curved stems surrounded at the base by an overgrowth of mycelium. Internally, stems have water-soaked, longitudinal streaks. Caps are tilted and dwarf. Tissues become spongy and dry (mummified). Sanitation and reducing free water are control measures.

Pseudomonas aeruginosa colonies on agar

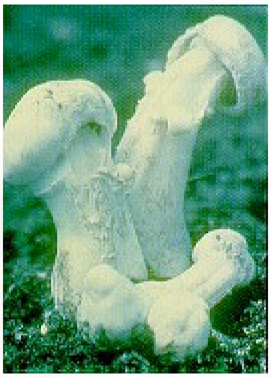
http://www.shroomery.org/index.php/par/26841

Wet Bubble - *Mycogone perniciosa*

Symptoms include malformed mushrooms with swollen stipes and reduced or deformed caps. Undifferentiated tissue becomes necrotic and a wet, soft rot with an offensive odor may follow. An amber liquid appears on infected mushrooms. Mushrooms become brown in color. Bubbles may be as large as a grapefruit. The fungus is spread via airborne dust and contaminated casing. It is also a parasite of wild mushrooms. Controls include sanitation and in some countries the use of the compound Sporogone, which is also very effective against Verticillium. Wet bubble is the most important Button mushroom disease in China.

Dry Bubble - *Verticillium*

This disease is caused by Verticillium, a species which produces sticky spores.
The symptoms produced vary with the developmental stage of the mushroom at the time of infection. 'Early' infection at pin head formation results in the production of malformed pin heads, which turn a grey/brown colour and remain leathery. Infection at a later stage causes a thickening of the stipe especially at the base, and also a crooked mushroom with a tilted cap and backward peeling stalk. Cap infection can occur at a very late stage in the development of the mushroom, resulting in circular superficial spots, initially pale brown in colour which become grey with age.



Verticillium sp. commonly occur in the soil which may be a primary source of the infection, however, it is more likely that they come with casing or by transfer of infection from house to house by pickers, flies or machinery. Spores can lie dormant until they come into contact with mushroom mycelium which stimulates them to grow. Because the spores are sticky the disease is spread on dust particles from the movement of earth or spent compost. This dust can contaminate fresh casing, or can enter through fans or doorways or be carried in by flies, pickers or even mites. The disease within the production house can be spread by water splash. The spores can also be spread on any other equipment used in an infected growing house. Appearance of the disease at pin head formation signifies infection at an early stage of development, probably at the time of casing. Development of the disease at later stages of the production cycle usually indicates infection has occurred from other cropping houses or from outside sources. Spread by water, flies and pickers can result in 30% of the crop being infected at the third flush and by the last flush virtually all of the crop. The highest standards of hygiene are essential for the control of Verticillium. Other methods of control are as follows:

Control:
1. Avoid soil movement near mushroom houses especially on windy days. Take measures to avoid the accumulation of dust in the vicinity of mushroom houses and also dust movement into the vicinity of mushroom houses.
2. It is essential to control flies and every effort should be made to prevent their entry into cropping houses.
3. As diseased mushrooms appear they should be removed from the beds using a cloth or sponge soaked in disinfectant and then placed in a bucket containing disinfectant.
4. Table salt on top of tissue paper can be used to contain disease.

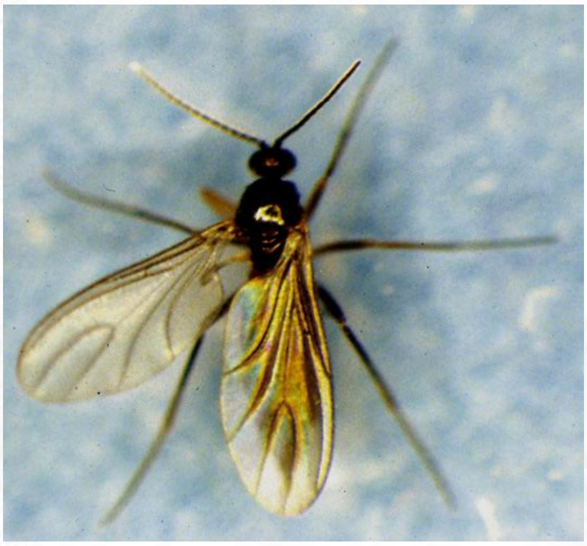
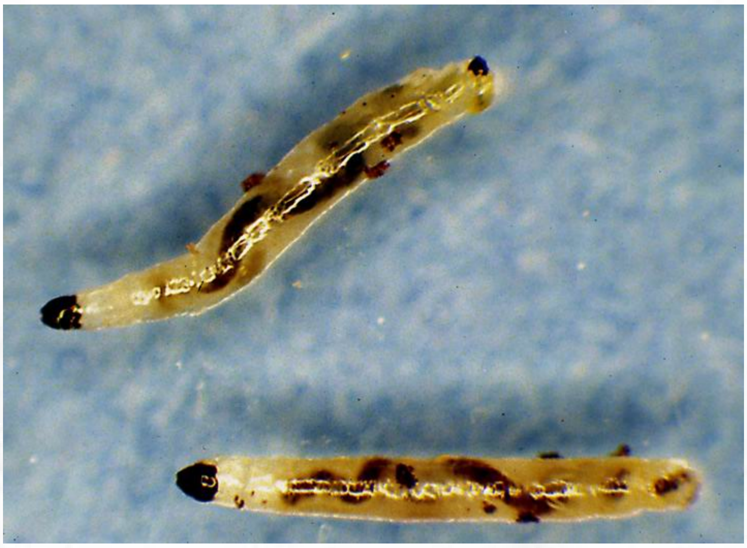
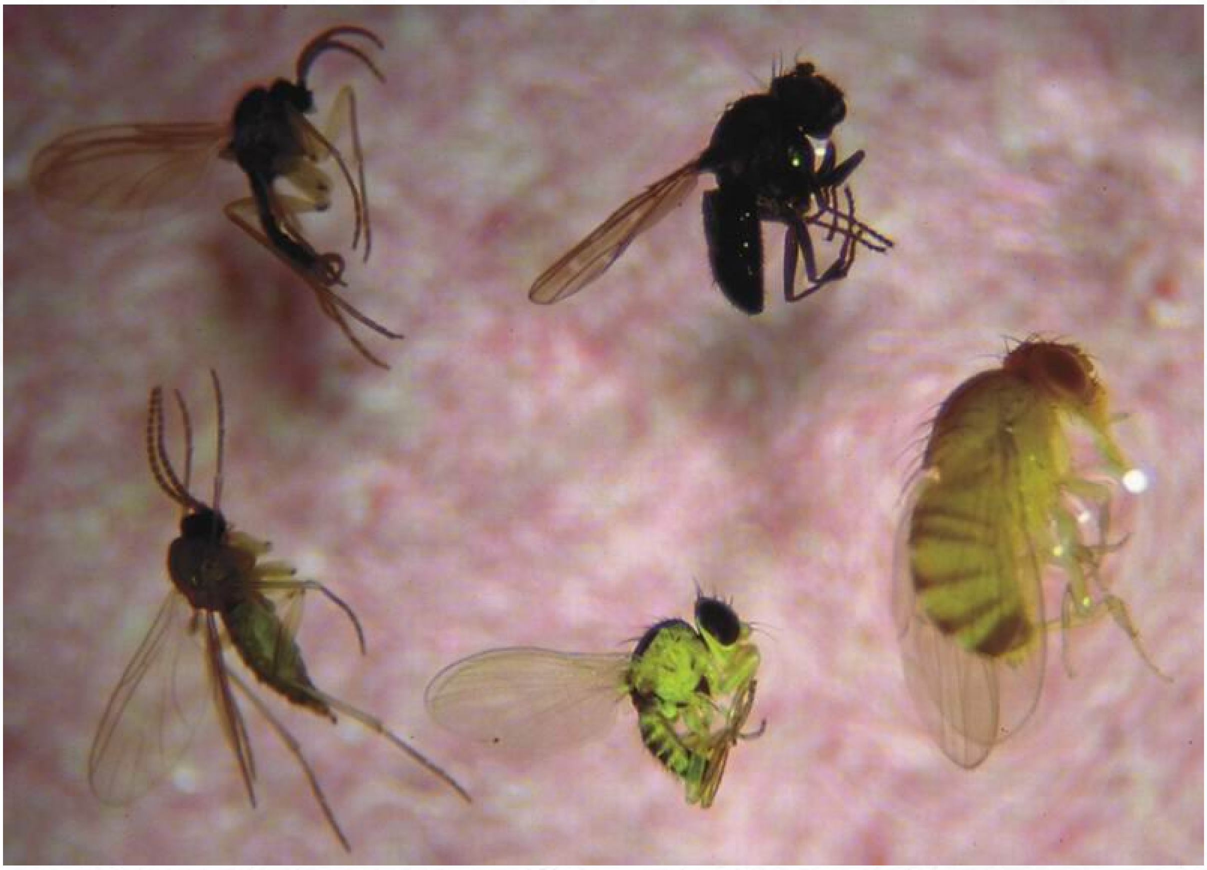
Fungus gnats (Sciarids) - (*Lycoriella spp.*) and phorids (*Megaselia spp.*)

Adults are small (1/8 inch long), fragile grayish to black flies with long, slender legs and thread-like antennae. Their wings are clear or smoky-colored with no pattern and few distinct veins. Larvae are clear to creamy-white and can grow to about 1/4 inch long. They have shiny black head capsules.
They are attracted to the mushroom crop and their larvae feed directly on mycelium, swarm over the mushroom, and tunnel into the developing or developed mushroom. Tissues that have been physically damaged by flies often become colonized by bacteria which cause soft rot, thereby accentuating the problem. Controls include strict sanitation and general farm hygiene. For example, the grow room must be air tight. Fresh air that is used is filtered. Even a small crack will serve as an entry for the flies. Most farms use sticky tape or some other method that allows monitoring of populations. A biocontrol using nematodes offers effective control when populations of flies are low. In addition to the damage which fly larvae cause by eating mushroom mycelium or killing pins, the adults also carry diseases such as Verticillium, Mycogone and Cobweb.







Mites

Many mites are commonly found in straw and manure, most species are beneficial to mushroom growing as they feed on eelworms and other mites, although some can cause damage.
Mites, like fly larvae, may feed on mushroom mycelium and on the mushrooms, where they can cause surface discoloration. They may also live on other fungi (weeds and indicator molds) found in mushroom culture. One example is the red pepper or pygmy mite (*Pymephorus spp*.). These mites are commonly associated with *Penicillium* and *Trichoderma* molds, upon which they feed. Pygmy mites do not feed on *Agaricus*. These mites have the ability to change into an intermediate stage called a hypopus, wherein they develop flattened bodies and a sucker plate with which they attach to moving objects, like flies. Mites at this stage swarm on top of mushrooms.

1. Tarsonemid mite

> These mites are pale brown and are so minute that they are only visible with the aid of a microscope.
> They cause damage by feeding entirely on hyphae of mushrooms and the grower will know if he has these mites present, as the base of the stem of the mushroom will show a reddish brown discolouration. Where severe infestations occur the whole base of the mushroom may be detached from the growing surface.
>
> Control
> 1. As with eelworms little can be done when mites are present in the growing house, therefore efficient composting and peak heating must take place to ensure that they are killed during the pasteurization process.
> 2. Good hygiene should be practised around the farm, especially in the clearance of crop debris.

2. Tyroglyphid mites (*Tyrophagus spp*)

> These mites can be identified as they are slow moving, translucent, with long hairs on their bodies.
>
> If these mites are present in abundance they eat small pits in the caps and stalks. These pits then suffer from bacterial decomposition, which breaks down tissues just below the surface. This results in the skin collapsing which leaves an open pit. Tyroglyphids may also feed on mushroom mycelium, where they are present in large numbers, crop reductions can be caused.
> Mites usually gain entry into the compost by clinging onto Sciarid flies when the mites are the migratory stage. These migratory stages are normally produced when mites become overcrowded.
> The mites should not be a problem where efficient composting and peak heating takes place. Organic debris should not be allowed to accumulate around the farm as it provides a breeding ground for mites.

3. Red Pepper Mites (*Pygmephorous spp*)

> These mites are not regarded as primary pests, their presence is usually an indicator that Trichoderma (green mould) is present in the compost. These mites feed on various weed moulds but not mushrooms, thus their presence indicates that the compost is unsatisfactory.
> The mites are yellowish-brown in colour, 0.25 mm in length and have a flattened appearance, they also are capable of rapid rates of reproduction.
> As already stated these mites are secondary pets and they often swarm on the casing and mushroom surfaces. Where this happens their presence makes the mushrooms unsaleable. These mites can also spread spores of Trichoderma from bag to bag.

Nematodes - *Aphlelenchoides composticola* and *Ditylenchus myceliophagus*

These nematodes are common inhabitants of most agricultural soils. Symptoms include a degeneration of mushroom mycelium and failure of mushrooms to form. Normally, an infestation is noticed at the time of third break. Mycelium in affected areas is completely destroyed and as the compost decomposes, it turns black and a medicinal odor is detectable. An effective Phase II is the primary control.

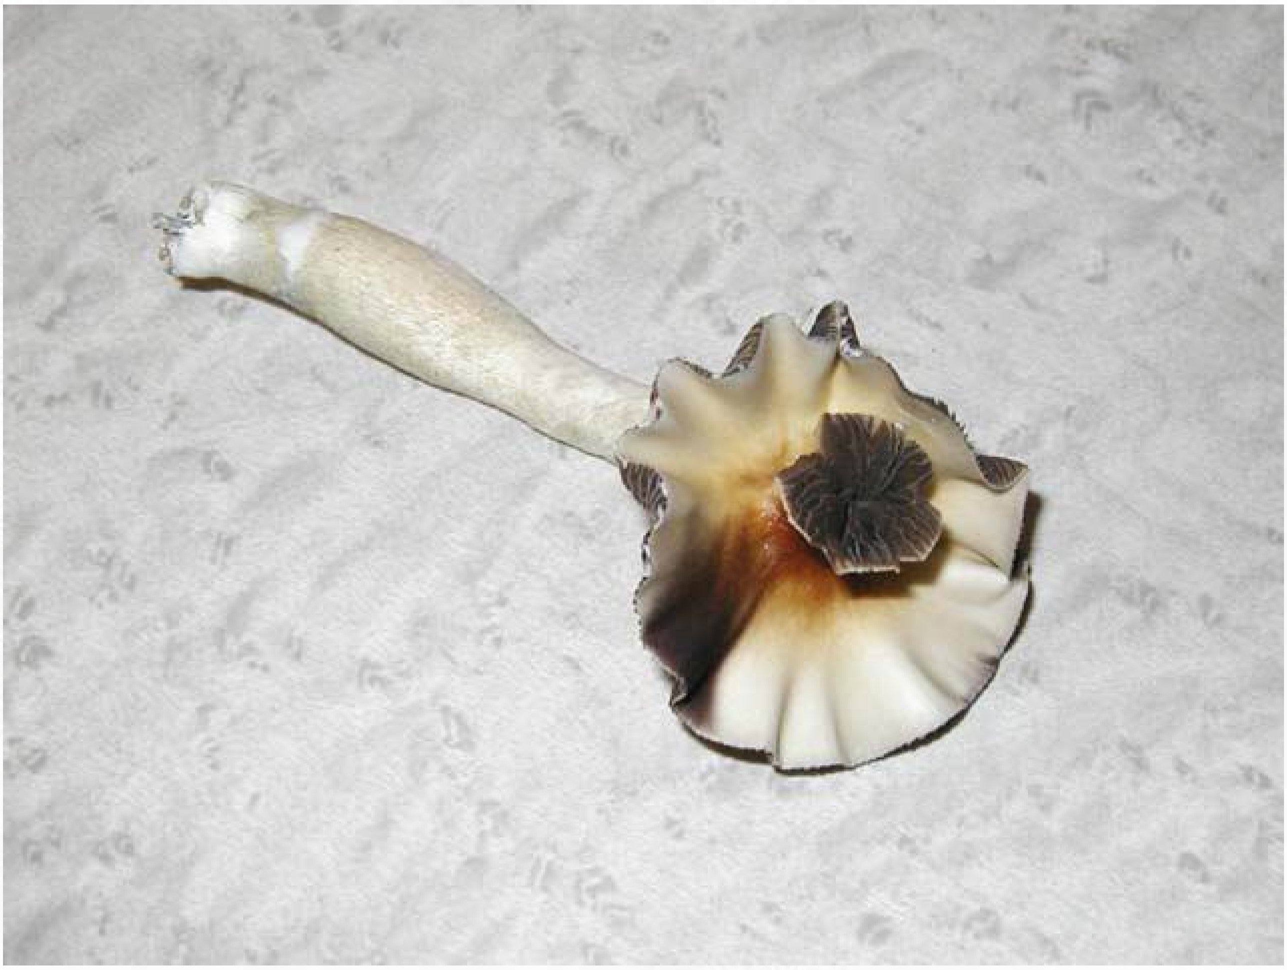
Abnormalities

Several disorders have abiotic origins. Common ones include:

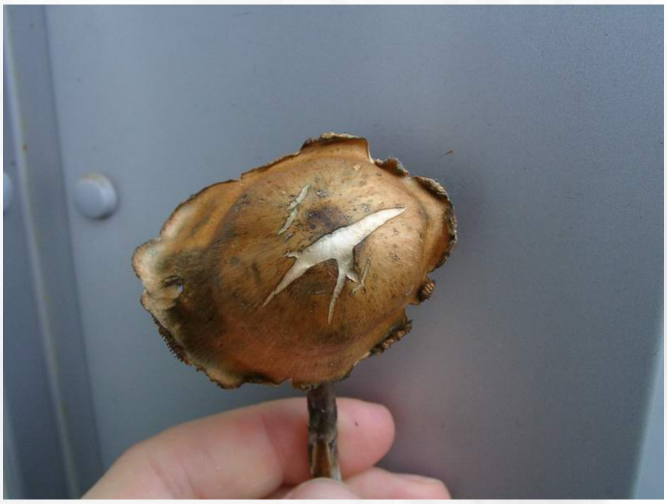
Browning - tyrosinase (phenolase) - Is the main enzyme responsible for browning in Agaricus. Calcium chloride in irrigation water decreases bruising by increasing the integrity of vacuole membranes (thus, tyrosinase is not released).

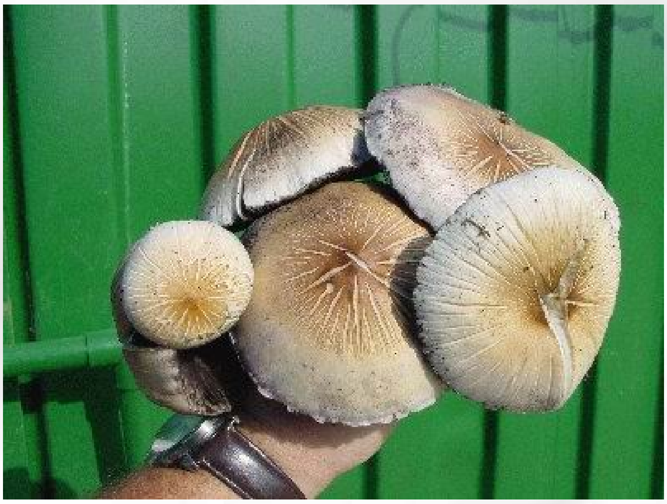
Flock, hardcap, and open veil - Physiologically induced malformation of cap and gill tissue. Cap opens prematurely. Causes include some diseases, petroleum based materials, and genetic abnormalities. Hollow core and brown pith - related to water stress, but exact factors unknown. Long stipes and small caps - insufficient light and/or fresh air.

Rosecomb - Condition where pink gill tissue, often with a porous appearance, develops on the surface of a mushroom cap. The cause has been attributed to contamination by petroleum based materials.

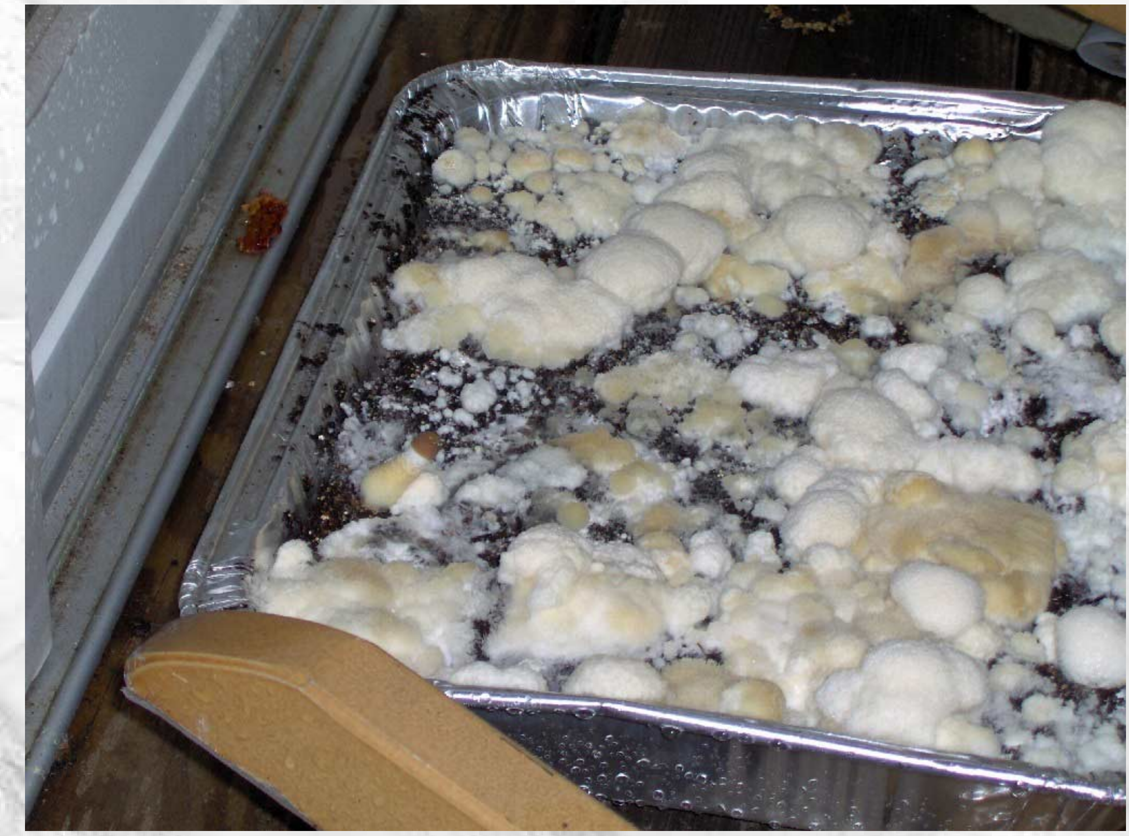


Scaling - The natural reaction of the mushroom cap to dry air.





Stroma - Dense mycelial growth without fruiting. Stroma occurs if spawn is mishandled or exposed to harmful petroleum-based fumes or chemicals. It also occurs in dry environments.



Weepers - Mushroom exudes water from cap. The cause is not known, but it is seen in low-moisture compost and high-moisture casing.

BIBLIOGRAPHY

MOULDS AND THEIR CHARACTERISTICS

Moulds, those dusty little spots often found spreading over bread, cheese, books, and other things in the home, cause the loss of millions of dollars to our economy every year and, even worse, may be a menace to your health. To deal with them successfully we must understand what moulds are and exactly what they are doing.

Moulds are microscopic, plant-like organisms, composed of long filaments called *hyphae*. Mould hyphae grow over the surface and inside nearly all substances of plant or animal origin. Because of their filamentous construction and consistent lack of chlorophyll they are considered by most biologists to be separate from the plant kingdom and members of the kingdom of fungi. They are related to the familiar mushrooms and toadstools,differing only in not having their filaments united into large fruiting structures. For our purposes here, we shall consider as moulds only fungi that are commonly encountered n the home and laboratory and that can be easily grown and studied.

When mould hyphae are numerous enough to be seen by the naked eye they form a cottony mass called a *mycelium*. It is the hyphae and resulting mycelia that invade things in our homes and cause them to decay.

Moulds reproduce by *spores*. Spores are like seeds; they germinate to produce a new mould colony when they land in a suitable place. Unlike seeds, they are very simple in structure and never contain an embryo or any sort of preformed offspring. Spores are produced in a variety of ways and occur in a bewildering array of shapes and sizes. In spite of this diversity, spores are quite constant in shape, size, colour and form for any given mould, and are thus very useful for mould identification.

The most basic difference between spores lies in their method of initiation, which can be either sexual or asexual. Sexually initiated spores result from a mating between two different organisms or hyphae, whereas asexual spores result from a simple internal division or external modification of an individual hypha. the recognition of a mating and subsequent spore formation is often difficult for an observer,and is usually reserved for patient specialists. However, for practical purposes one can learn to recognize certain indications of the sexual process, namely, the four kinds of sexually determined spores that appear in mould fungi: (1) oospores, (2) zygospores, (3) ascospores, and (4) basidiospores.

Oospores (Figure 1) are produced when male gametes (reproductive nuclei)enter a large spherical cell (*oogonium*) and fertilize the eggs within. The result, as seen in routine examination, is numerous oogonia containing one to several spherical and often brownish eggs. The oogonia are usually penetrated by one or more hyphae (*antheridia*) that give rise to the male nuclei.

Zygospores (Figure 2 and zygospore illustration) do not occur inside any kind of enclosing structure, but are produced by the direct fusion of two hyphal protrusions (*suspensors*) from neighbouring filaments. Usually zygospores are recognized as large,nearly spherical, often dark brown or black, rough-walled spores with two connecting hyphae, representing the two mating gametangia (figure 2C). Sometimes the zygospore may be surrounded by several finger-like extensions from the two gametangia.

Ascospores (Figure 3) are produced within spherical to cylindrical cells called *asci*, most often in groups of four or eight (figure 3A). Usually the asci are produced within some kind of enclosing structure and thus are not found exposed on the hyphae. In a few cases the asci may be borne among hyphae and resemble oogonia with eggs, but they will never be penetrated by any sort of fertilizing hypha. Fertilization occurs early in the life cycle and is not evident at the time ascospores are produced.

Basidiospores (Figure 4) are always produced externally on a structure called a *basidium*. Basidia come in a variety of forms, but those commonly encountered on moulds will be club-shaped and bear four or eight spores on sharp projections at the apex. At first it may be difficult to distinguish between a basidiospores and one of the asexually initiated spore types, but one should always suspect the presence of basidia when externally produced spores consistently occur in groups fo four or eight (figure 4). As with ascospores, basidiospores are the result of an early fertilization that is not easily observed.

Asexual spores usually occur either in sporangia or as conidia. *Sporangia* are modified hyphae or cells containing numerous spores (*sporangiospores*). They never have more than a single connecting hypha and the spores do not constantly occur in groups of four or eight as do ascospores.

Conidia are the most difficult group to characterize because of their great diversity of form. The only feature that most conidia have in common is that they occur externally on the cells that produce them. These conidium-bearing (*conidiogenous*) cells may occur within rather specialized or characteristic structures that resemble those that frequently bear asci, however, and it is often necessary to break them open to confirm that the spores are truly conidia and not ascospores. Conidia that are borne on the hyphae, without any kind of compound fruiting structure, are the most commonly encountered type. Structures that completely enclose the conidium-bearing cells are called *pycnidia*, and those resulting from a fusion of conidium-bearing cells are called *synnemata* if they are longer than they are broad or *sporodochia* if broader than long.

HOW MOULDS ARE CLASSIFIED

Strictly speaking, all fungi should be classified according to their method of sexual reproduction. In many cases this is possible, allowing us to recognize several groups of fungi. Fungi that are encountered most often or exclusively in the asexual condition create special problems and are discussed separately as *anamorphs*.

Chytridiomycota

The Chytridiomycota, or "chytrids" as they are commonly called, are a group of mostly unicellular fungi occurring in a variety of habitats ranging from soil and roots to the rumens of cows and deer. Asexual and sexual spores are produced in sporangia and escape as *zoospores* (swimming cells). Because of their basically non-hyphal nature and often unusual requirements for growth, the Chytridiomycota are seldom encountered as moulds.

The individual in the photograph above right is perched on top a grain of pine pollen. This is in fact an easy way to collect and examine chytrids. Many plants, including pine and other conifers, produce large amounts of pollen over a short period of time. This pollen can be gathered in small bottles and dried for later use. Sprinkle the pollen *very sparingly* over the surface of some pond water in a dish. Over the next few days examine the pollen under a microscope for evidence of chytrids.

Oomycota

Members of this group all reproduce by oogonia eggs. The hyphae have few or no cross-walls (*septa*) and thus appear as long, clear tubes. If a hypha is broken, most of the contents run out. Many oomycetes reproduce asexually by zoospores, which are motile and can swim quite rapidly. Because of their motile zoospores, oomycetes commonly require water for reproduction and are often encountered in water or wet soil.

An easy way to see oomycetes is to heat a few sesame seeds until they "pop" and then float three or four on the surface of some pond water in a dish. After a few days the oomycetes with form a thick white growth around the seeds. If you watch there carefully you may be able to observe the release of zoospores.

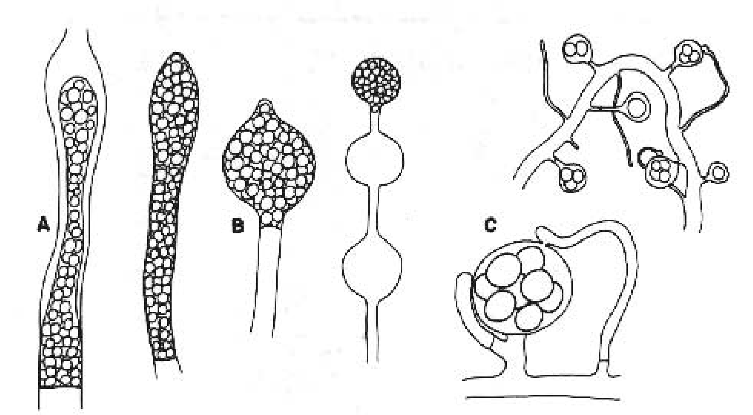

Figure 1 - Oomycota.

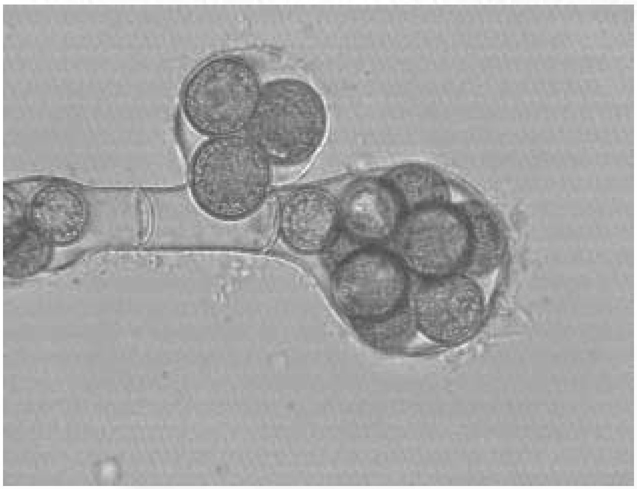
B: zoosporangia of *Pythium* sp.
C: oogonia and antheridia of *Saprolegnia* sp.



Oogonia of *Saprolegnia* sp., isolated from the Ramioul Cave in Belgium.

Zygomycota

As their name implies, these fungi all produce zygospores. They resemble the oomycetes in having hyphae that usually lack cross-walls or septa, but differ in lacking motile spores. Asexual reproduction is by sporangia or conidia. The members of this group are usually terrestrial and will be encountered only occasionally in aquatic conditions.

Zygomycetes are easy to observe. They will invariably grow if soil is sprinkled over strawberries or raspberries. Any attempts to isolate fungi from soil (see chapter on cultivation) will reveal numerous zygomycetes.

C: zygospore of *Zygorhynchus* sp.
D: sporangiophore and sporangiola of *Cunninghamella* sp.

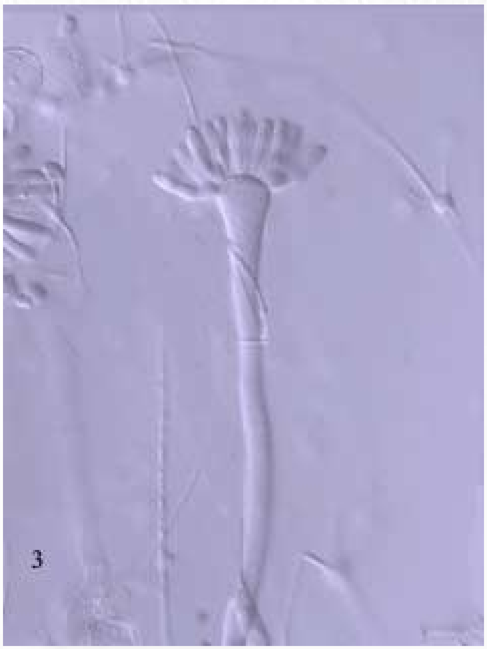

Figure 2b - *Syncephalis*, a member of the Zygomycota parasitic on other Zygomycota.

Ascomycota

All ascomycetes have ascospores borne inside asci. The hyphae always bear numerous septa. Asexual reproduction is by conidia that always lack motility. Although most ascomycetes are terrestrial, some occur in freshwater or marine habitats.

Ascomycetes are everywhere and can be collected year around. The minute black dots on rotting wood and leaves or the little cups on lichens will often prove to be perfect examples.

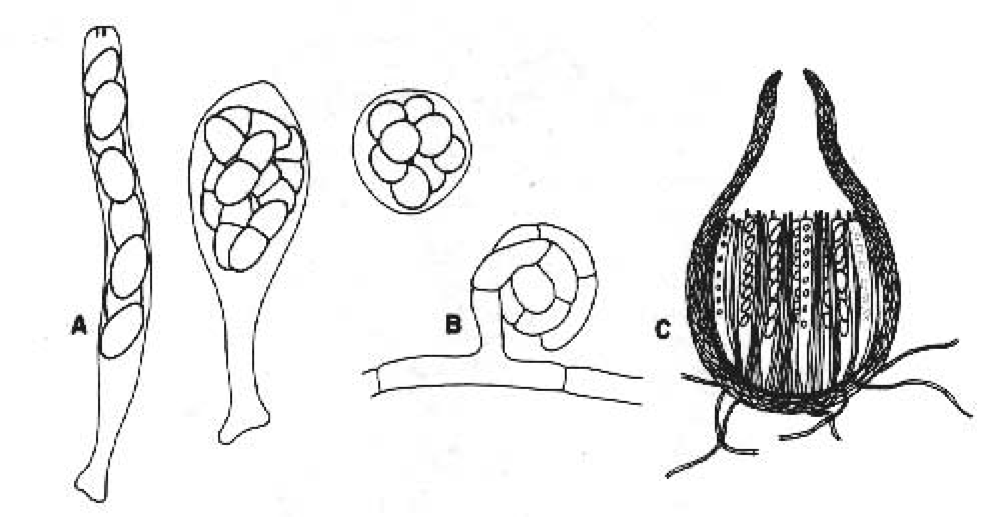

Figure 3 - Ascomycetes
A: three kinds of asci: cylindrical, clavate, and spherical.
B: initial phase of sexual reproduction.
C: cross-section of a flask-shaped perithecium bearing cylindrical asci.

Basidiomycota

This large group, which includes mushrooms and puffballs, is characterized by the presence of basidia and basidiospores. Like ascomycetes, to which they are related, basidiomycetes have hyphae with septa and lack motile spores. The hyphae of many basidiomycetes bear characteristic swellings, called *clamp connections*, that play a specialized role in nuclear migration. Asexual spores, when formed, are produced as conidia. Most basidiomycetes are terrestrial.

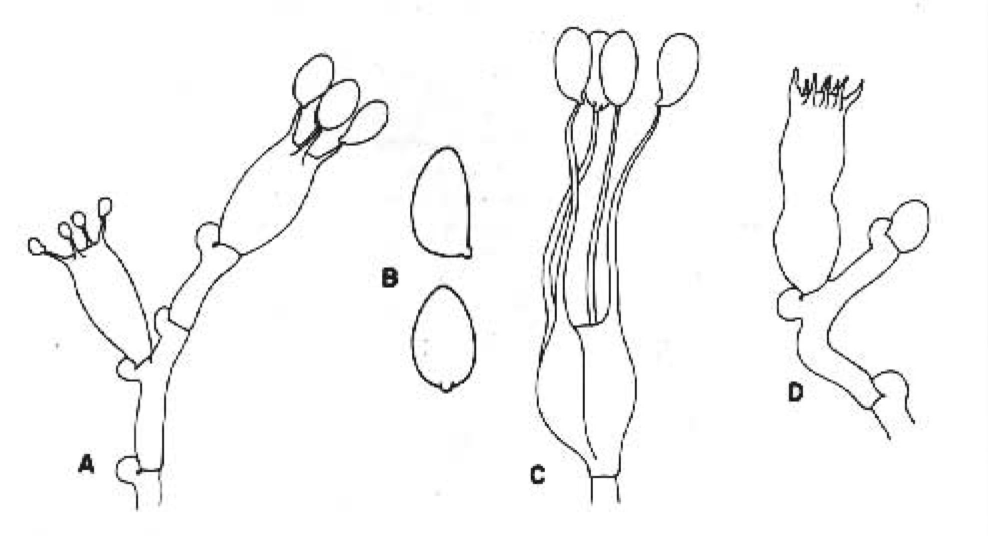

Figure 4 - Basidiomycetes A: four-spored undivided basidium (holobasidium); note the clamp connection at each cross-wall. B: two typical basidiospores, the upper one in side view and the lower in front view. C: a four-celled, cruciate basidium typical of many jelly fungi. D: eight-spored holobasidium typical of species of *Sistotrema*; the spores have been discharged.

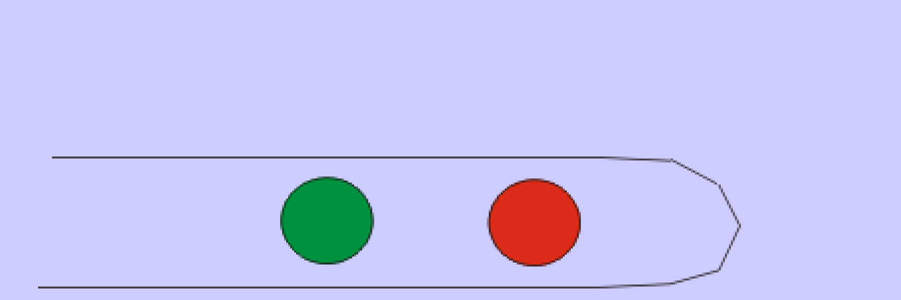

The role of a clamp connection in facilitating nuclear migration.
(Gif animation not available in PDF version.)

Anamorphs

This group comprises the large number of fungi known to reproduce asexually by conidia and is by far the most important in a study of moulds. The asexually reproducing structures of a fungus are called *anamorphs*, which, together with the sexually reproducing structures or *teleomorphs*, make up the *holomorph* or whole fungus. Until the recent advent of a practical genetic methodology the numerous fungi known only as anamorphs could not be classified confidently with the ascomycetes or basidiomycetes to which they undoubtedly belonged. Mycologists have long used a system of classification that allows anamorphs to be named separately from the holomorph of which they form a part. As a consequence, many fungi could have two different names. For example, the name *Eurotium repens* pertained to a holomorph with both ascospores and conidia, whereas *Aspergillus repens* pertained only to the anamorph of the same fungus. Current advances in nucleotide sequencing now allow quite accurate taxonomic placement of species, and as of 1 January 2013 the dual system has come to an end. We now adhere to the more intuitive concept of "One Fungus - One Name". Digging out from more than a century of double names will take time and mycologists temporarily use the old system, but in an admittedly informal sense. Once all the doubly-named species have been sorted out mycologists can breathe a sigh of relief.

Anamorphs show considerable structural diversity and can be classified or described according to three attributes: (1) the method of conidium production (conidiogenesis), (2) the locus of conidiogenesis, and (3) the sequence of conidiogenesis (See Figures 5 and 6).

Method of conidiogenesis

Production of a conidium involves the transformation of part of a cell into a separable spore. Sometimes a hypha or cell becomes separated into one or more segments by septa. The separate cells then thicken, swell, and finally separate. This kind of conidiogenesis, where the septa appear before the conidium is initiated, is called *thallic* (Figure 5A,C). When the new conidium is initiated, begins to swell or thicken, and *then* is cut off by a septum, the conidiogenesis is called blastic (Figures 5B, D;6). When the wall of the conidium is continuous with the cell that produced it, it is called either *holothallic* (when thallic) (figure 5A) or *holoblastic* (when blastic) (figure 5B). When only the inner walls of the conidium-bearing cell are involved in conidiogenesis, the prefix "entero-" is used, resulting in the terms *enterothallic* (figure 5C) and *enteroblastic* (figure 5D). Although enterothallic types are rare, enteroblastic types are probably the most common of all and are represented by the ubiquitous phialide.

The following genera, illustrated at the end of this document, illustrate features of this section:

Holoblastic: *Botrytis*, *Geniculifera*, *Trichocladium*

Enteroblastic: *Acremonium*, *Bipolaris*, *Penicillium*

Holothallic: *Geotrichum*, *Oidiodendron*

Locus of conidiogenesis

Conidiogenesis usually can be traced to a particular point or locus on the conidiogenous cell. If this point remains stationary and gives rise to more conidia it is said to be *stable* (figure 5D). If subsequent conidia are produced at new points on the cell the conidiogenous locus is said to be *dynamic*. Dynamic loci may gradually elongate and be called *progressive* (figure 6C), or move toward the base of the conidiogenesis cell and be *retrogressive* (figure 6B). Usually it is necessary to examine several cells to "reconstruct" the loci of successive spore productions.

The following demonstrate types of loci:

Stable: *Aspergillus*, *Monacrosporium*

Dynamic-progressive: *Arthrobotrys*, *Scopulariopsis*, *Stemphylium*

Dynamic-retrogressive: *Arthrinium*, *Geotrichum*

Sequence of conidiogenesis

If only a single conidium is produced on a conidiogenous cell (figure 6A), we can hardly speak of a sequence. If, however, more than one is produced they can occur either *simultaneously* (figure 5A, B, C) or *serially* (i.e. one after another) (figures 5D; 6B, C).

The following illustrate sequence types:

Solitary: *Monacrosporium*

Multiple, simultaneous: *Botrytis*, *Oedocephalum*

Multiple, serial: *Cladosporium*, *Phialophora*, *Ulocladium*

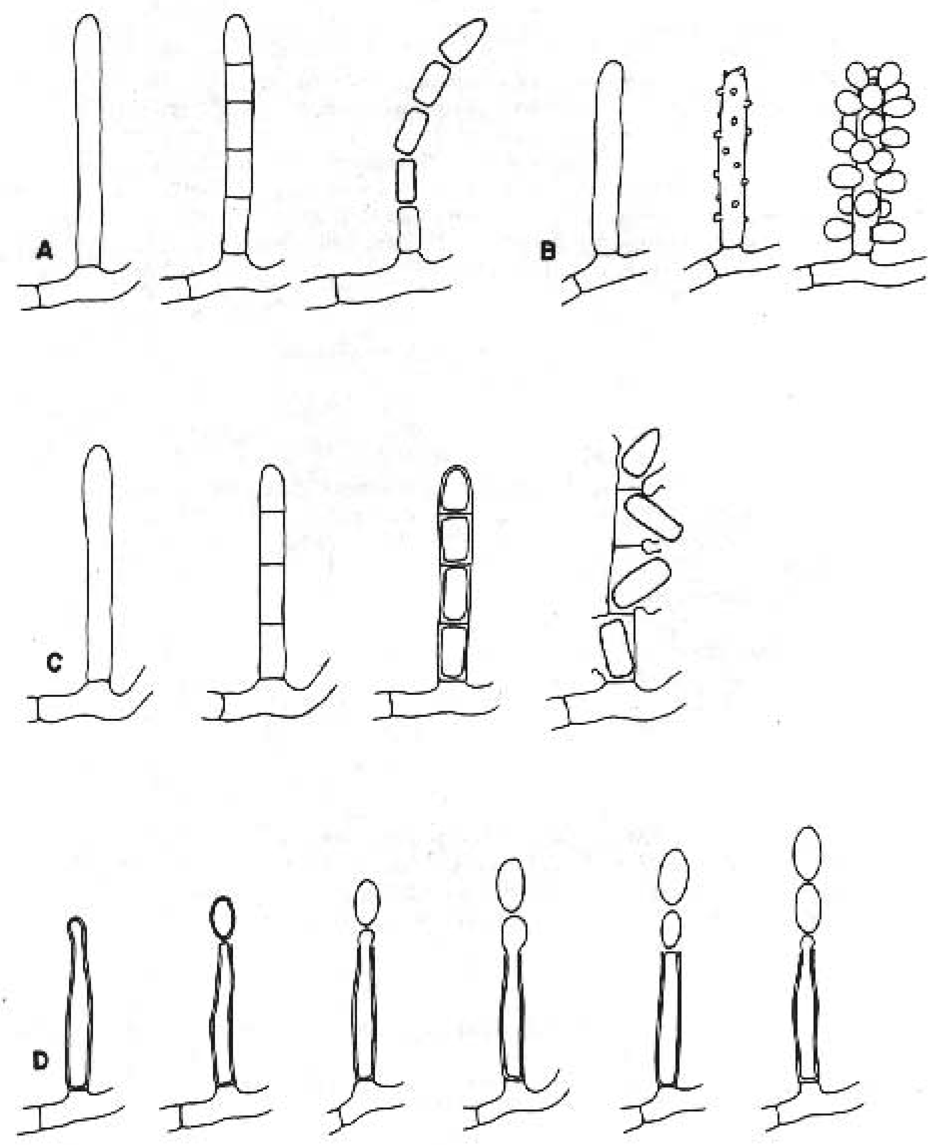

Figure 5 - Conidiogenesis 1.
A: holothallic; the multiple conidia are produced simultaneously.
B: holoblastic; the multiple conidia are produced simultaneously.
C: enterothallic; the multiple conidia are produced simultaneously.
D: enteroblastic; the multiple conidia are produced serially from a stablelocus.

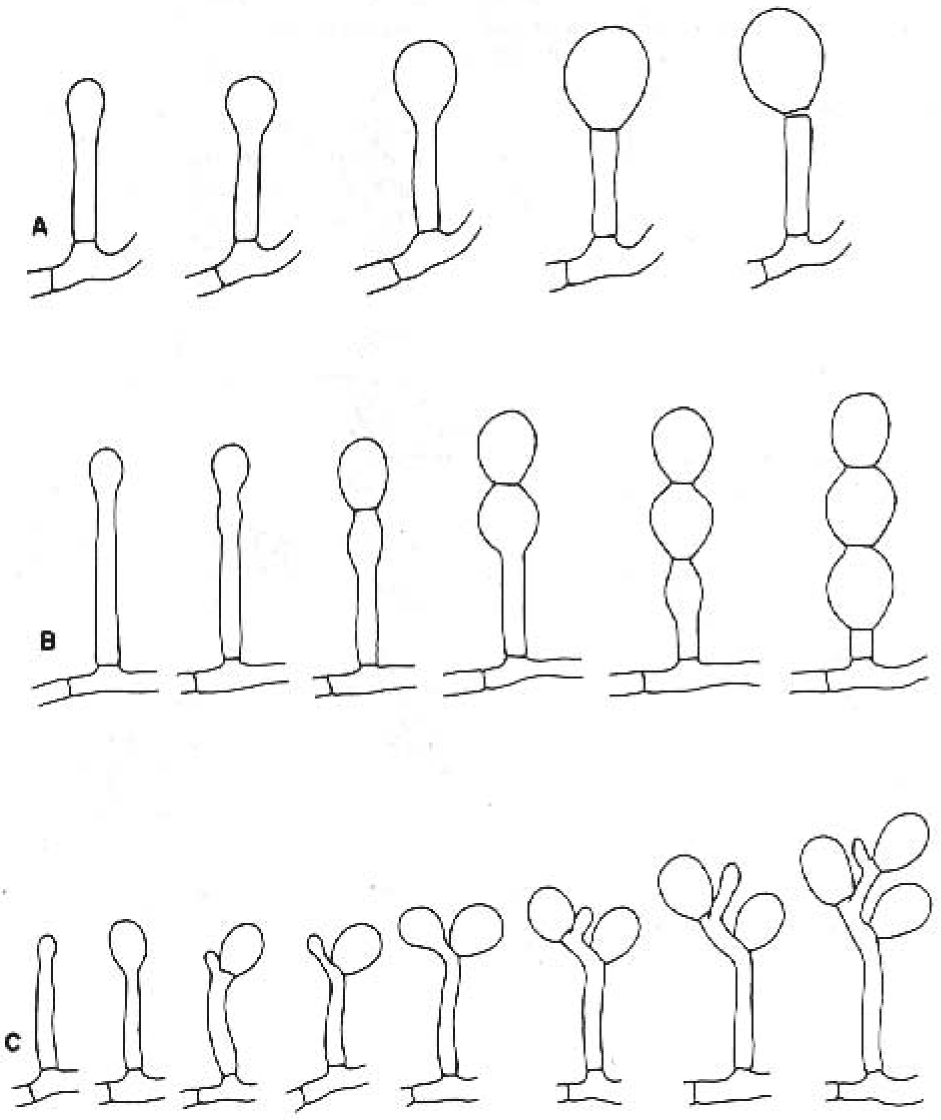

Figure 6 - Conidiogenesis II.
A: holoblastic; the conidium is solitary.
B: holoblastic; the multiple conidia are produced serially from a retrogressive locus.
C: holoblastic; the multiple conidia are produced serially from a progressive locus.

Other mould-like organisms

In routine work we often encounter organisms that are similar to moulds but do not fit our strict definition of the term. Either the organism is not filamentous or it is filamentous but not strictly a fungus. We can put four groups of organisms into this category; bacteria, actinomycetes, yeasts, and slime moulds.

Bacteria

Bacteria represent a very ancient group of organisms, perhaps as old as four billion years. Colonies of bacteria are composed of minute spore-like cells that together form a slimy mass. Such colonies never contain hyphae and are thus easily distinguished from those of true moulds. Bacterial cells, rarely more than 1 um in diameter, are difficult to examine, even with a good microscope, and are best seen when stained. Many bacteria are motile and swim vigorously.

Actinomycetes

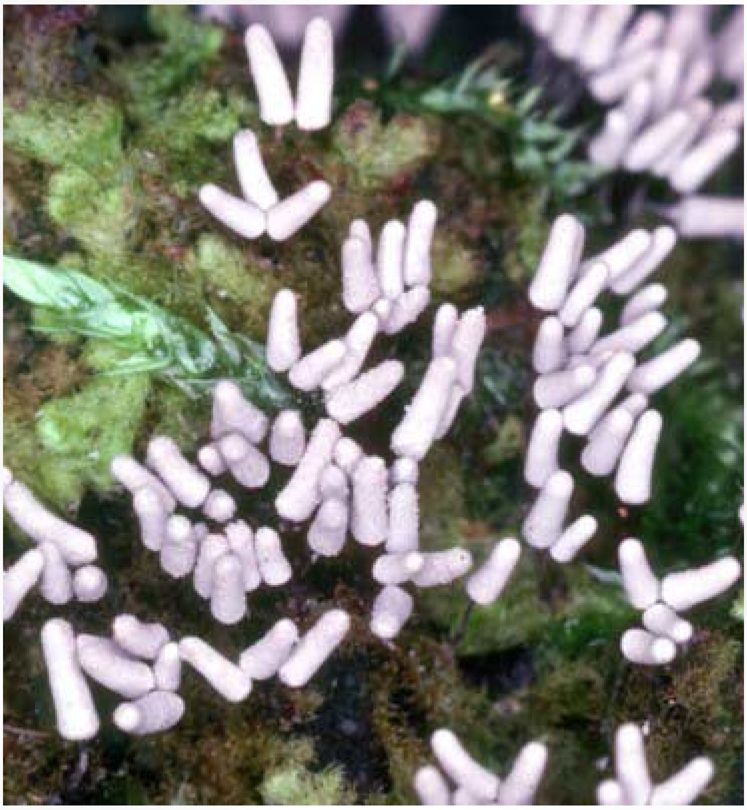
These organisms are usually classified as bacteria but have filaments like fungi. The filaments are seldom more than 1 um in diameter, however, and are thus considerably narrower than those of moulds. *Streptomyces*, the only actinomycete genus commonly encountered as a "mould", produces grey to brightly coloured powdery colonies, usually with a soil-like odour.

Yeasts

Yeasts are true fungi, but in lacking hyphae cannot be classed as moulds. They resemble bacteria in forming pasty or slimy colonies of spore-like cells, but differ in having these cells much larger, usually 2 um or more broad. Reproduction of yeasts is usually by budding, a process where a smaller cell appears to bubble slowly out of the parent cell.

Slime moulds

Slime moulds normally occur on logs and other natural materials but occasionally occur in the laboratory as "moulds". Cellular slime moulds, the most likely to appear in the laboratory, have creeping amoeba-like cells during part of the life cycle and sporangium-like structures in another. They most closely resemble members of the zygomycete genus *Mucor*, but differ in their complete lack of hyphae. Myxomycetes, another group of slime moulds, occur on rotting wood and vegetation in a great variety of habitats. The ones in the photograph at right were growing on an old moss-covered log.



WHERE MOULDS ARE FOUND

Almost any natural material, no matter how small, will support an indigenous population of moulds. Moulds are part of the economy of nature, quickly occupying dead or nearly dead materials and returning them to the basic building components of new organisms. As such, they are essential to what biologists call nutrient cycling, the process whereby nutrients never leave the realm of living things, but simply get used again and again; earth to earth, ashes to ashes, dust to dust.

While acknowledging that moulds are everywhere, it is useful to classify their habitats into a number of categories based on nutritional characteristics. Moulds have specialized nutritional requirements and usually do not range very far from their usual habitats: fungi that naturally decay seaweed on the beach will not be expected to occur on mouldy bread in the kitchen. The competition among moulds having similar nutritional requirements is intense and leaves no room for a mould adapted to another habitat.

Aside from nutritional and competitive barriers, other factors encourage habitat restriction among moulds. Most influential is spore dispersal. Although most moulds seem to produce astronomical numbers of spores, they are, in fact, practising a strict economy. In their highly competitive life there can be little waste; every minute bit of energy must be put to good use or a more efficient organism will prevail. Thus moulds will produce only enough spores to ensure reproduction of their species from year to year. If a mould were to put a disproportionate amount of energy into spore production, it would have to be at the expense of some other activity, such as rapid growth. Economy in spore production is best ensured by mechanisms of spore dispersal conferring a high probability of encountering suitable places to germinate and grow. Many different mechanisms exist and account for the great variety of spores and spore-producing structures found in moulds.

In many instances, moulds living together in particular habitats have similar methods of spore dispersal, even when the moulds themselves are not closely related, illustrating the idea that many structures in organisms are similar because of common ecological pressures rather than common ancestry. Thus we come again to a basis for subdividing habitats, and, as we shall see later, also a basis for applying certain techniques for the isolation and cultivation of moulds.

Living plants

Most plant diseases are caused by fungi. The largest group of plant parasites are the rusts, a highly specialized group of organisms that grow extremely slowly in the laboratory and are outside the usual definition of moulds. Powdery mildews, like the colonies of *Uncinula circinatum*parasitzing a maple leaf at right, have never been cultivated away from their plant hosts. Some plant disease fungi are less difficult to grow but are so specialized as parasites that they seldom occur in laboratories other than those of the plant pathologist. Many of these fungi have rather strict nutritional requirements to induce sporulation and are usually seen in cultivation only as sterile hyphae.

The plant disease fungi most commonly encountered as moulds are those having non-parasitic stages in their life-cycles. These fungi usually grow and sporulate well in the laboratory. Examples are species of *Phoma*, *Fusarium*, *Bipolaris*, *Graphium*, *Pestalotiopsis*, and *Monilia*.

Most parasitic fungi do not produce great numbers of spores and it is likely that they are transferred to uninfected plants by fairly specific means. Those having wet spore stages, such as species of *Phoma*, *Fusarium*, *Pestalotiopsis*, and *Ustilago* (a smut), are probably transmitted by insects or other arthopods, such as mites. Other fungi, such as *Cladosporium* and *Monilia*, produce large numbers of dry spores, and appear to be wind-dispersed.

Also conspicuous are fungi attacking plants weakened by senescence or disease. Such invaders are hardly parasites in the strict sense. Many of these fungi are now considered to be "endophytes", organisms that enter plant tissues while they are still healthy and remain there in a dormant state until the tissue is weakened or dies. Some ecologists now view these endophytes not as parasites but as the first arrivals in a long sucession of decay organisms. Many species of *Alternaria*, *Botrytis*, *Cladosporium*, *Fusarium*, and *Ulocladium* may belong here.

Dead plant material

Herbaceous plants

Moulds occurring on dead herbaceous plants are often the same species attacking dying ones. Thus we can again list *Alternaria*, *Cladosporium*, and others, as well as a few new ones such as *Epicoccum* and *Candida*. In temperate climates, where many plants die in the fall, there is a tremendous flush of mould activity in autumn. Because the dead plant material is so abundant, finely tuned dispersal mechanisms are not necessary and the moulds simply release their spores in the wind. The likelihood that a spore of *Cladosporium*, for example, will hit a dead plant part in the autumn is very great.

Nutritional specialization dictates that different plants will support different fungi, and we find, for example, dead grasses yielding a different flora of moulds than dead milkweeds or mustard, at least to a partial extent.

Wood

Dead wood is a good source of moulds and provides two distinct habitats, depending on whether it is covered with bark or not. Moulds occurring under the bark of fallen and standing trees cannot disperse their spores into the air and most often utilize insects and mites for their transmission. Although, as we might expect, many have wet spores ideal for sticking to the bodies of their dispersers, some have dry spores that appear to become trapped among the animals' body hairs. I have seen hundreds of the curved, dry ascospores of *Fragosphaeria purpurea* trapped among the bristles on the backs of mites under bark of maple trees in Ontario. Often the moulds under the bark of dead standing trees are different from those on fallen trees.

The surface of wood not covered with bark often has a distinct community of moulds. Although air dispersal of spores is possible in this situation and apparently often occurs, wet-spored moulds are still abundant. Again standing and fallen trees support different fungi. Freshly cut wood is a good source of moulds causing a phenomenon called blue stain. These moulds, common in lumber-yards as bluish to black discoloration on the wood, produce tall sporulating structures bearing wet drops of insect-transmitted spores. Closely related species occupy the tunnels and galleries formed by beetles under the bark of living and recently dead trees.

Leaves

Dead or dying leaves of trees support moulds similar to those from herbaceous plants, with some notable exceptions. However, tree leaves appear to support fewer *Alternaria* and *Cladosporium* colonies, thus often allowing a better chance to observe the more slowly growing or rarer fungi. For example, in Ontario fallen leaves of ash support a pin-sized mushroom called *Marasmiusminutus*, that never occurs on herbaceous plants.

Leaves submerged in water support a number of moulds with unusual spore forms. The spores may be needle-like, coiled like a watch-spring, or coiled into barrel-shaped structures that bob to the surface of the water and float away. Others have three or four narrow arms and look something like jacks with two or three of the arms missing. These moulds may be examined by submerging leaves in a bowl of water and stirring them vigorously. After a few minutes the spores will float to the surface, where they can be skimmed off in a drop of water. Best results are obtained with leaves likely to become submerged later in the natural habitat but have not yet become so.

Animals and humans

Diseases

A number of diseases of humans and animals are caused by mould and yeast-like fungi (Figure 7). Many are known only from this habitat and are quite specialized. Notable are the moulds called dermatophytes, the cause of a number of skin diseases such as ringworm and athletes' foot. The fungus grows on the outermost layer of skin, causing reddening of the surrounding tissues (zoophilic types) and sometimes scaliness (anthropophilic types). Dermatophytes do not normally attack deeper tissues; the symptoms are usually due to an allergic reaction. Because of their essentially non-parasitic nature dermatophytes are usually easy to grow in the laboratory. Many closely related species occur on substances similar to human skin, such as leather, feathers, hair, and horn, and are unable to grow on living animals or man. Probably the most commonly isolated dermatophytes are species of *Microsporum* (Figure 7A), *Trichophyton*, and *Epidermophyton*.

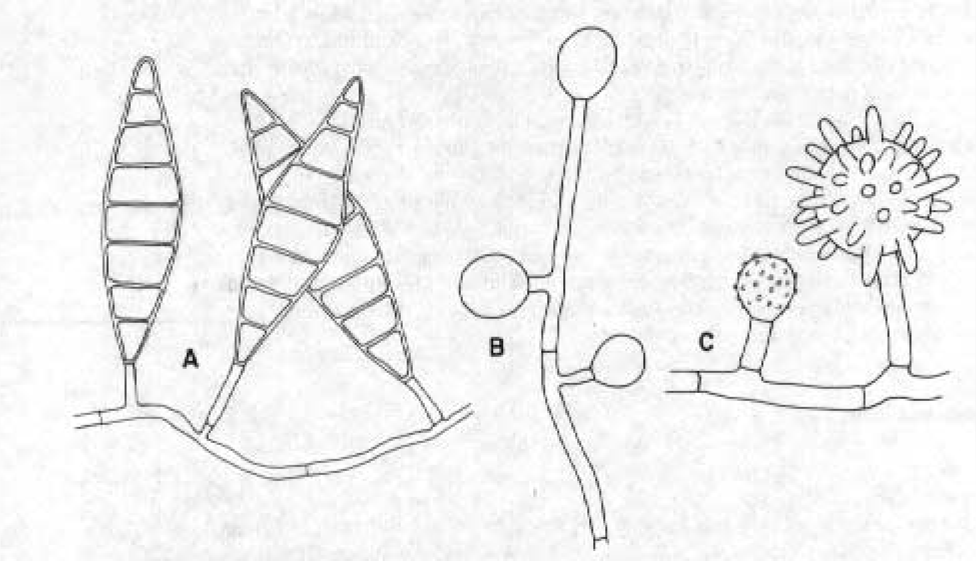


Figure 7 - Some fungi of medical importance.
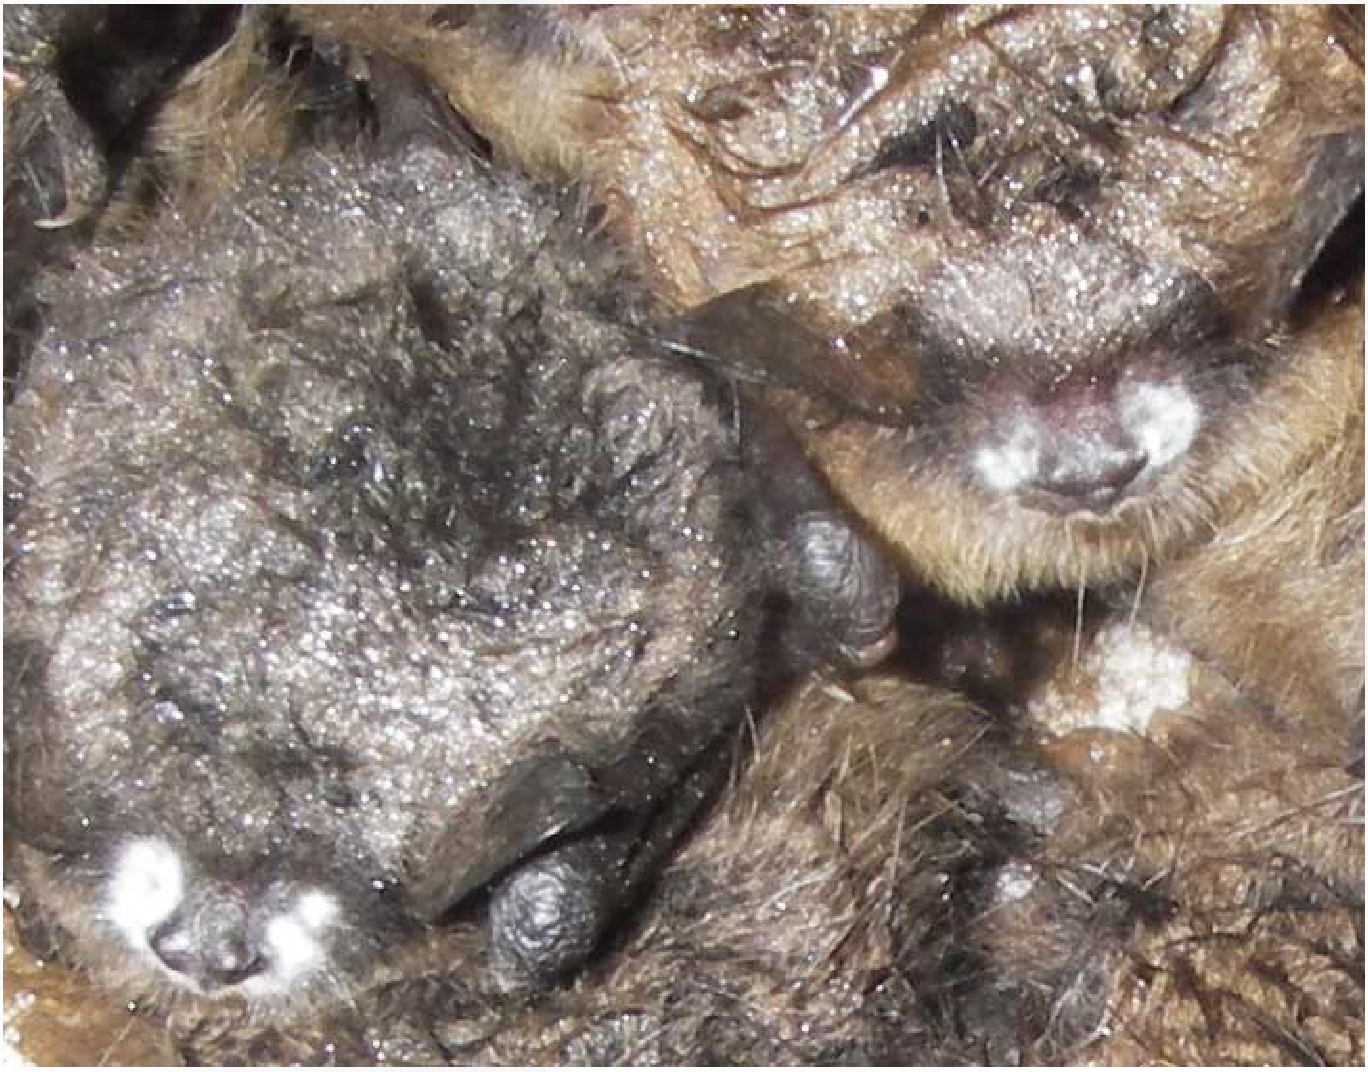
A: Microsporum, causative agent of ringworm and other skin diseases.
B: Blastomyces dermatidis, causative agent of North American blastomycosis.
C: Histoplasma capsulatum, causative agent of histoplasmosis.

Several fungi can occur on living tissues and cause serious disease and even death. Many such organisms are known only from individuals who have low disease resistance, due to prior infection, AIDS, old age, or other factors. Most commonly, infections by these fungi occur when the normal bacterial populations of the body are eliminated by the use of antibiotics. Without competition from bacteria these fungi occupy the tissues and grow rapidly, often causing considerable damage.

Other fungi attack healthy living tissues without the aid of antibiotics, causing more localized but very serious infections. Histoplasmosis, a disease with symptoms similar to those of tuberculosis, is caused by *Histoplasma capsulatum* (Figure 7C), a mould associated with bird nests in nature. It is frequently reported in perfectly healthy people who have been exposed to the dust from nesting materials, such as while tearing down old barns.

The study of medically important fungi is beyond the scope of this book and will not be discussed further. There are several good books dealing with medical fungi from a *mycological* (rather than medical) point of view. Especially useful are Hoog and Guarro, 1995; McGinnis (1980) and St-Germain and Summerbell, 1996.

One of the most devastating animal diseases to have appeared in recent years is the "White Nose Syndrome" in hibernating bats. This disease, caused by *Geomyces destructans* is now known from a large part of eastern North America where it has drastically reduced the numbers of bats. Some scientists have suggested that species such as the little brown bat may become almost extirpated in much of its geographical range. The fungus appears on the hibernating bats during the winter, causing them to awaken several times. It is thought that when they wake up they burn of valuable fat reserves necessary to carry them through until the return of flying insects in the spring. Infected bats attempt to leave their caves to feed in late winter and freeze or starve to death. The photo at right shows two infected bats photographed in an old mine in New Brunswick, Canada. The fungus can be seen at white circles on each side of the animals' noses.



Predation

Some moulds actually trap small (usually microscopic) animals. Best known are those that trap eelworms or nematodes (see Barron [1977] for an excellent account of these fungi). The traps produced by these fungi are composed of loops, networks of filaments, or knobs and branches. Some are reminiscent of the well known

Venus' fly-trap, and are sprung upon contact with an eelworm. When the worm crawls into a ring of one of these fungi, the ring rapidly constricts, holding the eelworm tightly. At first the worm struggles violently, but it soon becomes still and is invaded by the filaments of the mould. In other species, the loops and branches are sticky and hold the eelworm fast as soon as it touches them.

A second group of eelworm catchers produces spores that are swallowed by the worm, germinating later in the gullet. At least one species has an elaborate injection mechanism that, when sprung, forces a small portion of the spore right into the tissues of the side of the eelworm.

Soil

Soil is one of the most commonly studied mould habitats. It is source of plant disease fungi, some human disease fungi, predacious fungi, and a host of forms that bring about the transformation of dead plant and animal material into soil.

Soil is not a uniform substance; in fact, it is so complex that a study of soil is a science in itself. Scientists recognize several layers in the soil, starting at the surface and working down. These are:

L layer: the layer at the soil surface composed of undecayed plant litter. The origin of the litter is clearly identifiable.

F layer: the layer with identifiable but partially shredded or decayed plant material.

H layer: the layer containing much material of plant origin, but with individual structures no longer recognizable.

A layer: the layer with plant or organic matter present but unrecognizable as such or well mixed with loam (a mixture of sand, silt, and clay).

B layer: a mineral layer containing little organic matter.

C layer: the parent rock from which the mineral layer is derived.

Naturally these layers are not always distinct, and grade more or less evenly on into the other. Some soils, especially agricultural ones, lack stratification altogether. Soils differ from one another in the kind of plant material falling into them; the relative proportions of sand, silt, and clay in the mineral components; the moisture content; the relative acidity or alkalinity (pH); and in many other characteristics.

Fungi, because they are highly specialized users of organic substances, vary from one soil to another and with depth in the same soil. They are entirely dependent upon the kind of material falling into the soil: a fungus specializing in oak leaves will probably not colonize a pine needle. This factor alone will account for many differences between the mould populations of two soils. In addition fungi may be sensitive to moisture levels, pH, competition from other organisms, and many other influences.

As a leaf falls into the soil it is shredded by arthropods and digested by microorganisms. Gradually it becomes buried under newer generations of leaves and thus moves down into the lower layers of soil. It undergoes continuous decay by moulds, bacteria and other organisms until it finally disappears (somewhere in the B layer). Fungi that first invade the leaf, often while it is still on the tree, will grow on it until the particular nutrient they need is exhausted and then die back, to be replaced by new fungi extracting what *they* need from the leaf. In this way, a leaf moving down through the layers of soil will have a series of moulds on it, each replacing a previous population. This transition of populations as the habitat ages and is modified is called *succession* and is the object of much study and discussion among ecologists.

Although we tend to think of soil fungi as decomposers of litter, they play a number of other roles as well. Many are associated with animals and animal products and may trap eelworms and other soil animals, or decay the dead bodies of insects and earthworms. Some invade cast-off feathers and hair, and at least one group specializes in old hooves and horns.

Through their roots, living plants offer an attractive habitat for soil-inhabiting fungi. Some live around the root and decay away the dead root layers or substances exuded by the root. Others invade the living root tissues and either cause plant disease or live in harmony with them. The latter situation involves a form of symbiosis called *mycorrhizae*, where the root and the fungi within each benefit the other, In fact, most mycorrhizal fungi and plants cannot live apart. Only a few species of plants are consistently free of this association.

Air

Air, of course, is not a habitat for moulds, though many disperse their spores by air currents and are encountered in routine work.

Fungi have a variety of mechanisms for getting their spores into the air. Simplest is that of exposing dry spore masses to air currents. Many moulds use this method, especially those that colonize exposed leaves and stems. Species of *Alternaria*, *Cladosporium*, and some of the basidiomycetes called smuts are conspicuous for this kind of dispersal. These species usually produce large numbers of spores, a necessary expenditure if at least a few randomly dispersed spores are to land on a suitable place to grow.

Ascomycetes and basidiomycetes are usually capable of shooting their spores away into the air. Asci are like popguns: the water pressure inside the ascus builds up higher and higher until the spores are fired out the end with considerable velocity. Ascospores can, in fact, be shot a distance of several centimetres from the end of the ascus, a prodigious feat considering the microscopic size of these mechanisms. The equivalent at our own scale would be to fire a 30-cm projectile a distance of 6 km, a feat necessitating a 105-mm howitzer! With such a mechanism, ascomycetes need not be exposed directly to the wind but may grow in places allowing entry to the air of their discharged spores. Thus ascomycetes are often found growing closer to the ground than other air-dispersed organisms.

Basidia discharge their spores from the tips of small projections called *sterigmata*. Such spores, sometimes called *ballistospores*, are not shot very far, only far enough to clear the surface of the basidium and the fruiting structure. The fruiting structures of basidiomycetes may be microscopic in size and bear only a few basidia or they may be very large, as in mushrooms and bracket fungi. These last fungi often continue to produce spores throughout the growing season and can produce a staggering number. One of the most prolific of these, the "artist's fungus", *Ganodermaapplanatum*, may disperse its airborne spores many kilometres from the woods where it grows. Related to the basidiomycetes are the mirror yeasts, a group of yeasts that produce ballistospores on solitary sterigmata. Most basidiomycetes are not normally encountered as moulds, and are really outside our interest here, but a few, such as *Sistotrema brinkmanii* may be encountered in the laboratory.

Some spores become airborne by a mechanism known as *droplet adhesion*, a process dependent upon the presence of tiny water droplets in the air. When one of these droplets, as on a foggy day, encounters a mould spore attached to a leaf, for example, the spore adheres to the droplet by surface tension and is carried off on it. It is then either deposited when the drop comes to earth, or becomes truly airborne when the drop dries out.

There are a few other mechanisms whereby spores become airborne, but these are rather more specific to one or a few species. Most are forcible discharge mechanisms and may involve various kinds of spring, water jet, or bellows devices. A discussion of these and other common mechanisms is found in the excellent book on dispersal in fungi by C.T. Ingold (1953).

Dung

Although people expect dung to be a rather disgusting material to study, many become so intrigued with the moulds and other organisms found there that they soon overcome their initial objections.

Many fungi found on dung are highly specialized for growth there and never occur anywhere else. They do not produce large numbers of spores and thus require a high probability of success in getting their spores from one dung pile to another.

The most commonly cited life-cycle in dung-inhabiting or coprophilous fungi is that shown by many ascomycetes. The spores of these ascomycetes are very heavy, sticky, and dark, and when they are shot from the ascus their weight allow them to travel a relatively great distance. Because of this weight, however, they do not usually remain in the air long, but follow a parabolic trajectory and land near the dung pile. Because they are sticky, often with rather elaborate slimy coverings or tails, they adhere to whatever they fall on, and because of their dark colours they are not greatly affected by the ultraviolet radiation in the sunlight to which they are exposed for an often considerable length of time. Eventually they may be eaten, if they have fallen on vegetation, by a grazing animal, ultimately to be packaged up in a new pile of dung. Many of these spores have a dormancy mechanism that prevents them from germinating on the vegetation but that can be broken when subjected to the processes of the animal's digestive tract. Most coprophilous ascomycetes are light-sensitive and aim their spore shots away from the dark-coloured dung, a first step in their journey to a new dropping.

Other coprophilous moulds present their spores to the environment in wet drops at the ends of stalks. When one of the many insects or mites attracted to dung brushes against these stalked spore drops they carry with them a few of the sticky spores. Later, perhaps on a new dung pile, the spores rub off and germinate to produce a new colony. Most insect-transmitted fungi lack dormancy mechanisms in their spores, and are unlikely to be away from dung for more than a few hours.

The variety of coprophilous fungi is large, and many occur in the laboratory as moulds. Included are several kinds of ascomycetes, some small mushrooms, slime moulds, zygomycetes, and many anamorphs. It is a particularly rewarding group for study by the beginning mycologist.

One warning must be issued. Dung may contain the eggs, larvae or adults of parasitic organisms. While most of these are of danger only to the species of animal producing the dung, some are able to parasitize humans. Because of this dung should never be handled with bare hands.

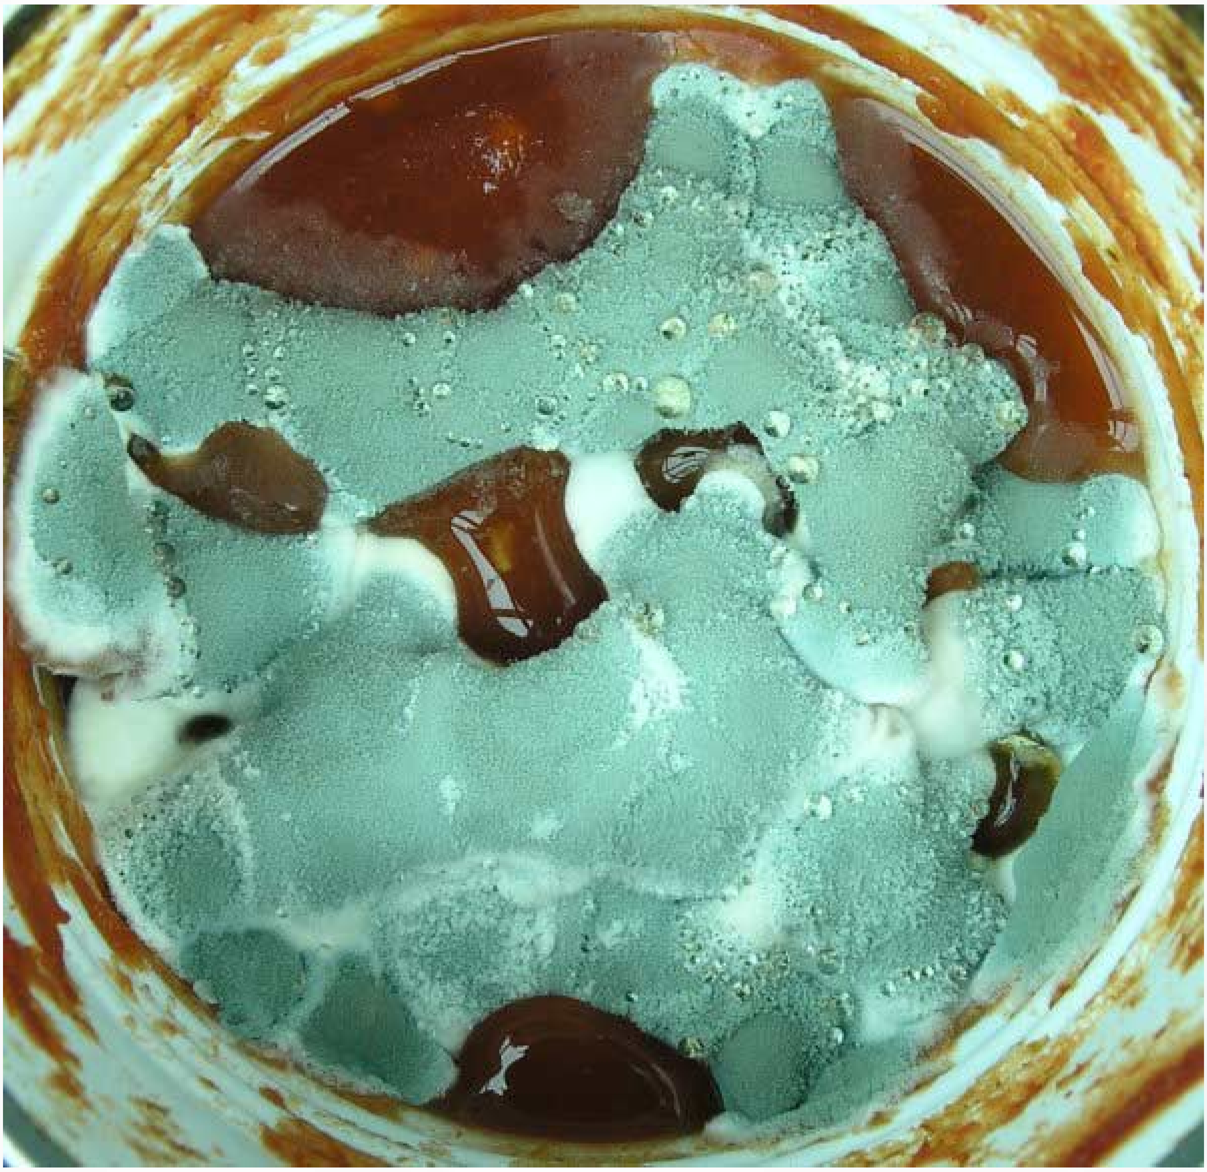
The human environment

Food

Aside from their role in plant, animal, and human disease, many moulds enter directly into human affairs, in either a harmful or beneficial way. On the plus side is the involvement of moulds in the greatest contribution to medicine of all time, that of antibiotics. The discovery of penicillin by Sir Alexander Fleming in 1928 probably resulted in the saving of more lives than all other medical discoveries combined. Penicillin, a product of the common mould *Penicillium chrysogenum*, is still one of the safest and most widely used of antibiotics, in spite of a more than fifty-year search for others.

The foods we eat are as nutritional to many moulds as they are to us, a fact often put to use in the preparation of food products. For example, several types of cheese, such as Roquefort, Danish blue, Camembert, and Brie, owe their distinctive flavour to the presence of mould growing on them. If the mould were absent, these cheese would not ripen properly. Yeasts, although not really moulds, are among the most important fungi in food preparation. Their value, at least for some *Saccharomyces* species, lies in their ability to produce carbon dioxide and grain alcohol. In wine-making, where the production of alcohol is valued, yeast is added to the grape juice to bring this about. In bread-making, the important product is carbon dioxide, which is necessary in the rising process, and, again, yeast is added to the dough. In the production of beer, both alcohol and carbon dioxide, to produce carbonation, may be necessary, although today the carbon dioxide may be added later artificially.



In the Far East, a number of moulds are used in food preparation that remain unexploited in most of the world. Among these are species of *Aspergillus*, *Monascus*, and *Rhizopus*, used to process various rice, bean and soybean products.

To most of us, the negative aspects of moulds in foods are more noticeable than the positive. Few of us have failed to notice the pink, black, and green moulds growing on bread or the green or blue-green *Penicillium* rots of citrus fruits. Moulds are one of the reasons food manufacturers include preservatives in their products. The picture at right shows a species of *Penicillium*, growing over the surface of some tomato sauce left too long in the refrigerator. The yellowish drops of liquid, called exudate, resting on the surface of the mould, and its overall blue-green colour suggest it is *P. chrysogenum*. Microscopic examination revealed it had smooth conidiophores and conidia, also indicating it to be *P. chrysogenum*.

One of the most destructive activities of moulds in foodstuffs occurs in stored seeds and grains. Certain species of Aspergillus, Penicillium, and Eurotium are able to grow under particularly dry conditions and attack stored grains. To guard against this, the grain must be dried to very low moisture levels. Keeping grains dry in the humid tropics is particularly difficult if not, at times, nearly impossible. Not only do such fungi damage the grains or render them unpalatable, they may also excrete toxins that can cause illness or even death. Most famous of these are the aflatoxins - produced by *Aspergillus flavus* and other moulds - which are not only immediately toxic but are also known to be carcinogenic. *Aspergillus flavus* often grows on peanuts and was first discovered in peanut feed given to turkeys in Great Britain.

Some of the same species of Eurotium that attack stored grain commonly appear on the surface of jams, jellies, and syrups. These very sugary substances tend to prevent water from entering the cells of most fungi and thus create what amounts to a microbiological desert. Eurotium species, with their ability to grow under dry conditions, are ideally suited to such habitats. Some products, such as prunes and dried apricots, are so dry and so sugary that even Eurotium species are unable to cope with them. They still can be decayed by certain specialized moulds, however. Probably the most remarkable to these is *Xeromyces bisporus*, which cannot even grow at the sugar concentration used to grow Eurotium species. Laboratory cultures of this species are rather difficult to establish and require very special conditions.

Cellulose products

Cellulose is probably the most abundant material of biological origin on the earth and is a prime source of energy for many fungi. We have met some cellulose-decomposing fungi already in our discussion of moulds inhabiting dead and dying plant parts, notably Alternaria, Cladosporium and Epicoccum. While these fungi are common enough, there are several others that seem to become especially common on man-made cellulose products, such as paper, cotton, cardboard, and wood products. Many mould growths on paper and cotton are commonly called mildews, but this term really has little meaning. These fungi are able to dissolve the cellulose fibres in cotton and paper and thus cause the materials to disintegrate. The process is especially rapid under moist conditions, as occur in damp basements or in the tropics. Many species of moulds are involved in cellulose decomposition, but none are more widespread than species of the ascomycete genus Chaetomium. During the Second World War, countries fighting in the South Pacific and Southeast Asian areas lost a great deal of equipment to these species. The resulting increased interest in Chaetomium is reflected most notably in Ames's (1963) monograph on the Chaetomiaceae, published by the United States Army.

Sawdust contains many cellulose-utilizing moulds that may cause unwanted decomposition. Particularly undesirable are members of a group of moulds able to grow at high temperatures (up to 60? C). The growth of these moulds may actually cause the temperature of the sawdust to rise. Combined with bacteria having an even higher temperature tolerance and natural chemical activities these moulds may eventually lead to spontaneous combustion, a common cause of fire in lumber-yards.

Other products

Many other manufactured products are susceptible to mould attack. Painted walls, particularly in humid places such as showers, can become overgrown by certain fungi, notably species of Phoma and Exophiala. Wallpapers also serve as a source of nutrition for some moulds. Commonly cited are the Scopulariopsis species which have been reported to grow on wallpapers containing arsenic pigments and to release very poisonous gases. With modern wallpaper pigments, which contain no arsenic, this cannot happen.

Leather is mainly protein and serves as a convenient source of food for moulds. Some of the moulds that occur here are related to the dermatophytes that attack the outer layer of human skin; others belong to quite different groups.

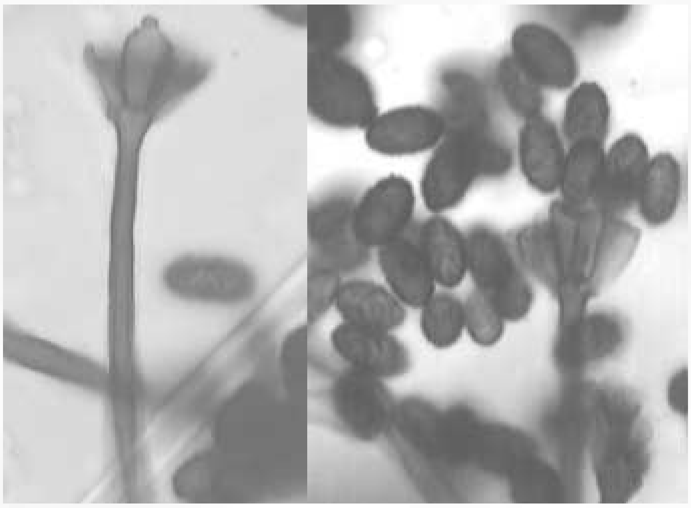
Some substances that seem to be entirely unlikely to support fungal growth may be found to be well colonized by these organisms. Exophiala species, for example, are found in syrupy solutions of polyvinyl alcohol. *Cladosporium (Amorphotheca) resiniae* often occurs on the surface of aircraft fuels in their tanks and can damage jet engines. *Penicillium ochrochloron* can be found in electroplating solutions that are extremely acid and contain very high levels of toxic copper salts. I was once involved in a search for the organism responsible for decaying inflatable life-rafts periodically soaked in seawater. The culprit eventually turned out to be a species of *Aspergillus*.

Moulds in the indoor environment

Increasing attention is becoming focused on fungi in indoor environments. Although most of the moulds occurring in human environments occur indoors, the interior of buildings are themselves a special habitat. It has long been known that indoor fungi cause allergies in sensitive persons, but only relatively recently have indoor moulds been linked to other health problems. While allergy sufferers generally react to substances in fungal spores, other health problems may be caused by voltile substances released by moulds into the air.

Virtually all buildings contain moulds, but some are mouldier than others. Indoor moulds can be remarkably tolerant of dry conditions but none can live without some moisture. Excessively mouldy buildings generally have a source of moisture leading to unusually heavy mould growth. The source of the moisture may be a leaky basement, a dripping pipe, a roof in need of repair or some other fairly obvious cause. In most cases the mould can be seen growing on walls or other materials in contact with the moisture. Sometimes the moisture can occur inside walls and not be apparent. A common but not obvious cause of moisture in cold climates is condensation inside north-facing walls. Severely mouldy buildings may have a musty smell, but not necessarily. Sometimes the only sign of a problem is persistant poor health of the occupants, such as headaches, nausea, respiratory symptoms, etc. It is now known that mouldy buildings can present a serious health risk to occupants. In fact, some infant deaths have been convincingly linked to indoor moulds. Any building with an apparent mould problem should be thoroughly investigated by qualified people.

Not all indoor moulds present a risk to human health, but an abundance of any mould is likely to be accompanied by others, including toxic ones. Species of *Stachybotrys* are particularly toxic. Obvious occurrences of *Stachybotrys* may be sufficient cause for a major "decontamination" by qualified technicians wearing special protective clothing. *Stachybotrys* species produce black colonies on dry wall, ceiling tiles and other materials containing cellulose. The easiest way to confirm the presence of *Stachybotrys* is to press a piece of cellulose tape against the mouldy spot and then examine it sticky side up on a slide under a microscope for the characteristic spore-bearing structures. The image at right illustrates conidiophores and conidia of a *Stachybotrys* species collected on tape from a basement in southern Quebec. Not all moulds are identifiable using this technique, but it works well for many, including *Stachybotrys*.



HOW MOULDS CAN BE ISOLATED

One of the joys of mycology is being able to go out into the field and isolate from among thousands of moulds a single interesting species. Almost any natural substance will have not one mould but a whole community of moulds growing on it. Each mould is distinct from all others and produces a characteristic colony when grown in pure culture. The isolation, or we might say domestication, of each is a challenge that never seems to lose its fascination.

A most difficult thing for the beginner is to come to terms with the small scale of mould communities. Even an area only 1 millimetre square can support more than one species of mould when nutrients are available. The only really practical way to get down to this scale is to work with a binocular dissecting microscope of sufficient magnification to allow spore-bearing structures to be seen. When this is possible, a sterile needle can be used to remove the spores of the particular mould that is to be isolated.

Isolation of fungi from natural sources is one of the basic skills in mycology that must be mastered by almost everyone concerned with moulds. Isolation techniques are numerous and often complex but can be quite effective in yielding just the mould one wants, while excluding all the others. Isolation techniques can be divided into two broad categories: (1) direct methods and (2) selective methods. Both are routinely used in mycology laboratories and can be further divided into a number of subtypes.

Direct isolation techniques

Direct transfer

The term "direct is applied to techniques involving the simple transfer of a mould from its natural habitat to a pure culture situation in the laboratory. At its simplest this is done by putting a piece of the habitat or substrate under a dissecting microscope so that the mould growth is easily visible. An inoculating needle is then heated until red hot, cooled, and used to transfer some of the spores into a sterile plate of culture medium. I find this easier to do if I first get a tiny piece of agar on the end of the needle for the spores to stick to. The piece of agar must be very small because it is often necessary to manoeuvre it into rather tight places where other moulds might easily contaminate it. An alternative is to moisten the needle with a slight amount of glycerine. Once the transfer has been made, it is only necessary to wait a few days for the mould to grow and form a colony.

The direct transfer technique is also used to obtain pure cultures of mushrooms and other large fungi. The fruiting body is broken open, without touching the newly exposed flesh, and some of the tissue is transferred to a sterile culture medium. If this has been done carefully, the tissue may give rise to a colony after a few days. For the beginner, the easiest large fungi to culture are those found inhabiting decaying wood. Most wood-inhabiting mushrooms and bracket fungi grow well on the semi-synthetic media listed in chapter 4, although few will form their large fruiting bodies in culture.

Moist chambers

Direct isolation of fungi is often more effective if the natural substrate has been kept moist for one to several weeks to allow moulds to grow and sporulate. The easiest method involves a container called a moist chamber (Figure 11). Moist chambers can take any number of forms, but are basically containers holding a material such as cotton, paper, cloth, sterile sand or soil, or peat moss that can be kept moist for several weeks. The specimen is placed on top of the moist material and left until moulds begin to grow on it. In my classes we use glass containers resembling very deep Petri dishes, and like Petri dishes they have loosely fitting lids. For the packing material we nearly always use peat moss, collected in the field and dried for later use. The container is filled with dry moss and then water is added. Peat moss is like a sponge in that it can absorb and hold a tremendous amount of water. When water is added to the moist chamber it soaks up into the moss. The excess can be poured off and the moss squashed down until it forms a moist layer no deeper than about one-quarter of the height of the container. We then place a single or double layer of filter-paper or paper towel over the moss layer so that the specimen does not come in contact with it. Thus prepared, the moist chamber is ready for the specimen.

In many areas peat moss, in its fresh form, is hard to obtain and it is necessary to find a substitute. Although many people use cotton for this purpose, I think that it is best avoided as it is a good substrate for mould growth itself. Instead, try using a layer of fine soil or very fine sand. Soil and sand will not hold water as well as peat, so watch carefully to make sure it does not dry out. But don't make it too wet or all you will get is mud!

When you are ready to add the specimen, moisten it slightly (unless it is already damp) and place it on top of the filter-paper. Cover the dish and leave it in a place where the temperature is reasonably constant.

Within a few days moulds will begin to appear on the specimen. Most beginners are unprepared for the extremely small size of many moulds and tend to overlook them completely. Invariably students using moist chambers for the first time complain that nothing is growing on their specimens, only to have an instructor point out at least half a dozen different moulds! Be sure to examine the material with a magnification of at least 15-20 times and with good bright illumination. Illumination is especially important and should be focused on the area of the specimen that is under examination. When something interesting is found, it can be removed for microscopic examination; but more about that part later.

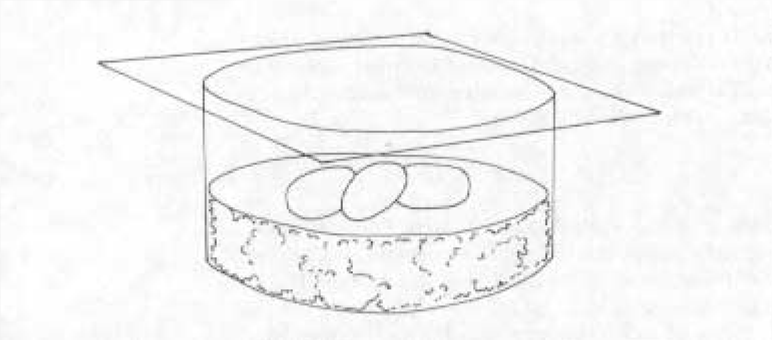


Figure 11 - A moist chamber containing three pieces of dung.

In order to obtain a pure culture of something in a moist chamber it is only necessary to follow the direct transfer procedure given above, making sure that the sterile needle picks up only the spores that are wanted. If the needle inadvertently touches the surface of the material in the moist chamber it will pick up all sorts of undesirable contaminants.

Moist chambers can be used for all kinds of materials. We have used them to incubate dung, wood, leaves, old stems, corn stalks, bark, seeds, fruits, old fungi, dead insects, and numerous other things. Natural materials are usually more productive than man-made ones, but sometimes old pieces of cloth or leather products can be good. You are only limited by your imagination. Moist chambers are also useful in mycological "detective work", to discover the cause of a particular decay. Placing the decayed material in a moist chamber often will result in abundant sporulation of the guilty organism in the area affected. This technique works well with diseased plant material as well as manufactural products.

With very small specimens, such as insect parts or seeds, it may be easier to use a Petri dish as a moist chamber. We sometimes simply put a few layers of filter-paper in a Petri dish, moisten them, and put the specimen on top. Such moist chambers may dry out very easily, however, and have to be tended closely. A better method is to make up a batch of water agar (a solution of 20 grams of agar in a litre of water), sterilize it, and pour it into sterile Petri dishes. Because the agar solution contains almost no nutrients it will support little mould growth and thus serves only as a water reservoir. The specimen can be placed on the agar surface and examined as in any other moist chamber. Agar media containing nutrients can be used here, but often they only become overrun by the fastest growing moulds at the expense of everything else.

Whether using a moist chamber or working with freshly collected material, one often discovers that moulds produce spores inside some kind of structure, such as a pycnidium. Direct transfer of these structures invariably leads to contamination by other moulds. To avoid the problem it is necessary to clean off the surface of the structure sufficiently that all foreign spores and bacteria are removed. I do this either by pushing the structure over, around, and through an agar medium for 10 minutes or more until it is clean, or by surface sterilizing it for about 60 minutes in a 10 per cent commercial chlorine bleach solution. The required times and concentrations of bleach in the latter technique will differ some what from one specimen to another; the technique is most effective if the treatment can be varied with several samples. The agar technique demands more dexterity but can be applied to a single specimen with predictable results.

Direct plating

Often it is most convenient to place materials that are of interest directly on a nutrient agar medium. As already noted, this technique encourages rapidly spreading moulds at the expense of other fungi but is nevertheless widely used. It is a simple technique, requiring the placing of small bits of the substance on the surface of the agar or the pouring of melted but cooled agar over the fragments. After a few days' incubation mould colonies appear on the surface, and can be transferred into pure culture.

The amount of material placed in the dish varies, depending upon how heavily it is infected with mould spores. This technique is commonly used in soil studies, requiring only a pinch of soil, evenly dispersed over the surface of the agar. It is difficult to apply any rules here, however, because a small amount of material may yield a different set of moulds from a large amount. If the amount of material is large, the result may be a combination of a plating technique and a moist chamber.

We find that Martin's Rose Bengal Medium is a good choice for direct plating, as the rose bengal dye and antibiotics in it slow down colony growth and keep the colonies from growing together at first.

Dilution plating

In this technique 1 gram (dry weight) of the material to be studied is ground up (if necessary) and dispersed in 9 ml of sterile water. One millilitre of this solution is transferred to a second tube containing 9 ml of sterile water, resulting in a 0.01 dilution of the spore mass in the original material. The process is repeated to yield dilutions of 0.001, 0.0001, and 0.00001 or even further if necessary. A 1-ml portion from each dilution is pipetted to a separate Petri dish, and cooled, melted agar medium poured over it. The plate should be moved gently on the table in a figure-of-eight motion to effect proper dispersion. Alternatively, the solution can be put on the surface of solidified medium and spread evenly throughout.

After a few days' incubation, colonies will appear in varying densities, depending upon the amount of dilution from the original material. The number of spores present in the original sample can be calculated roughly by selecting the plates showing 40-100 colonies and writing down the colony count. With this information the following calculation can be performed:

$$\textbf{Colonies per gram of original sample} = \frac{\textbf{Colony count}}{\textbf{Dilution factor}}$$

The accuracy of this technique is low when only one plate is counted. There are numerous contributing factors, including improper dispersion of spores during dilution, failure to break up spore masses, or mutual inhibition of growth by certain fungi. Greater accuracy is attained by doing several plates at the most desirable dilution, perhaps ten or more.

Dilutions are frequently used in studies on soil fungi. Although the technique has been criticized as not reflecting the "true" soil flora, it is probably the most commonly used method in this area of study. Even if the fungi isolated are not very representative of the whole flora, the technique does allow scientists to compare one soil with another on a statistical basis.

Airborne fungi

We have already discussed the subject of airborne fungi and have noted that certain moulds are more likely to get their spores into the air than others. Airborne mould spores can serve as an infective agent of plant disease and may also be allergenic. It is well known that allergy sufferers are sensitive to the spores of some moulds but not to others, and it is thus often helpful to know which mould species are present in the air at a particular time or place.

The sampling of airborne fungi is a subject that has attracted much attention in the last twenty years, resulting in the publication of several books. For a thorough treatment of this topic, see Gregory (1973). There are two approaches to air sampling, one that yields spores for microscopic examination and one that yields cultures. The former results in a lot of unidentifiable spores while the latter senses only those that can be cultivated (and many cannot).

It is well beyond my task here to go into all the different sampling techniques that are now in use. We can ignore the spore examination methods completely, as they deal only with spores, and concentrate on the cultural ones. The simplest culture techniques for airborne moulds involve the horizontal or vertical placement of Petri dishes containing a nutrient agar so that they trap any spores that fall on or blow into them. Usually 30 minutes to 3 hours out of doors is required for a good sample using this technique. Indoors the situation is more complicated and depends upon several factors, including the amount of traffic, the type of building, and its cleanliness. A good exposure time for an open Petri dish might be 1-2 hours, but only after testing can one be sure.

It has long been known that open Petri plates and other static spore traps have a rather low efficiency because of the layer of dead air on their surfaces. Any moving air, and its load of spores, will tend to pass over this layer and not reach the surface. To overcome the problem a number of devices have been invented that suck in air and force it against a sticky surface; one device, called an Anderson sampler, accommodates several Petri plates and will even sort spores out according to their size or mass. Such a machine is far more efficient than an open Petri plate but is bulky and is normally used only by specialists.

Baits

Many moulds have quite specific nutrient requirements and are specialized to use materials that other fungi use with difficulty or not at all. We can take advantage of this for the isolation of fungi by presenting a particular substance to the environment for colonization and then later recovering it for isolation of the fungi that occupied it. An example of a fungus sometimes recovered by baiting is the creosote fungus, *Amorphotheca resiniae*. To isolate it, some scientists coat matchsticks with creosote and place them on soil in Petri dishes for two or three weeks. *Amorphotheca*, a fungus particularly able to utilize creosote, grows from spores in the soil and invades the matchsticks, where it produces abundant hyphae and conidia. From here it is transferred into pure culture. Man inadvertently baits for this same fungus by allowing small amounts of water condensation to get into tanks containing jet fuel. The fungus grows in the water, utilizing the kerosene for energy, and ultimately forms mats of mycelium that can cause engine failure.

Other kinds of baits might be pieces of wood, insects, carrot chunks, plastics, hair, or anything else one can name. The bait can be submerged in a particular habitat in nature or in a moist chamber. To isolate dermatophytes, for example, it is customary to place hair on moist soil in a moist chamber and examine it periodically for sporulating moulds.

The most commonly baited habitat is water, both fresh and marine. Again, almost anything can serve as a bait and the water can be either naturally occurring or in a Petri dish. Good results can be obtained by putting some pond water in a Petri dish and floating on it a few sesame seeds that have been heated until they have popped. Within three or four days the seeds will be covered with oomycetes producing zoospores. Dead files, pollen, bits of apple or carrot, cellophane, and other materials are also productive baits. Since most moulds attracted this way are true aquatics it is necessary to purify them by transferring them to successive changes of distilled water containing new sesame seeds or other baits. When completely isolated into pure culture they can be transferred to solid media, but they may never sporulate there.

In the natural habitat it is interesting to submerge pieces of wood, whole carrots, apples, etc. on a string for several days or weeks and then bring them in for examination. Submerged wood blocks are one of the most commonly used materials for obtaining marine ascomycetes.

Special techniques

Aside from the rather broadly applicable techniques discussed above, there are many others that are quite specific in their effects. It is well beyond my purpose here to go into even a portion of these techniques, but a few are of particular interest and demonstrate some of the kinds of things that can be done to isolate a new set of moulds from a familiar habitat.

Stress techniques

All moulds are capable of withstanding environmental stresses, but eventually, when the stress is great enough, they will be killed. Not all moulds have the same tolerance to stress, however, and we can take advantage of this property by subjecting a material to just enough stress to kill some moulds but not others. The application of such techniques has turned up another interesting fact: that some moulds will not germinate *until* they have been subjected to conditions that kill most others. I have already mentioned one such group in my discussion of the dung-inhabiting or coprophilous fungi that produce spores that do not germinate until subjected to the rigours of the digestive tract of animals. Other fungi produce spores that germinate only after they are exposed to fires or freezing.

To explore these interesting adaptations we need only take a sample of soil, dung, wood, etc. and subject it to some kind ot treatment that we kill most fungi. We can steam the substance in an autoclave or steamer (without pressure), soak it in alcohol, acids, bases, or other chemicals, or alternately freeze and thaw it for several weeks. Almost any drastic treatment will yield a few fungal "holdouts" that might not otherwise appear. After treatment, the substance can be handled in any of the normal ways, such as plating, or moist chambers. Dr. De B. Scott (Scott 1968) outlined a method of this type for isolating species of *Eupenicillium* (an ascomycete) from soil. About 2 grams of soil were added to 18 ml of sterile water and heated in a water bath at 80°C for 30 minutes. After removal from the bath the soil suspension was treated according to the dilution plating technique described above.

Surface sterilization

In the section on direct isolation techniques I mentioned the method of sterilizing the surface of fungi with 10 per cent commercial bleach to kill adhering spores. Surface sterilization can also be used as a selective technique on a slightly larger scale. If we see a living leaf that has a dead circular spot on it we might guess that this is caused by a fungus. If we put the spot directly on the agar medium we will probably get some fast-growing fungus but not the causative agent. What we want is the fungus *inside* the leaf, not the surface adherents, and a good way to obtain it is to apply bleach long enough to kill the external organisms but not the internal ones. Although materials differ considerably, a sterilization time of about 1 hour in a 10% commercial bleach or 3% hydrogen peroxide will often work. If one is unsure, some longer and shorter times should be tried. Surface sterilization will also work for seeds, large fungi, wood, many man-made materials, dead insects, and other things.

Selective nutrients

This technique is essentially the same as the baiting methods discussed above. It differs only in that the substance to be sampled is added to the "bait" rather than vice versa. We might, for example. wish to isolate those moulds that can utilize cellulose. To select for these fungi we make a medium such as Czapek's, but using cellulose in place of sucrose. If a fungus is to grow well here it must make use of the cellulose; those that cannot will be excluded or grow only very poorly. The possibilities here are almost unlimited, except that when using agar media it is usually necessary to use a "synthetic medium" so that the nutrients that are being modified are known. Because of impurities in the agar, at least some growth of fungi not utilizing the specific ingredient will usually be obtained. These can often be recognized by their sparse growth.

Dr. Barron, in his highly interesting book on eelworm-trapping fungi (Barron 1977), describes a novel medium. He starts a culture of eelworms growing by feeding them dried pea soup and, when they became abundant, adds a little soil. Those fungi that can trap eelworms start to grow and finally dominate the plate. Here the eelworms are the selective nutrient upon which the soil is plated.

There are few organic substances that cannot be metabolized by at least one mould. We can thus prepare media with unusual substances and expect to isolate moulds. Several years ago I made a medium composed of little more than the amino acid tyrosine and isolated a fungus for which I had to describe a new genus and species! The substance one is interested in can be added directly to the medium or a water infusion of a particular substance can be made and agar then dissolved in it.

One commonly used infusion medium is prepared with hay. First 2.5 grams of dry hay are added to 1 litre of water and boiled for 15-20 minutes; then the mixture is strained through cheesecloth, 20 grams of agar are dissolved in the mixture, and it is sterilized as usual. The resulting medium is fairly weak and discourages many fungi that need a rich sugary medium, while encouraging those that are often reluctant to sporulate. Dung infusion agar is prepared in a similar way, but is instead made with 20 grams of dried horse or cow dung. Some materials, such as dead oak leaves or pine needles, will yield an infusion that is toxic to some fungi and not others, resulting in a medium that selects for fungi occupying those materials naturally.

Selective temperatures

Moulds that grow easily at room temperature are said to be *mesophilic*. Most fungi are mesophilic and are inhibited or killed at unusually high or low temperatures. There are some, however, that actually *require* unusual temperatures. Moulds requiring high temperatures (40°C or more) are said to be *thermophilic*, and those requiring low temperatures (15°C or less) are *psychrophilic*.

In searching for these fungi we simply incubate our plates or moist chambers at the appropriate temperature and isolate the moulds that develop; all isolates and subsequent transfers must be grown at their optimum temperature as well. Bird nests, for example, yield abundant thermophiles when incubated in a moist chamber at 45-50°C, while rabbit dung or compost materials produce several psychrophiles in moist chambers incubated at 0-5°C. The thermophilic forms are amazing for their rapid growth and are, in fact, the fastest growing of all fungi. Some psychrophiles can also grow quickly, however, proving that temperature is not the only factor contributing to rapid growth. Some thermophilic fungi, or at least those that can grow at 37°C, may cause serious infections in man and animals. In working with them, care should be taken to see that they are not exposed to air currents. I do not recommend the isolation of thermophilic fungi in situations involving large groups of students.

Osmophily

Many stored products, such as grain, museum specimens, and hides, undergo degradation by moulds. Most of us have also experienced mould growth on materials stored in damp places at home. Both phenomena are caused by fungi that can withstand unusually dry conditions. Such fungi are said to be *osmophilic*, a term that refers to their prevalence in environments of high osmotic potential. I have already discussed some of the osmophilic fungi in the section dealing with moulds on foodstuffs and will concentrate here on their isolation.

Osmophiles occur on relatively dry or sugary substances in the home. Most of the fungi encountered on old cloth or leather materials in the basement are osmophiles as are the moulds growing on the surface of jams and jellies. They are abundant enough in the home that they can be isolated simply by opening a Petri plate for 2 or 3 hours in the basement or kitchen. The critical thing is the medium within the Petri plate. Osmophilic fungi grow poorly on normal culture media and often sporulate abnormally or not at all. To isolate them the water actvities of media must be drastically decreased. This means increasing the sucrose in Czapek's Agar from 20 g per litre to 200-500 g per litre, or adding 200-500 g of maltose to each litre in Leonian's Agar instead of the usual 6.25 g. For the identification of osmophilic *Eurotium* species, most books will require them to be grown on Czapek's or malt agar with 40% sucrose or on media containing large quantities of glycerine.

Another excellent source of osmophilic fungi is dried fruit. Many producers, however, treat these products with non-toxic fungicides and effectively exclude most moulds. A sampling of dried fruit from several sources may be rewarding, since some may still be productive. As far as is known, the fungi on dried fruits do not produce toxins.

It appears that the seed caches of certain rodents may be good sources of osmophilic fungi, but this habitat has not yet been adequately explored.

Spore printing

Most ascomycetes and basidiomyces and some other moulds are able to eject their spores forcibly. We can take advantage of this property to isolate these fungi by suspending them over an agar surface and allowing the spores to be shot down on it. For mushrooms and bracket fungi a piece of the gill or tube tissue can be attached, perpendicular to the agar, on the lid of a Petri dish. The spores will then float down on to the agar surface and later germinate (if one is lucky). With large mushrooms it is sufficient to attach a single gill, flat side down, to the lid; with small ones the whole cap can be stuck on. We usually petroleum jelly as an adhesive in our laboratory, but other things, such as masking tape or an agar block, may work as well.

Ascomycetes, such as cup fungi, can also be suspended above an agar surface for spore printing. Some of them, however, are so small that they have to left attached to the material they are growing on and that stuck down as well. The problem of contamination from loose particles dropping down then arises, however, which can be avoided by turning the plate over and letting the spores shoot up. Most ascomycetes can shoot their spores far enough to reach the lid of a Petri dish, but basiomycetes cannot.

Suspending an open Petri dish over a moist chamber can be a good way to trap ascomycetes, particularly from dung. Be sure, though, that the agar does not touch the sides of the chamber of the material within. It is also wise to exclude any air currents that might carry spores upward to the agar.

Interesting isolations can be made from Petri plates that have been opened and inverted over soil, logs, and other materials in the field, if proper care is taken to exclude air currents.

HOW MOULDS ARE GROWN

Anyone who has to deal with moulds will sooner or later want to grow them. Identification of moulds most often depends upon observing their methods of spore production, which are not always obvious in the natural habitat. Often identification becomes so difficult that it is necessary to send a specimen to a distant university or government laboratory. Such specimens should preferably be sent as living colonies that can be grown out at the identifier's convenience. Even when the mould can be identified in its natural habitat one may still want to cultivate it - to get more material for study perhaps, or to learn something about its physiology.

Whatever one's reason for growing moulds, one needs to understand a few things about their nutritional requirements before starting. Moulds, like people, need a source of energy, a source of nitrogen, a few minerals, and sometimes vitamins. Some moulds are rather specific as to the source of these materials, and, like people, must have them in rather complete forms. In contrast, many fungi can supply all their nutritional needs from very simple materials and construct bit by bit all the highly complex molecules they need. If man has such abilities, he would be able to drink a paper cup full of a simple seawater solution, eat the cup, and go off to work confident that he had eaten a square meal!

Media

Whatever a particular mould needs, it must always be supplied with some form of organic carbon for energy, a source of nitrogen for protein and vitamin synthesis, and several minerals. The substance on which a mould is grown in the laboratory is called a *medium* and the mould growing on it, a *culture*. Culture media can be solid or liquid, depending on the sort of information one wishes to obtain. For the purposes of identification, solid culture media are usually more useful, as they allow the mould to sporulate more easily.

Solid media

Most culture media are prepared by dissolving the necessary nutrients in water, to obtain a balanced solution supplying everything the mould needs for growth. Preparation of solid media involves dissolving a solidifying agent in the solution that will harden to a gel upon cooling. In the past gelatin was used for this purpose, but is was soon found that gelatin, a protein, itself could serve as a nutrient for some fungi. As they grew on the gelatin, these fungi would cause it to liquefy, thus destroying the solidity of the medium.

Since the 1880s, a substance called *agar-agar* (or, more commonly, just agar) has been the solidifying agent of choice. Agar has the property of dissolving at a fairly high temperature (nearly that of boiling water) but solidifying at about 45°C. Thus, it can be poured over living fungi without killing them, yet can be used for organisms that grow at high temperature.

Agar is relatively stable and cannot be consumed by most organisms, aside from a few specialized bacteria. It is extracted from certain marine algae or kelp by a complex industrial process. It is fairly expensive these days, but extensively used in various food and industrial products, as an emulsifier, thickener, or jelling agent.

Most culture media fit into one of three categories: (1) synthetic, (2) semi-synthetic, and (3) natural. Synthetic media are composed of ingredients of known chemical composition and concentration. These media are useful in physiological or descriptive studies when it is necessary to duplicate exactly a previous batch of medium or to record the effects of the deletion or addition of a particular substance. Few fungi show their best growth on synthetic media; they must sacrifice speed in order to build their necessary cell components from relatively simple materials. However, many produce the sporulating structures necessary for identification more easily on synthetic media than on other kinds.

Semi-synthetic media resemble synthetic media in containing a known set of ingredients, but differ in that at least some of the ingredients are of unknown or variable composition. A synthetic medium, in which all ingredients are chemically defined, can be made semi-synthetic by adding a substance such as yeast extract. We know that the yeast extract contains thiamine and other vitamins, but we do not know the exact amounts or what else might be present. The result is a medium of quite predictable composition but one not completely known chemically. Semi-synthetic media are widely used in routine work and offer something of a compromise between synthetic and natural media.

Natural media are so called because they are partly or completely composed of natural materials, such as ground-up (or whole) plants or animals. A slice of potato is a natural culture medium, as is a piece of meat or bread. Some natural media may consist of a synthetic medium augmented by tomato juice, carrot strips, or plant stems. Natural media are often very good and allow sporulation in fungi that may otherwise remain sterile. Their major disadvantage is that they may differ considerably from batch to batch and thus not yield reliable experimental results. Nevertheless, natural media are widely used in laboratory work and cannot be replaced by any other kind.

Liquid media

Liquid media are employed in laboratory work when the entire colony must be recovered for weighing or chemical extraction. They are also useful when the culture medium itself is to be analysed for chemical changes. For identification purposes, liquid media are seldom chosen because few moulds sporulate well on them. The exception is in work with yeasts, a group of fungi especially adapted to liquid environments.

It has often been pointed out that any medium containing agar is at best a semi-synthetic medium. Agar contains numerous mineral elements and cannot conveniently be purified, even by repeated washings. Thus, for physiological studies, liquid media should be used.

A few useful media

The media described below have been chosen because they represent a sample of the variety of types used by mycologists. There are, however, many additional media; persons interested in pursuing this matter further should consult the more specialized literature.

Synthetic

Czapek's Solution Agar	
Sucrose	30 g
$NaNO_3$	3.0 g
K_2HPO_4	1.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g
KCl	0.5 g
$FeSO_4 \cdot 7H_2O$	0.01 g
Agar	15 g
Distilled water	1000 ml

Czapek's Solution Agar is a synthetic medium widely used in mycological laboratories, particularly for the identification of species of *Aspergillus* and *Penicillium*. Many moulds produce very characteristic colonies on it and may also exude pigmented substances. Aerial growth is often suppressed and sporulation may be enhanced. Some moulds, however, grow poorly on this medium and may even fail to sporulate altogether, often because of their inability to synthesize vitamins. Many members of the Zygomycota are unable to process sucrose or nitrates and will do very poorly on Czapek's. The high glucose level may also cause problems. As noted above, the addition of agar to this medium makes it, in reality, a semi-synthetic one.

***Penicillium* Reference Medium**	
Glucose	9.1 g
Tris buffer, adjusted to pH 8.0 with HCl	606 mg
KNO_3	425 mg
KCl	485 mg
$MgSO_4 \cdot 7H_2O$	493 mg
$CaCl_2 \cdot 2H_2O$	44 mg
$NaH_2PO_4 \cdot H_2O$	28 mg
$FeCl_3 \cdot 6H_2O$ chelated with 8.5 mg of disodium salt of EDTA	6.2 mg
H_3BO_3	6.11 mg
$MnCl_2 \cdot 6\ H_2O$	366 Ág
$ZnSO_4 \cdot 7\ H_2O$	461 Ág
$Na_2MoO_4 \cdot 2H_2O$	14.5 Ág
$CoCl_2 \cdot 6H_2O$	23.8 Ág
$CuSO_4 \cdot 5H_2O$	20 Ág
Thiamine chloride	20 Ág
Biotin	1 Ág
Vitamin B_{12}	1 Ág
Agar	15 g
Distilled water	1000 ml

The medium is prepared as three stock solutions that can be stored and later combined to form the final mixture. The solutions are:

1. Major salts stock: 4.85 g KCl, 4.93 g $MgSO_4 \cdot 7H_2O$, 0.441 g $CaCl_2 \cdot 2H_2O$, 0.88 g NaCl in 1 litre

2. Buffer stock : 60.6 g/l Tris adjusted to pH 7.8 with HCl.

3. Micronutrients + vitamins stock: One litre stock prepared by mixing 5 ml each of 54.4 g/l $NaH_2PO_4 \cdot H_2O$, 12.6 g/l $FeCl_3 \cdot 6H_2O$ chelated with 17 g/l of disodium salt of EDTA, 12.2 g/l H_3BO_3, 732 mg/l $MnCl \cdot 6H_2O$, 922 mg/l $ZnSO_4 \cdot 7H_2O$, 29 mg/l $Na_2MoO_4 \cdot 2H_2O$, 47.6 mg/l $CoCl_2 \cdot 6H_2O$, 40 mg $CuSO_4 \cdot 5H_2O$, 40 mg/l thiamine chloride, 2 mg/l biotin, 2 mg/l vitamin B_{12}.

The complete mixture contains in a final volume of l litre: 15 g agar, 100 ml each of major salts and micronutrient stocks, and 10 ml of buffer stock.

This medium was formulated by Dr. I. Ahmad for the cultivation of *Penicillium* species. Although it appears at first glance to be a complicated and difficult medium it is usually prepared from three stock solutions and does not take as long as one might expect. It can be modified in several ways to assess the physiological activities of moulds. Most commonly different sources of carbon are substituted for glucose and different nitrogen sources for nitrate. As formulated above,with nitrate as a nitrogen source, it may be unsuitable for certain fungi, such as many Zygomycota, unable to utilize nitrates. In such cases it may be better to use ammonium salts, although this may result in dramatic plunges in pH. Again, to be truly "synthetic", the medium should be used without agar.

Semi-synthetic

Modified Leonian's Agar	
Maltose	6.25 g
Malt extract	6.25 g
KH_2PO_4	1.25 g
Yeast extract	1.0 g
$MgSO_4 \cdot 7H_2O$	0.625 g
Peptone	0.625 g
Agar	20 g
Distilled water	1000 ml

Leonian's medium was devised by the American mycologist L.H. Leonian, and was designed to promote sporulation in certain moulds. Later, at the University of Toronto, R.F. Cain found it to be more suitable for ascomycetes if it contained a little yeast extract; hence the term "modified" in its name. It is a good general purpose medium that will yield good growth with most fungi. Certain fungi, such as many mycorrhizal forms, will not grow on Leonian's Agar because they are unable to use maltose as an energy source. For these fungi we use Modified Melin-Norkran's medium, which has a glucose energy component.

Potato Dextrose Agar	
Thinly sliced, peeled white potatoes	500 g
Glucose	20 g
Agar	15 g
Distilled water	1000 ml

Heat potatoes at 60°C for 1 hour and filter through cheesecloth. Make up volume to 1000 ml and add other ingredients. Cook 1 hour and then sterilize.

Potato Dextrose Agar, or PDA, as it is usually called, is an old formula used by plant pathologists and many mycologists for general laboratory use.

Sabouraud's Agar	
Glucose	40 g
Peptone	10 g
Agar	15 g
Distilled water	1000 ml

This is the standard medium used in medical mycology. It is probably no better for these moulds than Leonian's or PDA but is simply the traditional choice and thus the medium that must be used if colonies are to be compared with those described by medical workers. It can be used as a general laboratory medium in place of Leonian's or PDA, although the amount of glucose is rather high and may suppress sporulation in some fungi.

Martin's Rose Bengal Agar	
Glucose	10 g
Peptone	5 g
KH_2PO_4	1.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g
Streptomycin	30 mg
Rose bengal	30 mg
Agar	15 g
Distilled water	1000 ml

Ten millilitres of a 3.3 g/l stock solution of rose bengal is added to the medium after the other ingredients (except the streptomycin) have been dissolved. After sterilization, the streptomycin is added to the cooled medium.

This medium is useful in plating techniques (see below) when the aim is to slow down the growth of colonies in a mixed culture. It discourages the growth of bacteria and certain other organisms so that they will not swamp isolates from natural materials.

Dextrose-peptone-yeast extract Agar (DPYA)	
Glucose (dextrose)	5.0 g
Peptone	1.0 g
Yeast extract	2.0 g
NH_4NO_3	1.0 g
K_2HPO_4	1.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g
$FeCl_3 \cdot 6H_2O$	0.01 g
Oxgall	5.0 g
Sodium propionate	1.0 g
Chlortetracycline	30 mg
Streptomycin	30 mg
Agar	20 g
Distilled water	1000 ml

DPYA is an excellent medium for isolating fungi from soil and other natural substrates. The oxgall and sodium propionate restrict the growth of some rapidly spreading fungi, while the chlortetracycline and streptomycin discourage bacteria. It can also be prepared as a more general-use medium by omitting these four inhibitory substances.

Natural media

V-8 Agar	
V-8 vegetable juice	200 ml
$CaCO_3$	3 g
Agar	20 g
Distilled water	1000 ml

The V-8 juice used in this medium probably contains many nutrients that fungi can use, but we have little idea what they may be. It is a medium that is used routinely in plant pathology and seems to be a good complement to Leonian's or PDA. Moulds that fail to sporulate on those media often sporulate heavily on V-8, or vice versa.

Weitzman and Silva-Hutner's Agar	
Alphacel cellulose powder	20 g
Pablum baby oatmeal	10 g
Hunt's tomato paste	10 g
KH_2PO_4	1.5 g
$MgSO_4$	1.0 g
$NaNO_3$	1.0 g
Agar	20 g
Distilled water	1000 ml

Weitzman and Silva-Hutner's medium was designed to enhance sporulation in certain medically important fungi, but is useful for a great many other moulds as well. I have found it to be a good (and often better) substitute for V-8 Agar and use it routinely in my laboratory. I grow most of my moulds on both Weitzman and Silva-Hutner's and Leonian's Agar and find very few that fail to sporulate on one or the other. Although the original formula calls for a final pH adjustment, I seldom do this and yet get good results.

Preparation of media

Mixing

Culture media are not hard to prepare, even under relatively primitive conditions. It is often easiest to dissolve the agar separately in hot water and then add the other ingredients. The agar burns easily when it is heated, so it is best to avoid putting it directly on the stove or hotplate. I usually put the agar in a flask of water and then immerse this in a boiling water bath. After an hour or so the agar will be dissolved and the solution will be clear. Some people do not worry very much about whether the agar is completely dissolved or not, but to avoid an uneven batch it is best to be patient.

Once the agar is dissolved the rest of the ingredients can be stirred in; they must be completely dissolved as well. Some ingredients, of course, do not dissolve and must be mixed in suspension as thoroughly as possible.

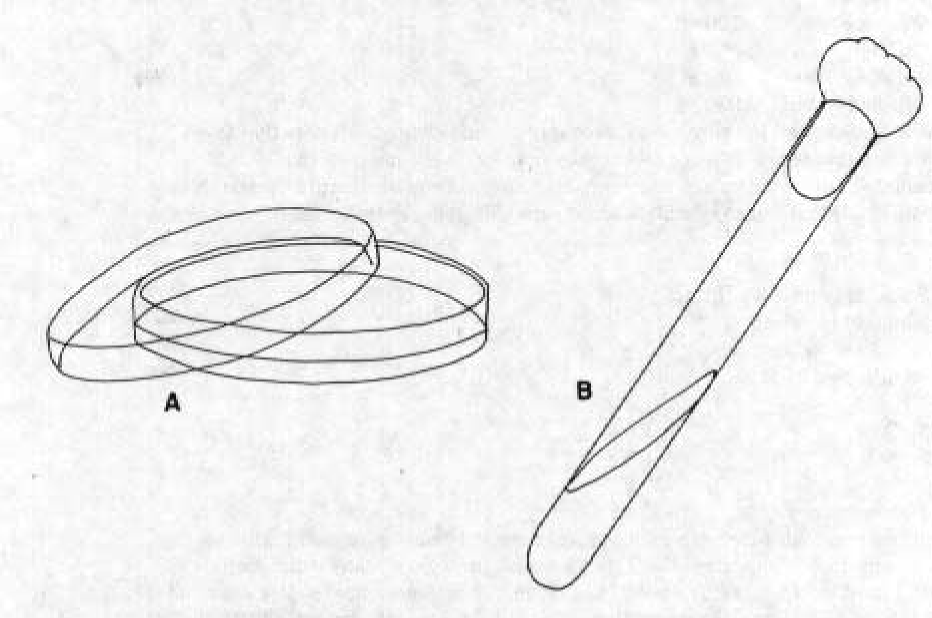

Figure 9 - Glassware for cultivating moulds.
A: Petri dish with lid partly removed.
B: test-tube with agar slant.

When the medium is completely mixed it must then be prepared for sterilization. Here one must stop and decide what use is to be made of the finished product. If fresh isolates are to be made from natural materials or some mould we already have is to be studied, we will probably want to use Petri dishes (Figure 9A). Petri dishes are small, round dishes, most commonly 9 cm in diameter, that have a bottom and a loosely fitting top that will admit air but discourage entry of foreign spores. They are the most commonly used vessels for growing moulds and are available either in permanent glass or disposable plastic form. The plastic plates are already sterile when bought, but the glass ones must be heated in the oven at 230°C (450°F) for 60 minutes, to kill all foreign organisms and spores, before they can be used. But more about Petri dishes later.

It is often necessary to save cultures for later use, or for mailing, in a way that they are less vulnerable to contamination by airborne spores. The conventional method is to use test-tube or bottle cultures that have only a narrow opening (Figure 9B). The culture medium is poured into the tubes, sterilized, and allowed to solidify at about a 30° angle. When cool, the agar inside has a smooth slanting surface for the colony to occupy. The tube or bottle is capped with a cotton plug that is just tight enough for the tube to be lifted without it coming out. In place of cotton a screw cap or one of several tube-capping devices can be used.

With the use of medium in mind, one can now proceed to prepare it for sterilization. If it is to be used in Petri plates it should be transferred into smaller containers that will make it easy to pour. It is impractical to sterilize filled Petri plates, so we pour them after sterilization. If the medium is to be used in tubes, they should be filled before sterilization and slanted afterwards. Sometimes it is advantageous to save sterilized medium in larger bottles and melt it down later to pour plates.

Sterilization

Sterilization is most often done in some kind of apparatus that will allow steaming at high pressures. In the laboratory we usually use a large sterilizer called an *autoclave*, but a simple pressure cooker works well, provided it has a pressure gauge. Most fungi and other organisms can be killed by boiling water, but there are a few, notably bacteria, that have highly resistant spores requiring sterner means. To be sure of killing *everything*, we sterilize at 121°C (250°F) for 20 minutes. To obtain this temperature the pressure must be raised to 1 kg/cm^2 (15 lb per $in.^2$ or 1 atmosphere).

When medium is sterilized in an autoclave it should not completely fill its container. Attempting to sterilize 1 litre of medium in a 1-litre flask will usually result in sudden and rather explosive boiling when it is removed from the autoclave. It is best not to fill the container more than half full. Inexperienced mycologists often assume that the 121°C for 20 minutes rule applies in all situations. However, not all materials will heat up enough to be sterilized in 20 minutes. It is an unpleasant surprise when a litre of medium becomes contaminated with bacteria because the person doing the sterilization attempted to do the whole batch in one container and barely managed to heat it to 100°C before the time was up.

After sterilization the medium is allowed to cool and solidify. Petri plates must be poured *before* the medium solidifies but while it is fairly cool. We usually test the medium by holding it against the inner side of the forearm; if it is cool enough to be poured it will not feel too hot. Beware, though of letting it cool too far, lest it solidify in the bottle! Pouring the medium when it is too hot results in unwanted condensation on the lid of the Petri dish.

Tubes, as stated above, should be left to solidify on a slant. Any agar medium that has solidified can be melted by heating in a boiling water bath. Melting of a 1/2-litre bottle of solidified medium will take about an hour if it is submerged well in boiling water. Petri plates dry up rather quickly, so it is often convenient to keep a number of bottles of solid sterilized medium that can be melted and poured when needed. When Petri plates are poured from melted agar, the neck of the bottle should always be heated over a flame first, either alcohol or gas, to kill any stray spore that may be on it.

Cultivation

Sterile technique

Once some Petri plates or tubes of sterile agar have been prepared, cultivation of one's moulds can begin. For the sake of simplicity, let us first suppose that a mould colony is already growing in a Petri dish and must be transferred to another. The essential thing to remember is that the air and all implements exposed to it are contaminated with mould spores and that these would germinate and grow if they got into the sterile plate. The steps we take to avoid this contamination constitute what is called *sterile technique*.

To transfer the culture we do the following:

1. Take an inoculating needle, usually a thin needle or wire at the end of a long pencil-like handle, and heat it in an alcohol or gas flame until it glows bright red (Figure 10A).
2. Allow the needle to cool for about 15 seconds. (A hot needle will kill the mould that is to be transferred).
3. Open the Petri dish containing the culture just wide enough to allow entry of the needle.
4. With the heat-sterilized needle, cut out a small portion of the colony margin. Hyphal tip transfers work best as they are usually the most active parts of the culture; in addition, transfers from the heavily sporulating central portions will result in spores being spread into the air. Especially in medical work,

hyphal tip transfers are essential. The excised colony margin should be only about 1 mm square (Figure 10B).

5. Transfer the square of colony margin to the sterile plate, making sure that the lid is opened only wide enough to admit the needle and make the transfer. Place the block at the centre, withdraw the needle and flame it until it is red hot, to kill all adhering spores and hyphae (Figure 10C,D).
6. Close the lid; label the plate with a marking pen, including name of culture and date. We usually wrap a thin strip of paraffin film around the sides of the plate to cover the opening, but this is not absolutely necessary; just a couple of pieces of masking tape to hold the lid down will do.
7. Leave the culture to grow in a protected place that has as little air movement as possible.

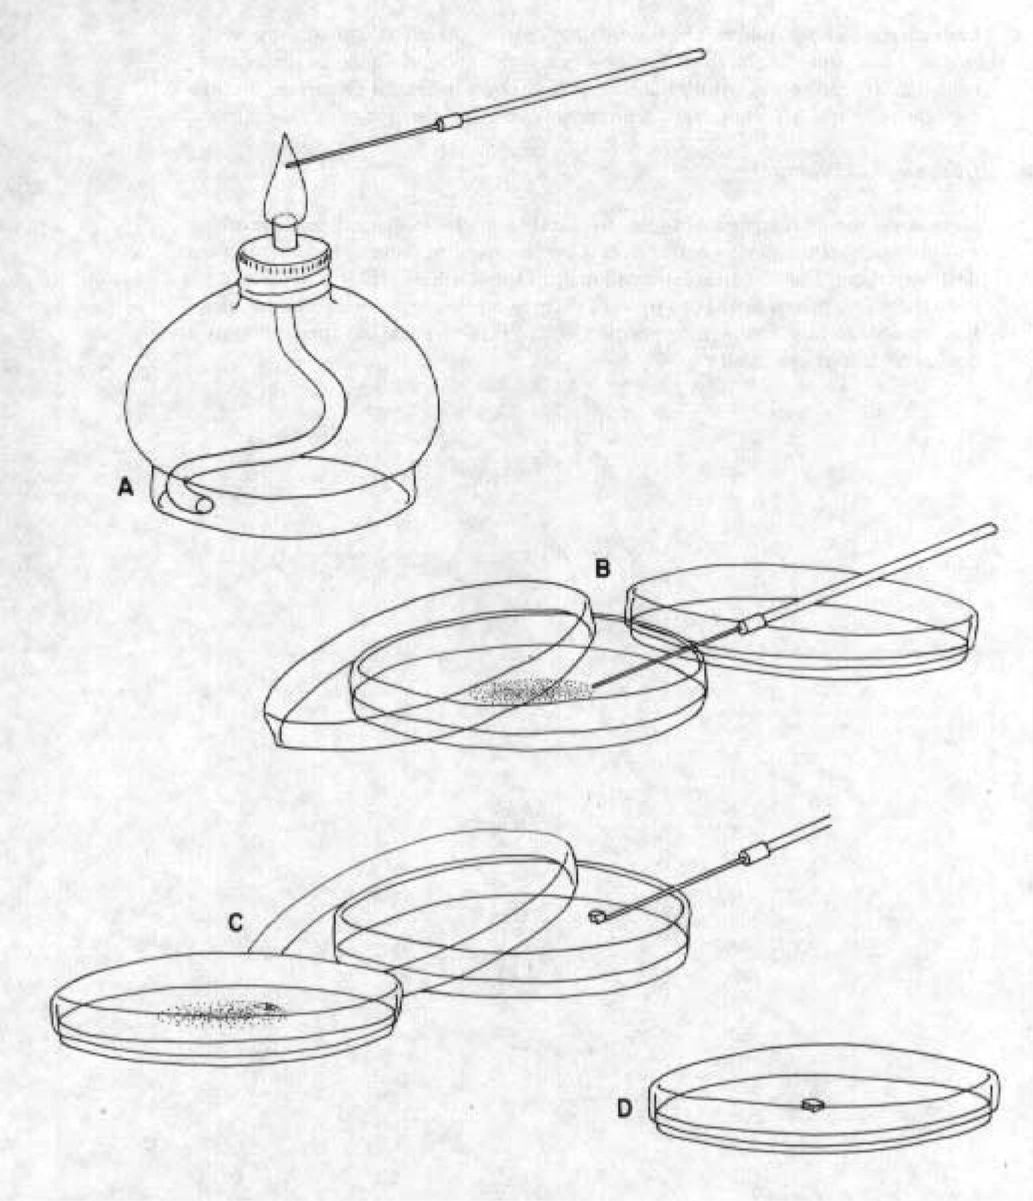

Figure 10 - Steps in sterile technique.
A: Inoculating needle is heated in an alcohol flame
B: Small piece of colony is removed from Petri dish
C: and transferred to a new dish of agar
D: yielding a plate containing a piece of the old culture at its centre.

Transferring from plates to tubes, tubes to plates, or tubes to tubes is done in a similar manner. When using tubes, always flame the mouth to kill any spores of airborne moulds. Never put the cotton plugs or lids of tubes on the table as they will pick up contamination.

The table itself should be clean and can be washed with water, alcohol, chlorine bleach, or other disinfectants. Some spores can survive long immersion in these substances, however, so one cannot thus expect to kill all spores on the table.

Many laboratories are now equipped with special inoculation chambers. Some, such as laminar flow chambers, have a layer of sterile filtered air flowing over the culture that excludes contaminating spores. Some models of such chambers, however, carry the air over the culture and into the worker's face. Such a device is a health hazard and should not be used. Other culture chambers consist only of an enclosed box, open at the front for the worker's hands, containing an ultraviolet light that kills all spores within the box. It is important here to be certain that the ultraviolet light is off while work is under way to avoid the risk of eye damage.

Disposal of old cultures

Since some moulds can cause human disease it is unwise to discard or wash tubes and dishes containing living cultures. It is best to sterilize them as before and then deal with them. Plastic Petri plates will melt in the sterilizer and it is necessary to keep them in a pan or bucket to prevent them from flowing over everything else. It is possible to buy non-melting plastic bags for this purpose, but these are only a convenience, not a necessity.

PREVENTION AND TREATMENT OF CONTAMINATION

The most exasperating problem confronting attempts to cultivate moulds is contamination by other moulds. Most mould spores are very light and easily transported by air. Even opening the lid of a Petri dish for a few seconds may allow the entry of contaminating organisms.

Contaminating agents

The worst contaminants are usually moulds, but bacteria and yeasts can also be a problem, especially when attempting to isolate from natural materials. The slimy or pasty bacterial and yeast colonies grow over the top of young cultures and simply smother them. Many bacteria are motile and "swim" along the mould hyphae, congregating at the end where they can share in the nutrients produced by the enzymatically active hyphal tips.

Actinomycetes may also invade cultures from time to time. In older cultures they may even grow on top of the mould colonies. Actinomycetes usually produce large numbers of spores and can be difficult to eliminate.

One of the worst causes of contamination is mites. Mites are small relatives of spiders and ticks that often feed on fungi. They crawl from one source of moulds to another and in the process carry spores of moulds and actinomycetes with them. Once they get into a culture collection they are extremely difficult to get rid of; usually one must go back and re-isolate all of one's cultures to purify them. The techniques for doing this may be difficult and extremely slow. Sometimes cultures may be lost altogether.

Mites are quite small, sometimes less than 1/10 mm long, and can come in a number of colours. The ones that most commonly get into cultures are white to cream-coloured and move rather slowly. Their eggs, also white, resemble tiny, smooth footballs scattered over the colony surface. All mites have eight legs, are usually covered with scattered bristles, and are often covered with spores.

If you find mites in one of your plates or tubes, separate it from the rest immediately and try to isolate the mould into a pure, mite-free culture. Setting the culture in an airtight box containing a dish of mothballs or paradichlorobenzene for several days will often kill the mites and spare the fungi, although the contaminants brought in with the mites will survive as well. If you have a duplicate culture or do not want the old one, sterilize the contaminated plate or tube, mites and all. I cannot emphasize strongly enough the necessity of keeping mites out of a collection.

Prevention of contamination

Airborne contaminants

The best way to avoid contamination is by cleanliness. Keep the work area as clean as possible, wiping down all surfaces with a 10% commercial bleach solution before starting to work. The major source of contaminants in pure cultures is airborne dust. While cleanliness is essential, it will not completely stop contamination; the cleanest of laboratories will still have problems. The number of airborne spores can be reduced drastically by eliminating as many air currents as possible. Fans, air-conditioners, and all kinds of traffic stir up dust continuously and should be avoided. At least an hour before beginning to work, shut the windows and doors, turn off fans and air-conditioners, and stay out of the room. Such precautions can be effective, even under difficult field conditions.

While transferring plate or tube cultures, open their lids for as short a time as possible. The less time allowed for entry of foreign spores the better. It is also wise to avoid opening Petri dish lids any wider than is needed for the accomplishment of the work in progress. I have seen many students open a Petri dish and put the lid down on the table. This habit is unnecessary and only invites contamination.

Spores sometimes stick to necks of tube cultures and can fall into the tube. For this reason it is wise to flame-sterilize the mouths of all tubes and bottles that one opens.

Contamination from natural sources

When a piece of natural material is put in a Petri dish a mixed culture of two to several organisms will often be obtained. Where one of these is a bacterium the culture can usually be purified by means of antibiotics. Media such as Martin's Rose Bengal Agar are especially designed for this purpose and nearly always inhibit the bacteria.

If moulds are a cause of contamination one of the selective isolation techniques discussed earlier will have to be followed or one of the "decontamination" procedures that follow.

In the initial isolation of fungi, the most important thing is to watch cultures closely as they first develop. Frequently the mould that is wanted will be accessible at first and easily transferred, but will be entirely overgrown by undesirable moulds later. In isolation from fresh material the first 12-72 hours are especially critical; cultures should not go unexamined for more than 15 hours at a time during this period.

Decontamination

The ability to purify mixed cultures is a skill that must be developed by everyone working with moulds. It is also one of the most difficult things to learn, as it requires a good knowledge of both the fungus one wants and those contaminating it. Although I will not be able to cover this subject in the detail required to purify *all* cultures, I can at least lay down some general guidelines.

Purifying cultures can be done in one of two ways: (1) mechanically or (2) chemically. In the first the organism one wants is physically separated from the rest while the second depends on the physiology of the organism. Often it may be useful to use both techniques simultaneously.

Mechanical methods

The simplest means of separating moulds is to spread their apart far enough that the colonies resulting from their germination will not grow together for a time. A common method is to place a spore mixture on the agar on one side of a Petri dish and streak it up and down that side until the spores are evenly spread along a line. The streaking is done with an inoculating wire having its tip bent into a loop so that it will not cut the surface of the medium. Sterilize the loop and do a second streak at right angles to the first along another side of the dish. This results in a second line bearing far fewer spores than the first. Repeat this a third time to yield another line. If it seems necessary, do it a fourth time, but be careful not to streak into the first line. After two or more days one of the streaks will be seen to contain several separate colonies that can be used for transferring. The previous streak will be too crowded and the subsequent one too sparse. This simple technique is the one I use most commonly for purification of mixed cultures (Figure 12).

A similar result can be obtained by using dilutions as described in the section dealing with isolation techniques. It will prove more useful than the streaking technique when the mould that is wanted is greatly outnumbered. Just take a mixture of spores and stir it up in about 10 ml of sterile water. Dilute this down several times and plate out each dilution separately. The ideal dilution will produce a plate containing about 60 colonies, of which at least some will be the desired mould.

When a mould is contaminated with yeasts or bacteria, dilution techniques usually work well. At times, though, yeast or bacterial cells so outnumber the spores of the desired fungus that dilutions are useless. Then it may be helpful to take advantage of the tunnelling or bridging abilities of fungus filaments. A technique sometimes used is to embed glass rings in the medium and surround the contaminated colony. A sterile glass ring, about 10 mm high and 15 mm in diameter, with three "feet" 2-3 mm in diameter glued or welded to the rim on the bottom, is placed on the bottom of a Petri dish. Sterile medium is then poured in to the usual depth, being careful not to overtop or wet the glass ring. After the medium has solidified, the mixed colony is inoculated into the glass ring. The mould filaments will be able to tunnel down under the ring and back up to the surface, while the bacteria or yeast, lacking the forward pressure of hyphae, will be confined to the ring.

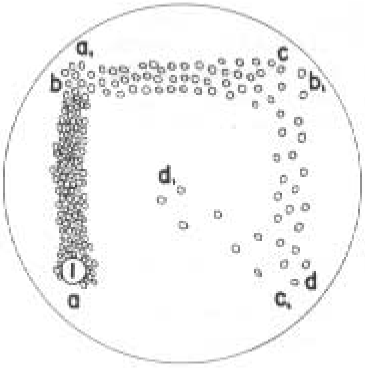

Figure 12 - Streaking technique to separate mould or bacterial colonies. An inoculum of spores is placed on the agar surface at point I and is streaked along the line a-a1 with a sterile wire loop. A second streak b-b1 is made at approximately right angles to the first streak and is followed by a third right-angle streak at c-c1. A fourth streak d-d1 is made into the centre. Each successive streak contains fewer spores and resulting colonies than the one preceding it, finally yielding at d-d1 several widely separated colonies.

The apical growth of mould hyphae can be used to bridge gaps in the medium insurmountable to bacteria and yeasts. A good method to follow is to make a small moist chamber by putting a few layers of wet filter-paper in a Petri plate. Then flame-sterilize a microscope slide, put a square of agar medium near the edge of it, inoculate the agar with the mixed culture, and put the whole thing in the moist chamber. After a few days the hyphae of the desired mould may extend out into the air from the agar block. If they do, place another agar block on a second sterile slide and move it close enough to the first block to contact the aerial hyphae but not the block itself. If one is successful, the hyphae will grow into the new block, leaving the yeast or bacteria behind.

Chemical methods

In some cases, mechanical purification techniques just don't seem to work. If they don't one can take advantage of the chemical or nutritional differences between micro-organisms. The most basic technique is to use antibiotics to discourage bacteria. Most bacteria are sensitive to antibiotics, although no antibiotic will work for all of them. In routine isolation work we use a mixture of antibiotics, most often streptomycin and chlortetracycline at a concentration of 30 and 2 mg/l respectively. Few bacteria are able to grow in such a medium, while most fungi are unaffected. In fact, fungi are so tolerant of these substances that we sometimes just sprinkle a little of the powdered antibiotic right on the agar surface in a Petri plate.

In the formula for Martin's Rose Bengal medium, given in the previous chapter, the rose bengal dye is added because it acts as an inhibitor to the growth of bacteria and many moulds. It can be added to any medium and is often useful in helping to separate otherwise rapidly spreading colonies. Oxgall, used in the formulation of DPYA, serves a similar function.

Most moulds have at least some nutritional preferences that distinguish them from other moulds. These preferences can be used in the purification of cultures if the physiology of the organisms involved is known. Zygomycetes, for example, grow rapidly on glucose or maltose media such as Leonian's and will overgrow everything, but cannot grow on some complex compounds like cellulose. Thus a medium such as Czapek's, with cellulose substituted for sucrose, will put zygomycetes at a distinct disadvantage.

The use of selective media for purification of cultures is so dependent on experience with moulds that it is difficult to generalize. A beginner should experiment with several media to see what will happen. The section on selective nutrients in chapter 5 offers suggestions about specific substances.

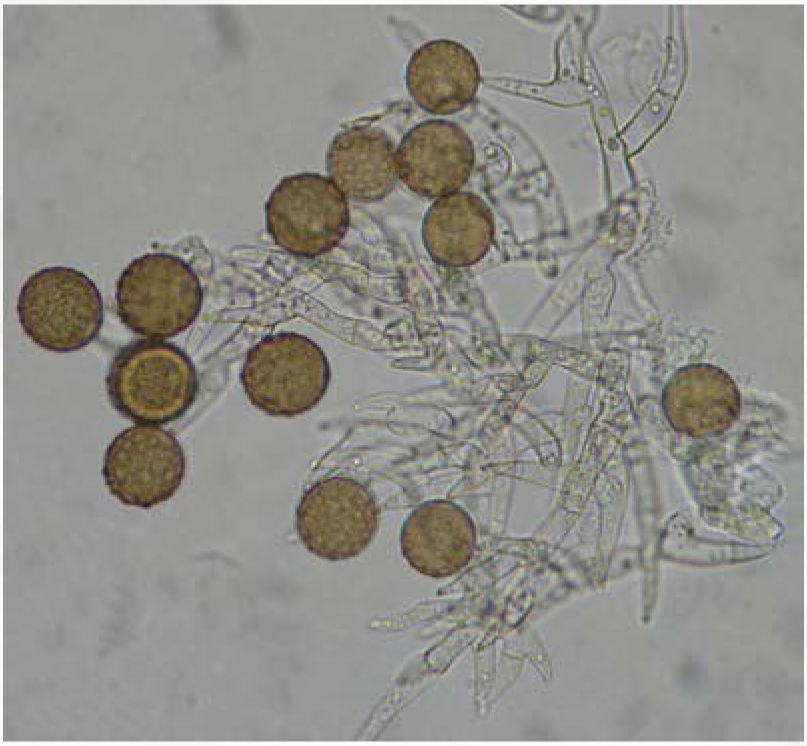
MOULDS UNDER THE MICROSCOPE

There are many good texts on the theory and use of the microscope and I am thus going to assume the reader either has some knowledge of microscopy or can find it. My main interest here is with the particular skills necessary for microscopic examination of moulds.

Preparation of slides

Most beginners find moulds difficult to prepare for microscopic examination. Often preparations seem to contain only spores or mycelium, or structures that are so unlike any of the illustrations available that they are unidentifiable. Most of these problems can be overcome with a little practice and will, in time, seem trivial.

The first rule to remember in mould studies is to examine young, actively growing material. Older parts of colonies or moulds on natural material will often be partially decomposed or so covered with spores as to be unrecognizable. The best way to begin is to examine the growth from the margin of the colony where spores are being actively produced. It may require two or three attempts before the area of active sporulation is located, but when it is all the features of spore production necessary for identification can be seen. If the colony has been in Petri plate with other moulds for several weeks and is no longer actively spreading it will not yield good material for examination.



To make a good microscopic preparation from a mould colony, start by putting a *small* drop of mounting medium on a microscope slide. Microscope mounting media come in a variety of types and will be discussed separately; at the beginning, use water. Then, using a sterilized dissecting or inoculating needle remove a small (no more than 2 mm square) portion of the colony near the margin, taking with it a very thin layer of the agar surface. If the colony is thick and woolly, it may not be necessary to take the agar, but in the more appressed type it is essential. Place the piece of colony in the mounting medium, and, with a second needle, tease it out so that the filaments are well spread. A mount that has not been teased out will appear as an opaque lump yielding little information. Place a cover-slip over the mount, lowering one edge to the slide before the other so that air bubbles can escape. The remaining air bubbles can be removed from the mount by *gently* heating it over an alcohol flame. If it is heated too vigorously, the cover-slip will pop off explosively, splattering fungus and medium into one's face, so it is *essential* to heat it only until its steams slightly, *not* until it boils. The picture of *Harzia verrucosa* above was made from a simple water mount and photographed through the eyepiece of a microscope using a point-and-shoot digital camera. This is usually all that is needed to see what you want.

An interesting technique used by some mycologists for preparing microscope mounts involves sticking the mould to a bit of cellophane tape. The tape is pressed lightly against the colony so that some of the hyphae and spores stick to it. This is then placed *sticky side up* in a drop of mounting fluid (see below) on a microscope slide and covered with a cover slip. This technique is not restricted to colonies in Petri dishes; it works well on naturally occurring colonies in most habitats. The cellophane tape technique is commonly used for sampling moulds in indoor environments.

Slide cultures

Most moulds will yield good results if prepared as outlined above, but a few present extra difficulties. The most problematic are those that tend to disintegrate as soon as they are mounted. Species of *Cladosporium*, *Monilia*, and *Alternaria* have spores connected in very fragile chains that can fall apart at the slightest movement of air. Mounts of these fungi invariably reveal only loose spores and a network of hyphae. To overcome this problem it is useful to set up slide cultures (figure 13). Slide cultures are made by setting up a small Petri dish moist chamber containing a V-shaped piece of glass tubing resting on several layers of moistened filter-paper. A sterile block of agar medium about 1 cm square is placed on a flame-sterilized microscope slide and the slide is then set in the moist chamber on the tubing. The fungus is inoculated near the four edges of the agar block and a sterile cover-slip is put over it. After a few days the slide can be mounted on a microscope, and the undisturbed mould structures viewed as they are growing. Later, if desired, the agar block can be removed from slide and cover-slip and two conventional slide mounts made from them. If they are allowed to dry before this is done, the mould structures are less likely to break apart.

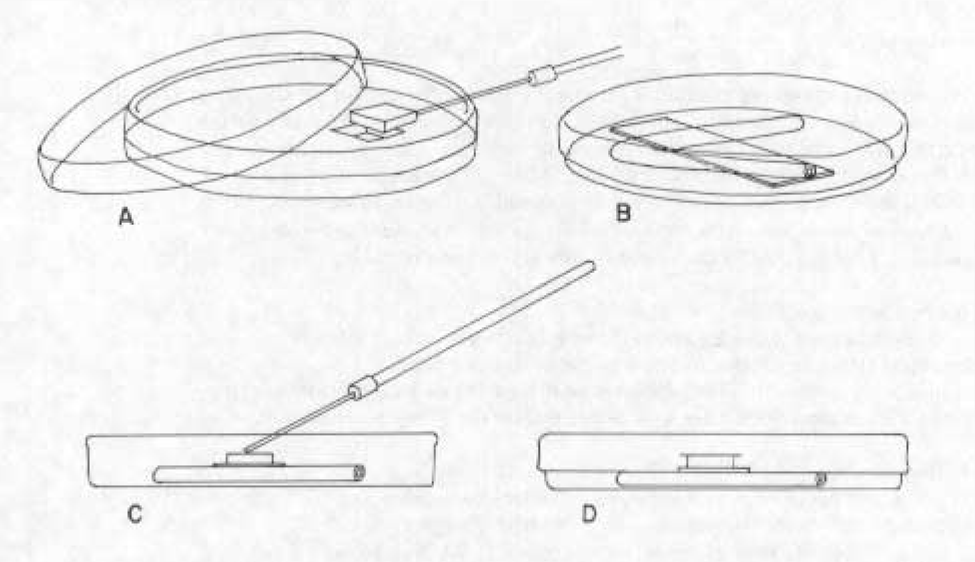


Figure 13 - Slide culture technique. A block of sterile agar is cut out of a Petri dish (A) and is placed upon a sterile slide resting on a bent glass tube within a sterile Petri dish (B). A few spores of a fungus are inoculated at the edges of the sterile agar block (C) and topped with a cover-glass (D) for incubation. A disc of moist filter-paper in the dish maintains humidity for the culture.

Mounting media

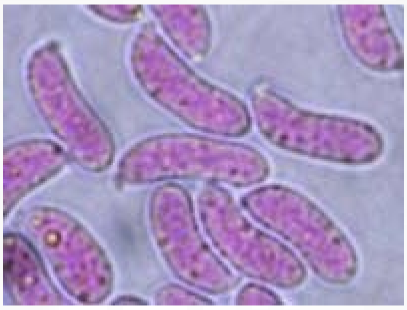
Using water as a mounting medium is easy and is often sufficient for satisfactory preparations. Water mounts dry up quickly, however, and do not allow any particular structures to be seen better than others. To overcome these problems, many different mounting media have been devised. Although the preparation and use of mounting media is a specialized and rather personal matter, there are a few that are in routine use in most laboratories because they offer distinct and well-known advantages. I offer below formulas and comments on some of these.

Water + wetting agent	
Distilled water	100 ml
Wetting agent	A few drops

Several products intended to be used as a photographic wetting agents can be used, eg. Kodak Photo-Flow or Edwal Kwik-wet.

This mounting medium has the advantage of preventing air bubbles from sticking to many fungus structures. I sometimes use it in place of water for making mounts of particularly dry moulds. Many fungi are difficult to "wet", even when a wetting agent is used. For these, I suggest putting them in a drop of 95% ethyl alcohol for a few seconds and then, before the alcohol is completely dried out, adding a drop of the required mounting medium. This often works wonders with the dryest of moulds.

KOH + phloxine	
Solution 1	
Phloxine (a pink dye)	0.025 g
Distilled water	100 ml
Solution 2	
KOH	10 g
Distilled water	10 g



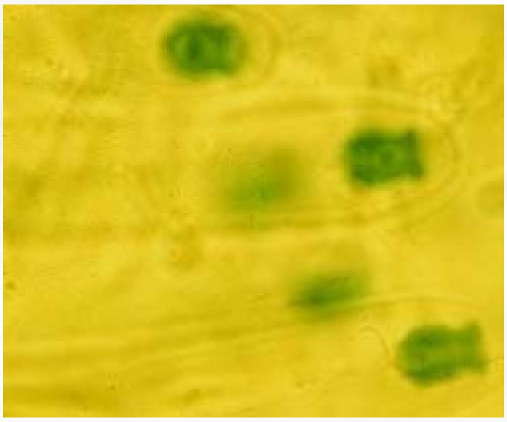
The two solutions are kept in separate dropper bottles. A drop of each is put on a microscope slide and mixed with a needle just before use.

This is a useful staining medium for basidiomycetes and other fungi with compact and difficult-to-spread tissues. The mould hyphae are stained a bright pink colour and are thus more easily seen than in water mounts. It is best to draw as much liquid out from under the cover-slip as possible so that the background colour will be much paler. The picture at right is of basidiospores of *Dacrymyces lacrymalis* mounted in KOH + phloxine.

Lacto-fuchsin	
Acid fuchsin (a pink dye)	0.1 g
Lactic acid (pure)	100 ml

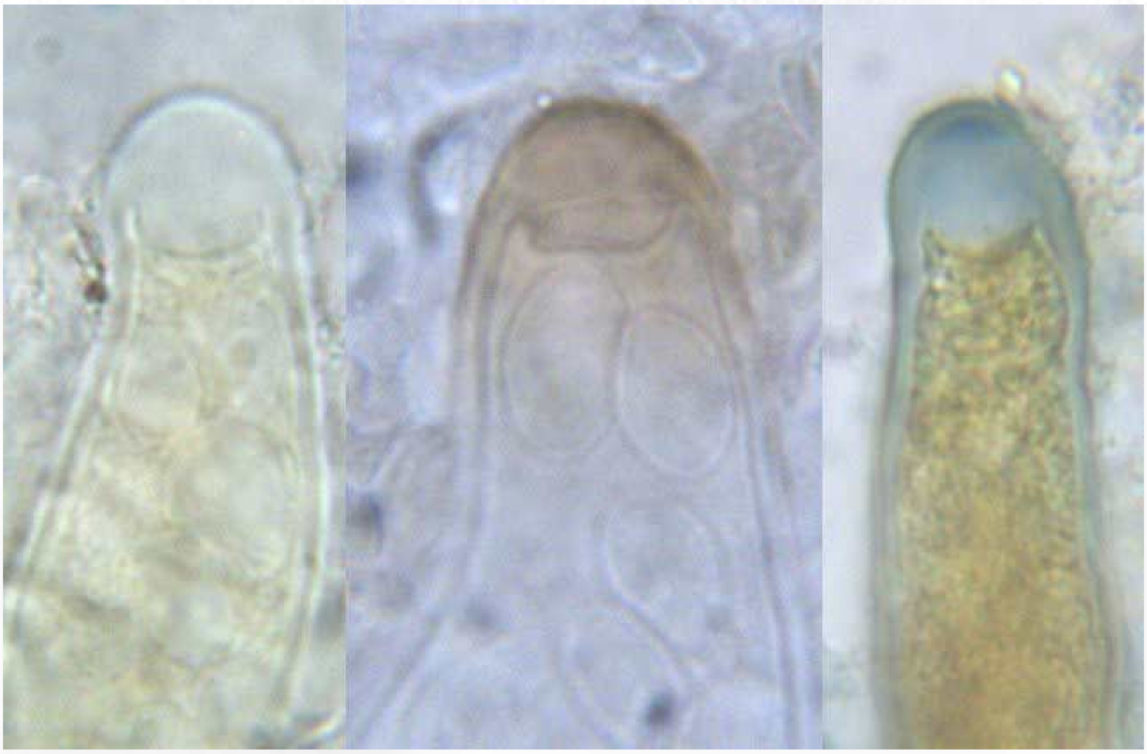
Lacto-fuchsin will not dry up on the slide for several weeks and is thus useful if a slide must be saved for awhile. Drying can be prolonged even further by sealing the edges of the cover-slip with clear nail polish. Lacto-fuchsin is a strong stain that is especially useful for mounts of anamorphs and other easily spread structures.

Melzer's Solution	
Chloral hydrate	100 g
Potassium iodide	5.0 g
Iodine	1.5 g
Distilled water	100 ml



This mounting medium is used extensively in mycology. Certain tissues turn blue to blackish in it and are said to be *amyloid*; others stain red or dark orange and are called *dextrinoid*. In the illustration at right the asci of *Ustulina vulgaris* were treated with Melzer's Solution. The ordinarily clear ascal plugs have stained blue. Melzer's Solution is a good general mounting medium that clears the material somewhat and allows particularly brilliant resolution with a microscope. For good resolution and colour in photographs through the microscope, I make up Melzer's Solution without the iodine, which yields a very clear solution. WARNING: Chloral hydrate should be handled with care as it is toxic. In addition it may be listed as a controlled substance in some jurisdictions, requiring special permission for purchase and possession.

Some mycologists prefer to use iodine-containing mounting media without chloral hydrate. Lugol's Solution (0.5 g iodine, 1.5 g potassium iodide, 100 ml distilled water) and IKI (1.0 g iodine, 3.0 g potassium iodide, 100 ml distilled water) are both substitutes for Melzer's Solution and will produce an amyloid or dextrinoid reaction in many fungi. In fact lichenologists (people who study lichens) routinely use Lugol's and only rarely use Melzer's. The amount of iodine can be varied according to the sensitivity of the group of fungi being studied. Although arguments have been made in favour of all of these media, using them in combination will probably yield the most information.



The photo above shows three asci of *Agyrium rufum*, a fungus commonly encountered on dry branches in sunny locations. The one at left was mounted in Melzer's Solution and yielded no colour changes. The one in the middle was placed in heated 5% KOH solution and then transferred to Melzer's, giving a brown reaction to the ascus tip (perhaps due more to the KOH than to the Melzer's). The one at right was mounted in Lugol's Solution and shows an amyloid apex and dextrinoid contents. This illustration seems to indicate that Lugol's Solution is the best treatment to use, but it's not that simple: many structures can be strongly amyloid in Melzer's alone, as seen in the picture of *Ustulina vulgaris*, or in Melzer's with KOH pretreatment, so only using all three techniques will give a complete profile.

Shear's mounting medium	
Potassium acetate	6 g
Glycerine	120 cc
Ethanol 95%	180 cc
Distilled water	300 cc
Ink Blue	0.1-0.2% by weight

A very good, all-purpose mounting medium that does not dry upon the slide for several weeks. As with Lacto-fuchsin, it can be sealed in with nail polish for even longer life. Ink Blue was not a part of the original formula but is useful as a stain for the walls of certain fungi. The picture at right shows an ascus of a *Claussenomyces* species mounted in Shear's Mounting Medium with Ink Blue. The ascospores and ascus contents have become stained blue while the walls of the ascus remain unstained.

Certain mounting media, such as lacto-phenol, are widely used in mycological laboratories but are very toxic and offer no particular advantages over those listed above.

IDENTIFICATION OF MOULDS

Identification of moulds is based almost entirely on the structures bearing spores and on the spores themselves. Therefore it may be useful for the reader to go back to the beginning and reread the sections in chapters 1 and 2 describing the different kinds of moulds and their anatomy. The process of identification usually involves keys, specialized flow-charts leading to the name of the organism at hand. There are many kinds of keys in use; we present two here, dichotomous keys and picture keys.

Use of dichotomous keys

The most common means of identifying moulds is by the use of a *dichotomous key*, a very clever device presenting a series of alternatives for consideration. A glance at any of the keys that follow will serve as a demonstration. In the key for Group I, for example, there are two choices at number 1, two at number 2, two at number 3, etc., on up to number 14. Each pair of choices represents a decision to be made about the mould which is under examination. In number 1 one has to decide whether the mould's spores are composed of one cell or divided by cross-walls into two or more cells. If they are one-celled, the key sends one on to consider the choice in number 2; if they are more than one-celled, one must go to 12. Eventually the series of decisions will lead to a name.

Most books the reader may wish to use will have dichotomous keys that work in the same way as the ones here. But beware; some authors introduce a third or even fourth, fifth, or sixth choice in their keys that may not be noticed as first!

It is difficult to recommend one or even a few books on identification. The best I can do is direct the reader to a few texts as a good starting points. Ainsworth, Sparrow, and Sussman (1973) and Arx (1981) offer keys to most of the groups of fungi you are likely to encounter. If the mould under examination appears not to be an ascomycete, basidiomycete, or zygomycete, try starting with Barron (1968), Barnett and Hunter (1987), or Carmichael *et al*. (1980). Fungi forming spores in pycnidia can be identified in Nag Raj (1993) and Sutton (1980). For zygomycetes, start with O'Donnell (1979). Domsch *et al*. (1980), a monumental work treating all fungi known to occur in soil, includes keys, illustrations and extensive literature citations. It is an indispensible book for anyone doing serious work with moulds. De Hoog and Guarro (1995), Gravesen *et al*. (1994), Samson, *et al*. (1995), and St-Germain and Summerbell (1996) are beautifully illustrated books, the first and last dealing with fungi of medical interest and the others with fungi found on foods and other human-associated materials. Wang and Zabel (1990), dealing with fungi isolated from utility poles, is a very useful reference for wood-inhabiting fungi. It contains extensive keys and illustrations.

Keys to sixty common genera of moulds

Two approaches are taken to identification in this section: a set of dichotomous keys and a set of picture keys. Which you choose depends upon your individual preference. Some people are verbal in nature and do best when everything is written out; these people usually prefer dichotomous or other types of textual keys. Others are visual and prefer to match what they see to an image. You may even find you do best with a combination of the two.

The dichotomous or text keys

The dichotomous keys are designed to work like the mind of an experienced mycologist, eliminating the most common or most expected fungi first and relegating the less common ones to the end. These are composed of keys to several *groups* of genera. Group I contains the most commonly encountered genera, group II those that are a little less common, and group III those that are less common yet, and so on down to the end. To use the key, start with the key to group I. If you are satisfied that the fungus you are trying to identify is not there, try the key to group II. If that does not work, go to Group III, and so on. The chances are greatest, of course, that the mould you want to identify is in group I, since these are the commonest of all moulds. If your fungus is not among the 60 genera in the whole key, you will have to turn to more complete or specialized books, such as those listed above or in the bibliography.

It should be pointed out that all identifications should be checked against the appropriate description and illustration following the key. It may also be necessary to turn to the references given there. Fungi from one group may be identified incorrectly in the key to another group and only the description and illustration will reveal the mistake. For example, *Paecilomyces* of group II will key out to *Penicillium* in group I, but this problem will only be discovered when checking the descriptions and illustrations.

Go on to the text key for: Group I, Group II, Group III, Group IV, Group V.

The picture keys

These keys are arranged in the same way as the dichotomous keys: that is, the first set of pictures illustrates the most comonly encountered moulds. Those in the second set are also common, but not quite as common as those in the first group. To use the keys, browse over the first group to see if your unknown specimen matches one of the pictures. If you think it fits one of them, click on the picture for further information. If the fit is not very good, go back and try again. If the unknown is not in Group I, go on to Group II.

Go on to the picture key for: Group I, Group II, Group III, Group IV, Group V.

Keys to some common genera of moulds

Group I

1. Spores 1-celled 2.

1. Spores with more than one cell 12.

Usually this is obvious. Occasionally spores may have darkened areas resembling septa, but these will not be visible in optical section when you focus on the centre of the spore.

2. (1) Colonies, spores, and other tissues colourless or brightly coloured 3.

2. Colonies, spores, and/or other tissues dark coloured 8.

The dark colour is either brown or black. The best indication of dark colours comes from looking at the culture itself, either directly or with a dissecting microscope. Under the compound microscope many brown structures will appear nearly colourless.

3. (2) Spores produced in chains 4.

Often chains of spores break apart thoroughly when placed in a water mount. In many species of *Aspergillus* and *Penicillium* a few spores will remain together in a group, so that you can assume that they were originally in chains. On the other hand, species of *Cladosporium* produce chains of spores that completely disassociate on contact and leave no clue about their original orientation. The easiest way to check this is to examine the colony under the 10X objective of a compound microscope, being careful not to get spores on the lens.

3. Spores not produced in chains 6.

4. (3) Conidiophores with a swollen head or vesicle bearing bottle-shaped phialides -»

Aspergillus.

4. Conidiophores not swollen at apex 5.

5. (4) Spores in unbranched chains, borne from clusters of cylindrical to bottle-shaped phialides; colonies usually green -» *Penicillium*.

Compare with *Paecilomyces* (Group II), *Gliocladium* (Group III), *Scopulariopsis* (Group III), and *Talaromyces* (Group IV).

5. Spores borne in branching chains from undifferentiated conidiophores; colonies often very fast growing and pink -» *Chrysonilia*.

6. (3) Spores borne in a sporangium with a columella; often with only the columella evident as a swollen hyphal tip; hyphae not septate -» *Mucor*.

Compare with *Rhizopus* (Group I), *Mortierella* (Group II), *Absidia*, *Circinella* (Group V), and *Zygorhynchus*.

6. Spores produced externally; hyphae septate7.

7. (6) Conidiophores well-developed and usually with a central axis; very fast growing and with conidiophores usually produced in small cushions of hyphae; often green -» *Trichoderma*.

Compare with *Verticillium* (Group II), *Gliocladium* (Group III).

7. Conidiophores poorly developed or lacking; phialides produced singly along the vegetative hyphae; hyphae often aggregated into "ropes"; seldom or never green -» *Acremonium*.

Compare with *Verticillium* (Group II), *Sporothrix* (Group IV), and *Phialophora* (Group IV).

8. (2) Spores in chains, produced externally (9).

8. Spores not in chains, produced inside sporangia or fruiting bodies (pycnidia)Spores not in chains, produced inside sporangia or fruiting bodies (pycnidia) (10).

9. (8) Conidiophores with a swollen head or vesicle bearing bottle-shaped phialides; conidial chains unbranched -» *Aspergillus*.

9. Conidiophores lacking a swollen apex; spore chains often branched; spores often both 1- and 2-celled -» ***Cladosporium***.

10. (8) Spores produced inside a fruiting body (pycnidium) with a cellular wall; hyphae septate -» *Phoma*.

Compare with *Pyrenochaeta* (Group IV), *Microsphaeropsis* (Group IV), and also be sure that asci are not present at a very early stage.

10. Spores produced within a sporangium with a columella, often with only the columella evident as a swollen hyphal tip; hyphae not septate 11.

11. (10) Sporangiophores with rhizoids (branched "roots") at base -» *Rhizopus*.

Compare with *Absidia* (Figure 2B).

11. Sporangiophores lacking rhizoids -» *Mucor*.

Compare with *Mortierella* (Group II), *Absidia* (Figure 2B), *Circinella* (Group V), and *Zygorhynchus* (Figure 2C).

12. (1) Spores with transverse septa only 13.

12. Spores with both transverse and vertical septa 14.

13. (12) Spores dark, produced in branched chains -» *Cladosporium*.

13. Spores colourless or brightly coloured, mostly with more than two cells, often canoe-shaped, usually produced in slimy masses; colonies often pink -» *Fusarium*.

Compare with *Cylindrocarpon* (not treated here), *Candelabrella*, *Monacrosporium* (both Group III), and *Trichophyton* (Group V).

14. (12) Spores usually in chains, usually club-shaped; colonies grey to brown -» *Alternaria*.

Compare with *Ulocladium* and *Stemphylium* (Group II).

14. Spores in clusters but not in chains, usually spherical; colonies often (but not always) bright orange or yellow and purplish in reverse -» *Epicoccum*.

Compare with *Stemphylium* (Group II).

Group II

1. Colonies composed of hyphae, or at least with some hyphae present 2.

1. Colonies lacking hyphae; short chains of "budding" cells may be produced 16.

2. (1) Spores 1-celled 3.

2. Spores with more than one cell 14.

3. (2) Spores and hyphae colourless or brightly coloured 4.

3. Spores and/or hyphae dark coloured 10.

4. (3) Spores produced in chains 5.

4. Spores not produced in chains 7.

5. (4) Spores produced from small clusters of tapering phialides, often rather pointed at the ends -» *Paecilomyces*.

Compare with *Penicillium* (Group I), *Talaromyces* (Group IV) and *Verticillium* (Group II).

5. Spores produced by the simple fragmentation of hyphal segments into individual cells 6.

6. (5) Colonies very slow growing (slower than 5 mm/week), often grey, often with a strong earthy odour; hyphae usually less than 1 µm in diameter -» *Streptomyces*.

6. Colonies growing faster, with a fruit-like odour or odourless, hyphae larger -» *Geotrichum*.

Compare with *Geomyces* (Group IV).

7. (4) Spores produced in sporangia, with sporangia often broken and represented only by simple blunt sporangiophores (no swollen columella); colonies often velvety in texture and pink to brown -» *Mortierella*.

Compare with *Mucor* (Group I) and *Absidia* (Figure 2B).

7. Spores produced externally 8.

8. (7) Spores produced in large numbers and completely covering the surface of large terminal cells; cells of conidiophores often flattening in alternating planes as they dry; colonies often producing black stony sclerotia -» *Botrytis*.

Compare with *Chromelosporium* (not treated here).

8. Spores produced at the tips of terminal cells and never covering them; cells of the conidiophore

not flattening characteristically upon drying 9.

9. (8) Conidia produced in small round masses at the tips of phialides; phialides in whorls, tapering gradually to a very narrow tip -» *Verticillium*.

Compare with *Acremonium* (Group I).

9. Conidia produced singly at the ends of short branches; or in short chains, not on phialides; spore-producing cells not in whorls -» *Chrysosporium*.

Sepedonium and *Trichophyton* (both Group V) and *Geomyces* (Group IV) are similar.

10. (3) Spores produced in sporangia or in fruiting bodies 11.

10. Spores produced externally 12.

11. (10) Spores produced within densely hairy fruiting bodies (perithecia), very dark; asci present when young -» *Chaetomium*.

11. Spores produced in sporangia (Go back to 7).

12. (10) Conidiophores united to form large synnemata that have a sterile base and a spore-bearing upper part, often accompanied by spores of *Echinobotryum* (Group V), -» *Cephalotrichum*.

Compare with *Trichurus* and *Graphium* (both Group III).

12. Conidiophores never united to form such structures 13.

13. (12) Spores arising in dense masses directly from swellings on the vegetative mycelium; colonies usually rather flat and moist -» *Aureobasidium*.

Compare with *Exophiala* (Group III).

13. Spores completely covering the terminal cells of erect conidiophores; colonies cottony and rather dry; black sclerotia often present -» *Botrytis*.

14. (2) Spores with transverse walls only, colourless; colonies white to pink; often associated with eelworms -» *Orbilia*.

Compare with *Trichothecium* (Group V). Species formerly referred to *Arthrobotrys*, *Candelabrella*, *Dactylella*, *Geniculifera*, and *Monacrosporium* also belong here.

14. Spores with transverse and vertical walls, dark brown 15.

15. (14) Conidiophores more or less straight because of their elongation directly through the scar of the previous spore, bearing only one spore at a time -» *Stemphylium*.

Compare with Pithomyces (Group IV).

15. Conidiophores often with a slight zigzag appearance due to new growth from just below the tip, often bearing a spore at each bend -» *Ulocladium*.

Compare with Pithomyces (Group IV) and *Curvularia* (not treated here).

16. (1) Cells very small, seldom more than 1-2 µ in diameter, dividing by simple fission into two equal-sized daughter cells, sometimes containing a single internal spore -» Bacteria.

16. Cells usually larger than 1-2 µ in diameter, dividing by budding, with the daughter cell seen as a small "bubble" arising from the wall of the parent cell, sometimes containing one or more internal spores (ascospores) -» Yeasts.

Compare with Aureobasidium (Group II), Candida and Exophiala (both Group III).

Group III

1. Spores 1-celled 2.

1. Spores with more than one cell 10.

2. (1) Conidiophores united into complex synnemata with a sterile base and fertile upper part 3.

2. Conidiophores solitary, never forming complex structures, sometimes not present 4.

3. (2) Spores produced in a large colourless drop of fluid at the tip of the synnema -» *Graphium*.

Compare with *Pesotum* (not treated here).

3. Spores produced along the sides of the upper part of the synnema, dry, interspersed with loosely coiled hairs -» *Trichurus*.

4. (2) Spores produced in chains 5.

4. Spores not produced in chains 6.

5. (4) Spores brown, produced from a cluster of strongly swollen cells (phialides) -» *Memnoniella*.

(see Stachybotrys)

5. Spores usually grey, tan, or colourless, produced from clusters of bottle-shaped cells (annellides) -» *Scopulariopsis*.

Compare with Penicillium (Group I) and Scedosporium.

6. (4) Spores produced in small clusters at several "nodes" along the length of erect conidiophores

-» *Gonatobotrys*.

6. Spores apical or conidiophores not obviously well-developed 7.

7. (6) Spores borne along the length of the hyphae from apparently undifferentiated cells; colonies white, moist, and flat -» *Candida*.

7. Spores produced at the apex of distinct conidiophores or phialides; colony appearance various 8.

8. (7) Conidiophores small and inconspicuous, usually consisting of short cells or branches functioning as annellides; colonies often black and yeast-like; spores collecting in wet masses at the apex of the conidiophores, sometimes budding -» *Exophiala*.

8. Conidiophores large and conspicuous; colonies never yeast-like 9.

9. (8) Conidiophores unbranched or rarely very simply so; spores arising from an apical cluster of swollen cells (phialides) -» *Stachybotrys*.

9. Conidiophores highly branched; spores borne from clusters of narrow cells (phialides), produced in a slimy mass -» *Gliocladium*.

Compare with *Leptographium* (Group V), *Penicillium* (Group I), and *Scedosporium*.

10. (1) Spores dark brown, rather large, several-celled -» *Bipolaris*.

Compare with *Pithomyces* (Group IV) and *Trichocladium* (Group V).

10. Spores colourless; usually associated with eelworms. Anamorphs of Orbiliaceae go here 11.

11. (10) Spores solitary at the tip of a long unbranched to weakly branched conidiophore -» *Orbilia*.

Species formerly referred to *Arthrobotrys*, *Candelabrella*, *Dactylella*, *Geniculifera*, and *Monacrosporium* also belong here.

11. Several spores on each conidiophore 12.

12. (11) Spores produced along the length of an elongating and more or less zigzag conidiophore -» *Orbilia*.

Species formerly referred to *Arthrobotrys*, *Candelabrella*, *Dactylella*, *Geniculifera*, and *Monacrosporium* also belong here.

12. Conidiophores producing a series of short branches from a single locus (candelabrum-like), with each branch bearing a spore -» *Orbilia*.

Species formerly referred to *Arthrobotrys*, *Candelabrella*, *Dactylella*, *Geniculifera*, and *Monacrosporium* also belong here.

Group IV

1. Spores 1-celled 2.

1. Spores with more than one cell 11.

2. (1) Spores produced within a distinct fruiting body having a hyphal or cellular wall 3.

2. Spores borne externally 6.

3. (2) Fruiting bodies or spore mass brown or black 4.

3. Fruiting bodies and spore mass colourless or brightly coloured 5.

4. (3) Spores brown; fruiting bodies (pycnidia) lacking spines -» *Microsphaeropsis*.

Compare with *Myrothecium* (Group V).

4. Spores colourless or brightly coloured; fruiting bodies (pycnidia) with spines around the apical opening -» *Pyrenochaeta*.

5. (3) Fruiting bodies (cleistothecia) composed of hyphae; usually with an abundant brush-like anamorph -» *Talaromyces*.

Compare with *Gymnoascus* (Group V) and *Arachniotus* (not treated here).

5. Fruiting bodies (cleistothecia) with a distinctly cellular wall; usually with a conspicuous anamorph characterized by bottle-shaped philides borne on a swollen apical vesicle -» Teleomorphs of *Aspergillus*.

Species of *Penicillium* may have similar teleomorphs.

6. (2) Spores distinctly dark brown or black 7.

6. Spores colourless or quite pale 8.

7. (6) Spores usually spherical and roughened, with two hyphal connections; hyphae mostly not septate -» Zygospores of Mucorales.

Usually associated with *Absidia*, *Mucor*, *Rhizopus*, *Zygorhynchus* (similar to *Mucor*), etc. Read about Zygosporangia for a more detailed discussion of how these structures are formed.

7. Spores discoid or egg-shaped, often with a colourless band, usually smooth, with only one connection to the conidiophore; hyphae septate -» *Arthrinium*.

Compare with *Wardomyces* and *Nigrospora* (both Group V).

8. (6) Spores in chains (sometimes interrupted by sterile cells) 9.

8. Spores not in chains 10.

9. (8) Spore chains often characterized by an alternating series of spores and narrow sterile cells (bead-like in appearance); filaments never dark -» *Geomyces*.

Compare with *Chrysosporium* (Group II).

9. Spore chains composed of uniformly cylindrical spores, never with alternating sterile cells; conidiophores often dark -» *Oidiodendron*.

10. (8) Spores borne from the apex of flask-shaped phialides with a flaring collar -» *Phialophora*.

Compare with *Exophiala* (Group III).

10. Spores borne at the tips of somewhat jagged conidiophores -» *Sporothrix*.

11. (1) Spores borne in fruiting bodies (pycnidia), 2-celled -» *Diplodia*.

11. Spores borne externally, with more than two cells -» *Pithomyces*.

Compare with *Trichocladium* (Group V).

Group V

1. Spores 1-celled 2.

1. Spores with more than one cell 11.

2. (1) Spores borne in dense masses within some kind of structure 3.

2. Spores produced externally, never from any kind of compound structure 5.

3. (2) Spores produced inside thin-walled sporangia that are recurved on short hooks -» *Circinella*.

Compare with *Mucor* (Group I).

3. Spores never produced in recurved sporangia 4.

4. (3) Fruiting structure a sporodochium containing a layer of conidiophores; spores in slimy masses, very dark green -» *Myrothecium*.

4. Fruiting structure a cleistothecium containing asci (when young) and ascospores; spores dry at maturity; never associated with phialides -» *Gymnoascus*.

5. (2) Spores brown to black 6.

5. Spores brightly coloured or colourless 8.

6. (5) Spores roughened, with a prolonged apical snout; often associated with *Cephalotrichum* (Group II) -» *Echinobotryum*.

6. Spores smooth 7.

7. (6) Spores usually borne in small clusters, usually egg- or bullet-shaped, with a narrow colourless band (germ slit); may be associated with *Scopulariopsis* (Group III) -» *Wardomyces*.

7. Spores solitary, usually spherical to somewhat flattened spherical, often with a germ slit -» *Nigrospora*.

8. (5) Conidiophores dark brown, densely branched at the apex and bearing the colourless spores in a drop of fluid -» *Leptographium*.

Compare with *Phialocephala*, *Thysanophora*, and *Verticicladiella* (not treated here).

8. Conidiophores colourless 9.

9. (8) Spores completely covering a large swelling at the apex of an erect conidiophore -» *Oedocephalum*.

Compare with *Cunninghamella*.

9. Conidiophores not well-developed and lacking a terminal swelling 10.

10. (9) Spores relatively large, usually spherical, roughened -» *Sepedonium*.

Several fungi produce large sphaerical scultured spores. Important among these are *Histoplasma capsulatum* and some *Mortierella* species. *Histoplasma capsulatum* is a serious human pathogen; if you believe that it is present in your culture; **do not open the lid**.

10. Spores quite small, usually egg-shaped, smooth; often causing skin infections in animals, including humans -» *Trichophyton*.

11. (1) Spores dark (at least some of the cells) 12.

11. Spores colourless 13.

12. (11) Spores with long appendages at the apex, borne in sporodochia -» *Pestalotiopsis*.

12. Spores lacking appendages, not in sporodochia -» *Trichocladium*.

Compare with *Dendryphiella*.

13. (11) Spores 2-celled, produced in chains from the apex of erect conidiophores -» *Trichothecium*.

13. Spores usually with more than 2-cells or irregularly 1- to several-celled, not arising from distinct conidiophores; often causing skin infections in animals, including humans -» *Trichophyton*.

Compare with *Microsporum*.

Acremonium

Acremonium murorum

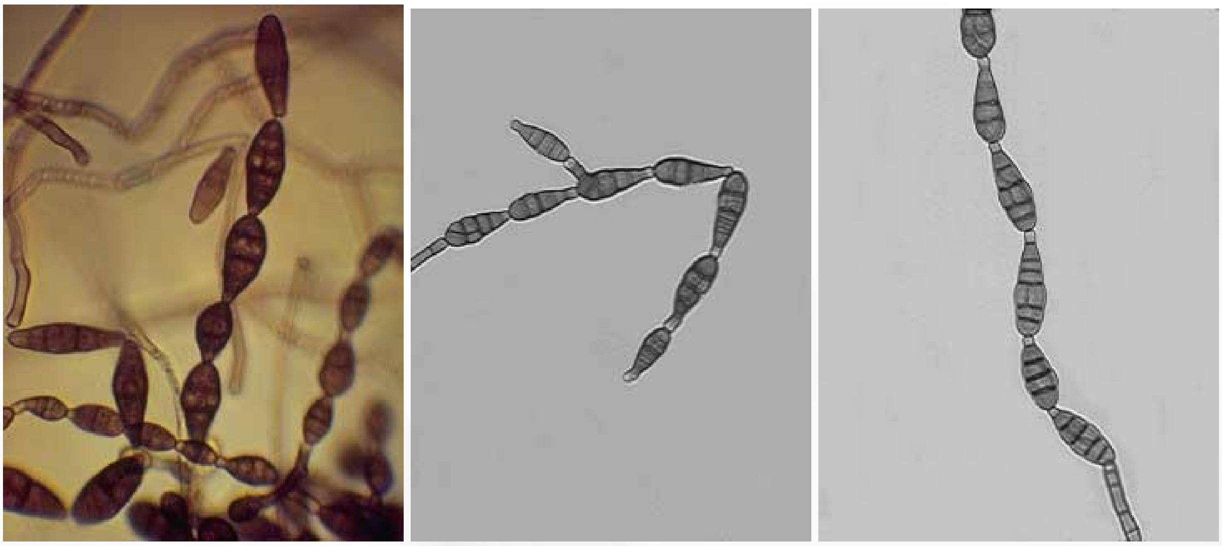
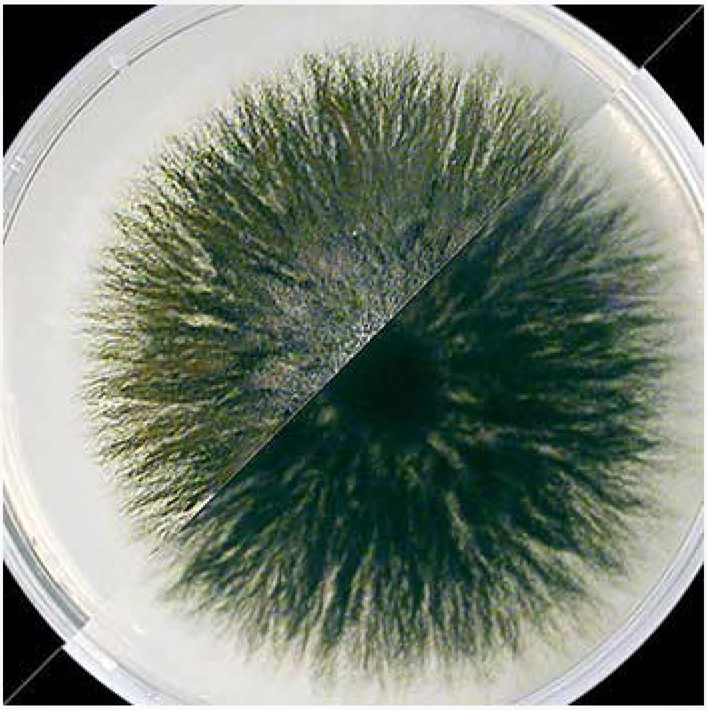
Species of *Acremonium* are recognized by solitary to weakly branched, tapering phialides arising from vegetative filaments and bearing a wet cluster of mostly 1-celled spores (conidia). The filaments are sometimes bound together into "ropes" several cells in diameter. The illustrations here present *Acremonium* in its narrower sense, but a great variety of species have been included in the genus at one time or another. Almost any species bearing colourless or brightly-coloured conidia on rather simple unpigmented phialides might be referred to *Acremonium*. Seifert *et al.* (2011) present a key to no fewer than 50 genera that might be confused with *Acremonium*. Even when taken in its narrowest sense, species of *Acremonium* are nearly impossible to identify without the use of molecular methods.

Common in soil, plant debris, rotting mushrooms, etc. Some appear to be parasitic on living fungi.

Classification: in a narrow sense of *Acremonium* the species are mostly members of the Hypocreomycetidae.
Holomorphs: *Emericellopsis*, *Hapsidospora*, *Leucosphaerina*, *Nectria*, and many others.
Ref: Domsch *et al*, 1980,; Gams 1971.

Alternaria



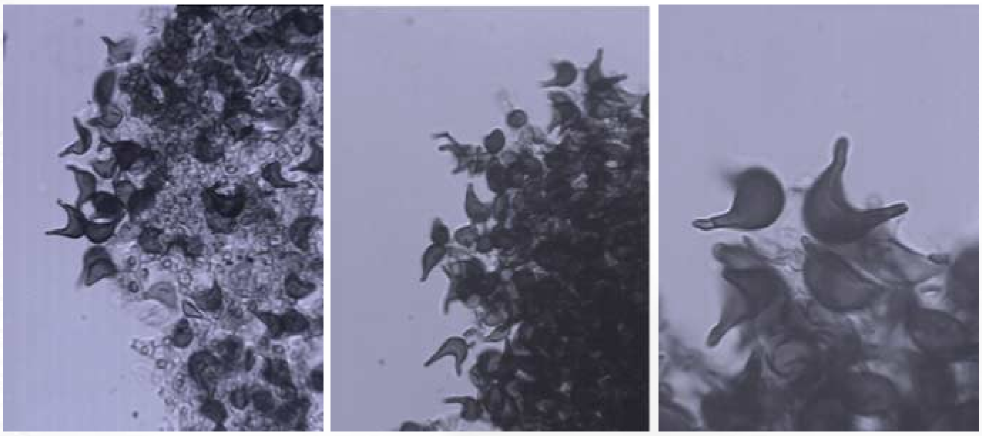


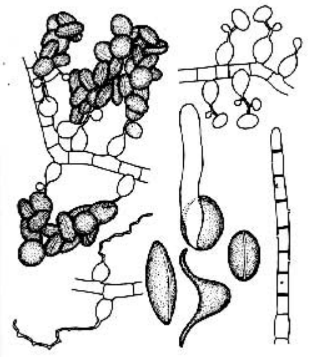
Alternaria alternata - top/bottom

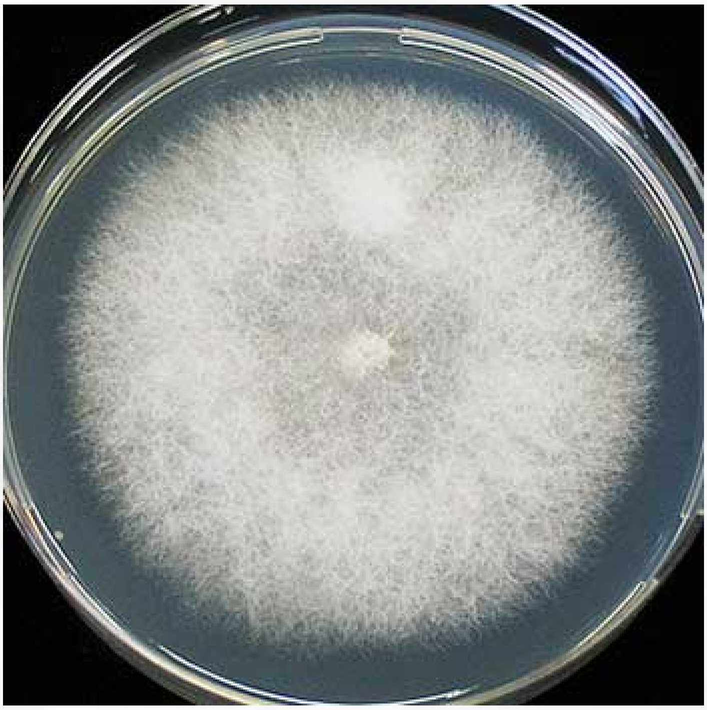
The dark brown spores are borne in simple or branched chains from the tips of simple dark conidiophores and are divided into several cells by transverse and vertical walls. New spores are produced by the extrusion of wall material through a pore at the tip of the previous spore. Commonly isolated from decaying plant materials; also causing plant diseases. Spores of *Alternaria* species are dispersed by air currents and are usually abundant in outdoor air.

Classification: Pleosporales.
Holomorphs: *Clathrospora*, *Comoclathris*, *Leptosphaeria*, *Lewia*.
Refs: Ellis 1971, 1976; Joly 1964; Simmons, 1967, 1981, 1982a, 1982b, 1986a,1986b, 1986c, 1990, 1993a, 1993b, 1993c, 1994a, 1994b, 1995, 1996a, 1996b, 1997, 1998, 1999, 2000.

Arthrinium





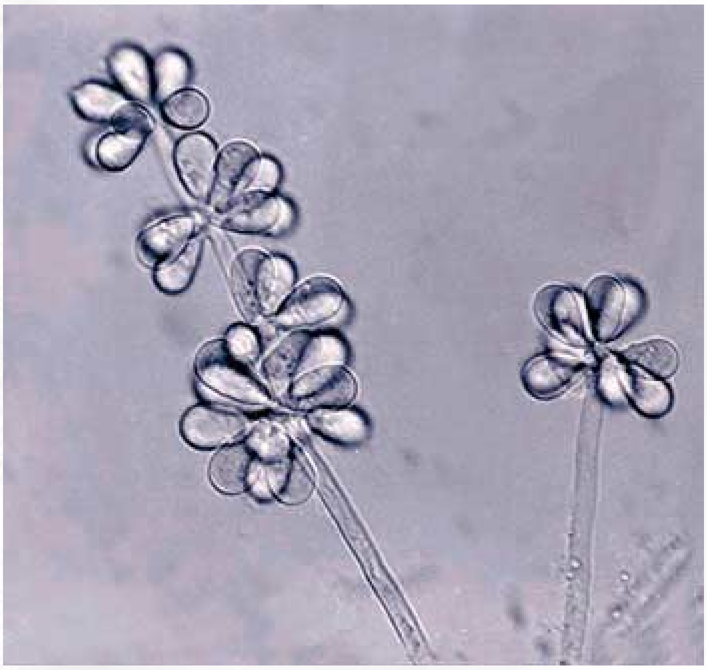


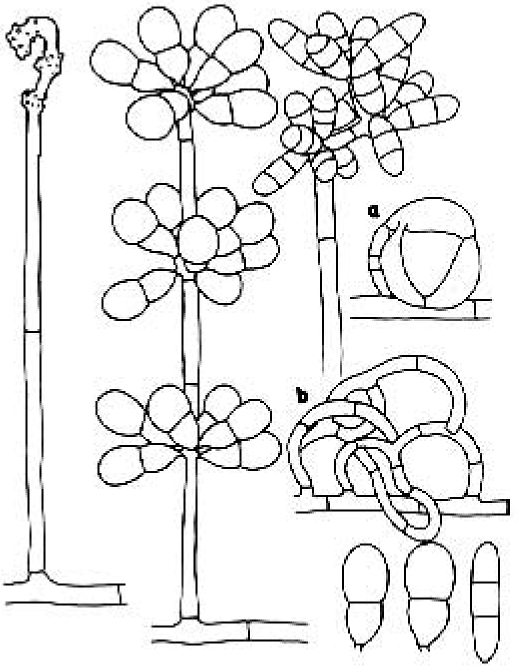
Arthrinium phaeospermum

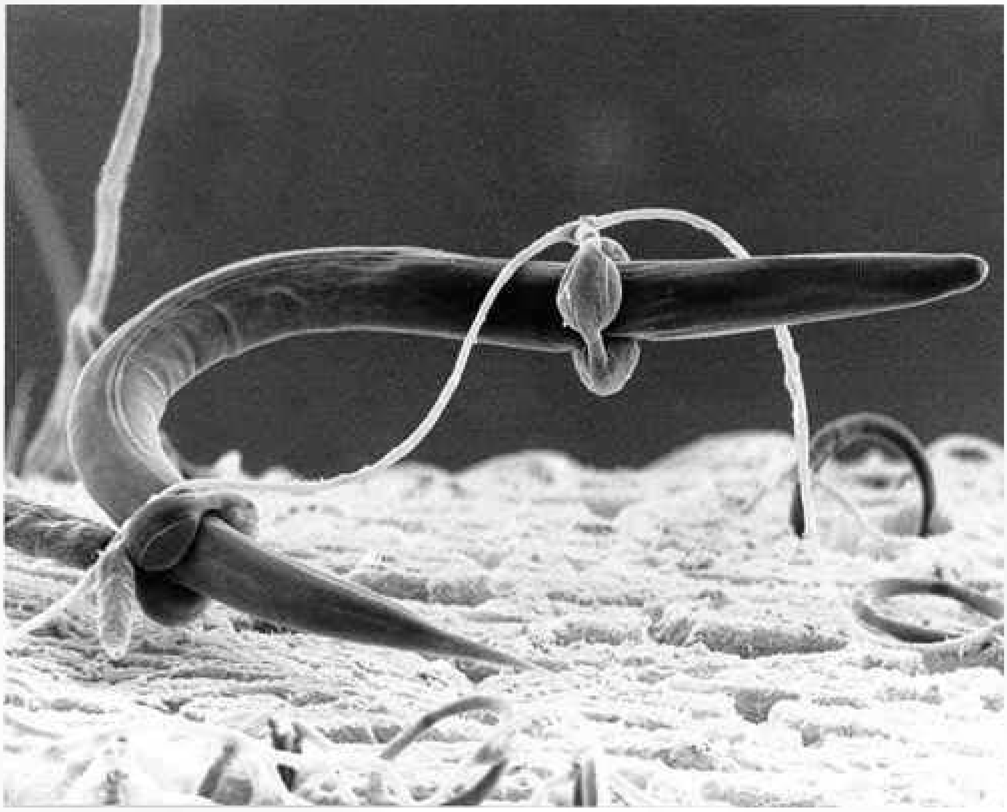
The spores (conidia) are dark brown and usually occur in grape-like masses on white woolly colonies. The spores are flattened and have a colourless line at the edge. When germinating they break along the line in the manner of a clam shell. In some species the filaments have dark cross-walls. Common on dead plants, especially grasses and sedges, and often isolated from air near grassy places in the autumn. The drawing at right illustrates several species. The photographs are of *Arthrinium cuspidatum* found growing on dead grass stems in a salt marsh in St. Andrews, New Brunswick.

Classification: Apiosporaceae (Sordariomycetidae).
Holomorphs: *Apiospora*, *Physalospora*, *Pseudoguignardia*.
Ref: Ellis 1971.

Arthrobotrys







Arthrobotrys anchonia chwyta nicienia

Characterized by tall, colourless conidiophores bearing clusters of spores (conidia) at the tip and often at several swollen points below. The conidia are pale, 2- to 3-celled, and leave conspicuous scars on the conidiophore when released.

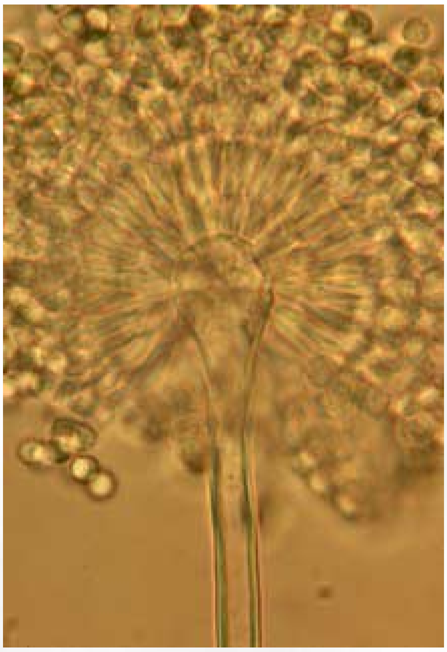
Species of *Arhrobotrys* are probably all predators on eelworms (nematodes). They employ several devices to capture these microscopic worms, including (a) constricting rings and (b) sticky networks of loops. Constricting rings work something like the well-known Venus' fly trap. When a nematode, intent upon searching for bacteria and other small edible particles, enters one of the rings, the cells of the ring suddenly inflate and the nematode becomes entrapped. The constricting action of these rings is so powerful that the nematode is almost cut in half. Sticky networks are less theatrical than constricting rings, yet they have their own brand of terror. When a nematode enters the network of loops it is held by a very strong "glue" and is unable to escape. In both cases, the captured worm first struggles wildly and then seems to become comatose. The fungus then sends its filaments into the worm and digests it. When it has obtained sufficient nutrients from its prey the fungus reproduces by producing clusters of conidia at the tops of long conidiophores.

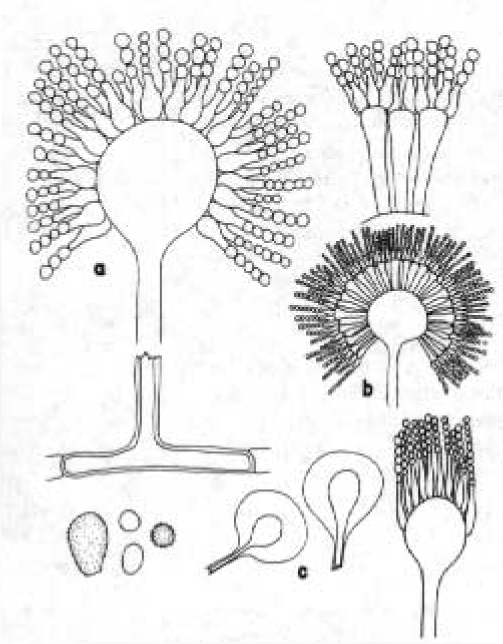
Thanks to the groundbreaking research of Drs. Donald Pfister and Michael Liftik (Pfister, 1994, 1997; Pfister and Liftik, 1995) we now have a much better understanding of the life histories of *Arthrobotrys* species. These authors provided convincing evidence that *Arthrobotrys* species are the asexual expression of the well-known discomycete genus *Orbilia*, a group of ascomycetes commonly found on dead wood, decomposing plant materials, soil and dung. Although species of *Orbilia* were previously thought to be simple decomposers we now realize they can be active predators.

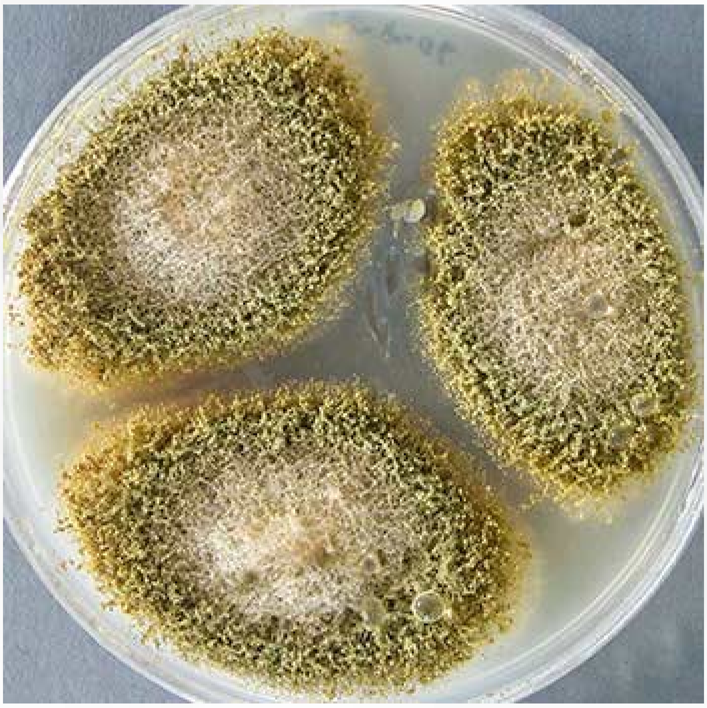
Arthrobotrys species are undoubtedly important in controlling numbers of nematodes, including those causing damage to agricultural crops. To study them it is necessary to first have a culture of nematodes. We maintain them on a weak medium spread with yeast or bacteria. Dehydrated pea soup mix also seems to be good food for nematodes. To see *Arthrobotrys*, a pinch of soil is introduced into the nematode culture. After a few days the traps will become abundant.

Classification: Orbiliaceae. Although the sexual stages resemble one of the inoperculate discomycetes, they may not be closely related. Dr Joey Spatafora, writing on The Tree of Life website assigns them to the Class Orbiliomycetes, a group of discomycetes distinct from both the Leotiomycetes and Pezizomycetes.
Holomorphs: *Orbilia*.
Ref: Haard 1968, van Oorschot, 1985, and Rubner, 1996.

Aspergillus







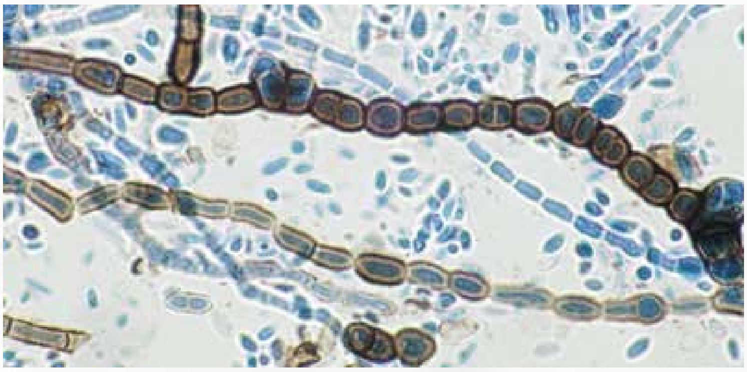
Aspergillus tamarii

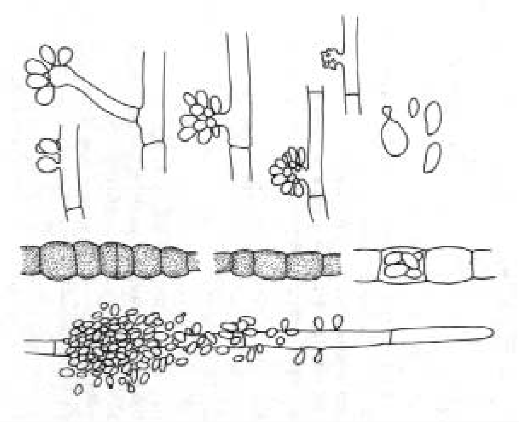
Recognized by its distinct conidiophores arising from a well-defined "foot cell" and terminated by a swollen vesicle bearing flask-shaped phialides. The phialides may be borne directly on the vesicle (a) or on intervening metulae (b). Some species may form masses of thick-walled cells called "hülle cells" (c). The spores come in several colours, depending upon the species, and are produced in long chains from the ends of the phialides. Commonly isolated from soil, plant debris, and house dust; sometimes pathogenic to man.

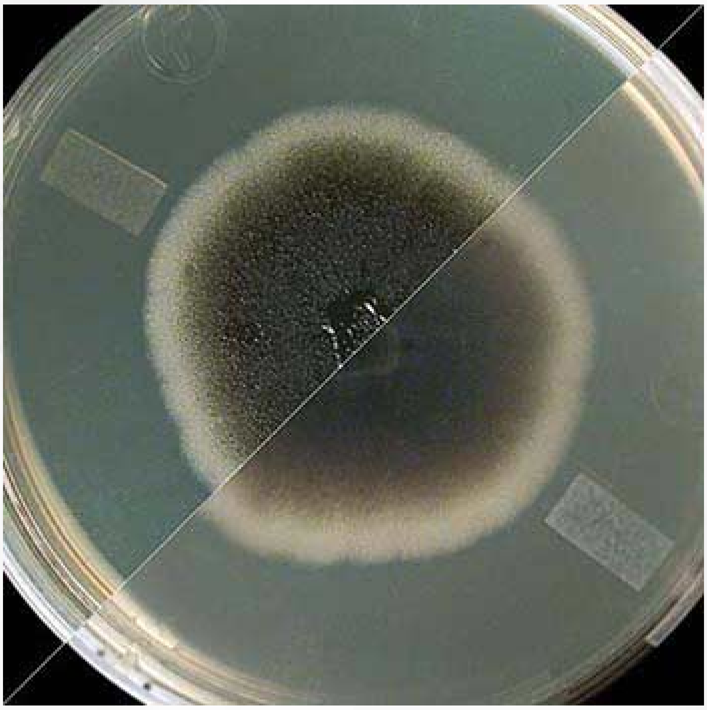
Classification: Trichocomaceae (Eurotiales).
Holomorphs: *Emericella*, *Eurotium*, *Neosartorya*, and others.
Refs: Klich, 2002; Klich and Pitt, 1988; Raper and Fennell 1965; Samson 1979; Samson and Varga, 2007; Samson *et al*., 2011; Seifert, 2000. Samson *et al* (2004) have a excellent presentation with a key, illustrations, discussions and descriptions of the species commonly found on foods and indoor environments. This will work

very well for most species of *Aspergillus* found in indoor environments, but will be less useful for outdoor habitats, especially in the tropics.

Aureobasidium





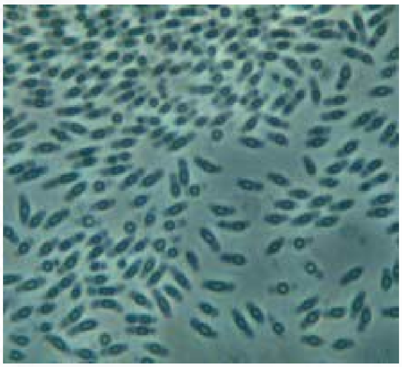


Aureobasidium pullulans - top/bottom

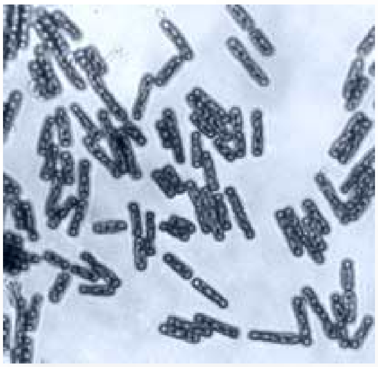
This is one of several genera of "black yeasts", characterized by mostly slow-growing, black, pasty colonies. The spores are produced in great masses along the filaments and occur on short lateral branches or pegs. When the spores are released they leave minute roughened scars. Exophiala species are similar but the spores do not leave rough scars as in *Aureobasidium*. Black yeasts occur in many habitats; some species of *Exophiala* may even cause human disease. *Aureobasidium pullulans*, the most frequently reported and possibly only species of *Aureobasidium* is a common inhabitant of the phylloplane (leaf surfaces) but is also frequently reported from soil, wood, rocks stone monuments and human skin. Stone buildings that have become black over the years often have abundant growth of *A. pullulans*.

Classification: Dothioraceae (Dothideales).
Holomorphs unknown.
Ref: Hoog and Hermanides-Nijhoff 1977; Hoog and Yurlova, 1994; Takeo and Hoog, 1991.

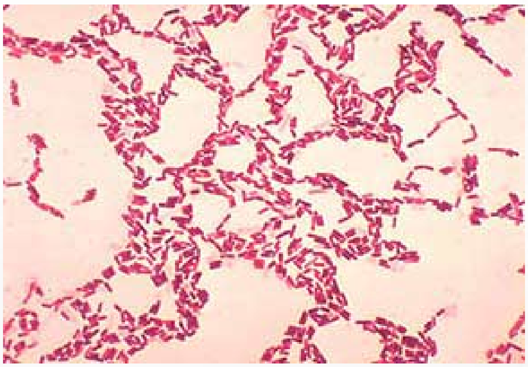
Bacteria



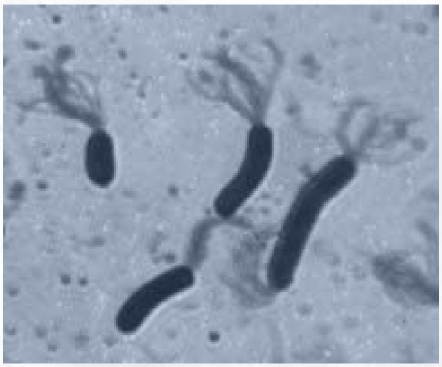
Bacillus



Bacillus aureus

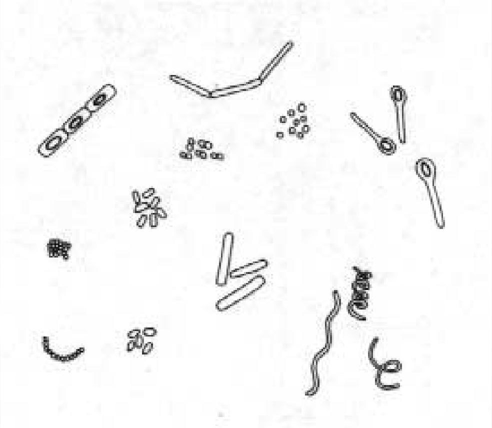


Bacillus coagulans



Spirillum

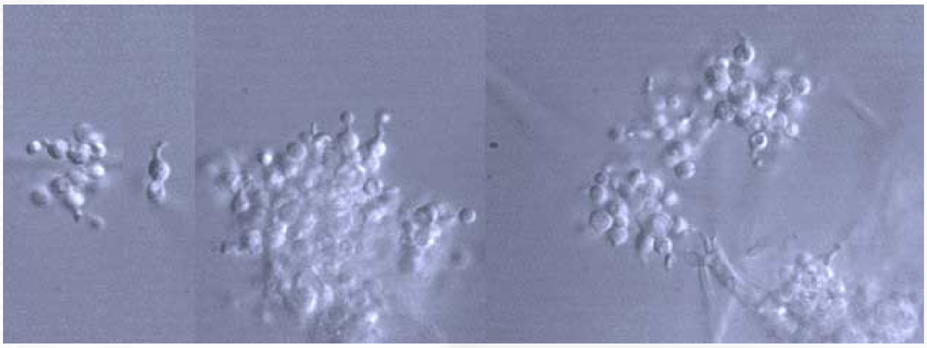
Escherichia coli

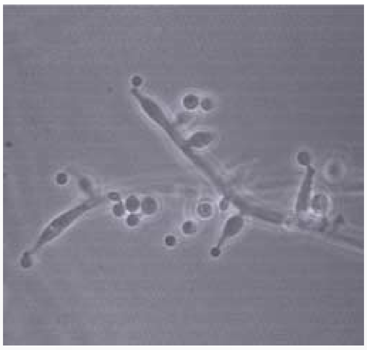


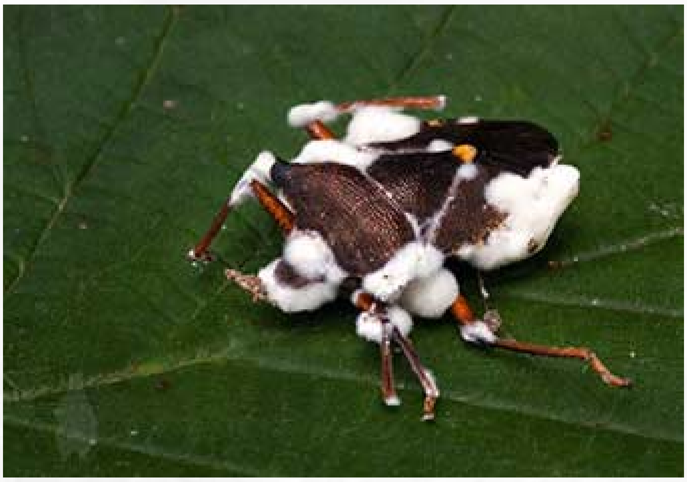
Bacteria are not fungi and are included here only because they will always be found where fungi occur. They form wet or slimy colonies, often with rather bright colours and unpleasant odours. The cells are nearly always *very* small and take a variety of shapes including the well-known rods (bacilli), spheres (cocci) and helices (spirilla). Some species, such as those of *Streptomyces* and related genera can form multicellular filaments. Many bacteria are motile, swimming freely around a microscope slide or wet Petri plate. The photographs above illustrate several features of bacteria. At left is a colony of a species of *Bacillus*, photographed in a sample of pond water. Each of the rod-shaped cells contains a thick-walled endospore. At top-center is a group of rods of *Bacillus aureus*, a species that can be isolated from certain foods such as fried rice and which can cause diarrhea in humans. *Escherichia coli*, at bottom-center, is a normal inhabitant of the human intestinal tract that occurs in both benign and beneficial forms. Because *E. coli* is always in the intestinal tract, its presence in water and other materials is a good indicator of fecal contamination. The organism at bottom-left is a species of *Spirillum*, common in nutrient-rich ponds. Note the curved shape that will become a loose helix in larger cells and the fasicle of flagella at the end of each cell. Flagella, which may occur singly or in clusters, are the main means of bacterial locomotion. Bacteria must be handled with great care as some are pathogenic to humans.

The routine identification of bacteria requires specialized facilities not normally available to mycologists. Although morphology can play a role in identification it is also necessary to utilize a battery of nutritional and physiological tests as well. Taxonomic studies based on nucleic acid homologies have shown that the traditional methods for classifying bacteria are often at odds with genetic evidence. Present-day bacteriologists still rely on traditional methods, but these are quickly being replaced by more reliable methods using genetic sequences. The basic reference for traditional methods is the 9th edition of Bergey's Manual of Determinative Bacteriology (Holt, 1994).

Beauveria







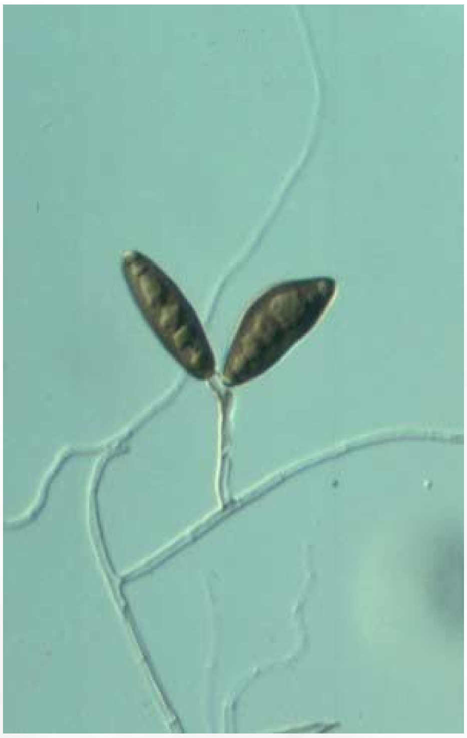
Beauveria bassiana

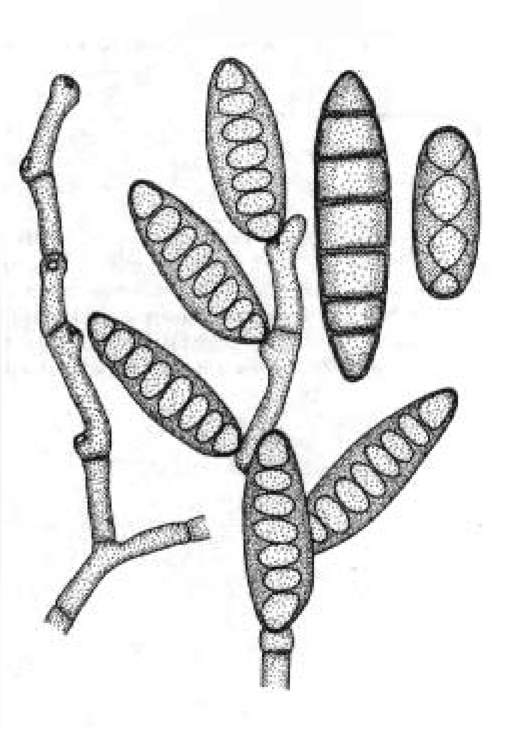
Species of *Beauveria* produce rather slow-growing white cottony colonies. Reproduction is copious and the conidia are easily detached, a condition often leading to scattered colonies when you thought you had carefully transferred only one. The one celled colourless conidia are borne along a thin filament that elongates in a zig-zag fashion as the conidia are produced. The conidia are produced on short spikes or denticles, giving the conidiogenous cells a spiny appearance. Species of *Tritirachium* are similar to some *Beauveria* species in having zig-zag conidiogenous cells, but differ in lacking denticles on their conidiogenous cells and in producing yellow brown to purple colonies. *Beauveria* species are commonly found associated with insects or habitats supporting insects. They commonly occur in private dwellings, where they probably decompose the dead bodies of insects, spiders and mites. They may also attack living insects and cause small epidemics. *Beauveria bassiana*, the best-known member of its genus, has been investigated widely as a potential agent for the biological control of harmful insects.

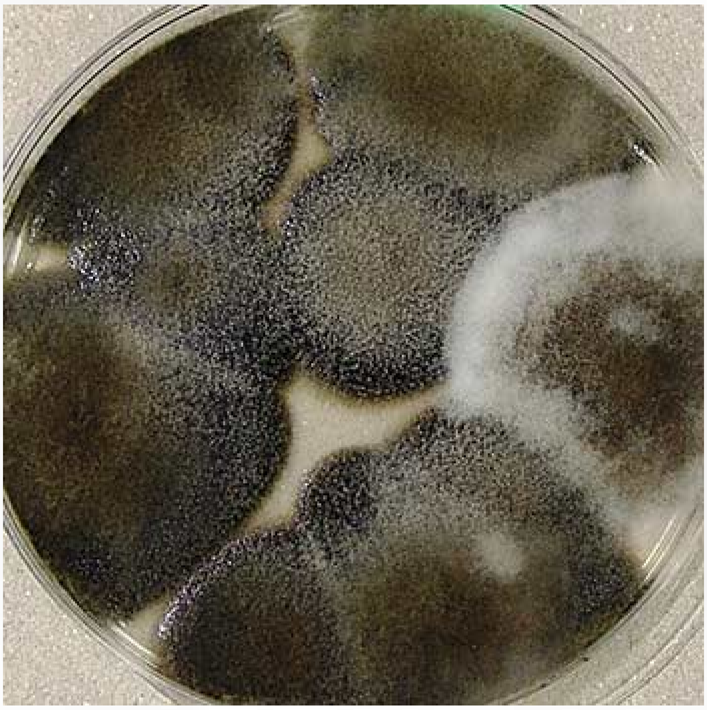
Glare and Inwood (1998) and Rehner and Buckley (2005) carefully examined cultures of *B. bassiana, B. amorpha, B. brongniartii, B. caledonica* and *B. vermiconia* as well as certain strains of *B. bassiana* that did not fit the concept of that species very well. They utilized traditional as well as molecular tools in their analysis and concluded that all of these species fall into distinct clades. This suggests that all are therefore "good" species. Unfortunately neither of these papers supplies identification keys, although Glare and Inwood did provide a chart of spore measurements that might be some aid in determination.

Classification: Cordycipitaceae.
Holomorph: *Cordyceps*.
Refs.: Domsch *et al*, 1980; Hoog, 1972.

Bipolaris





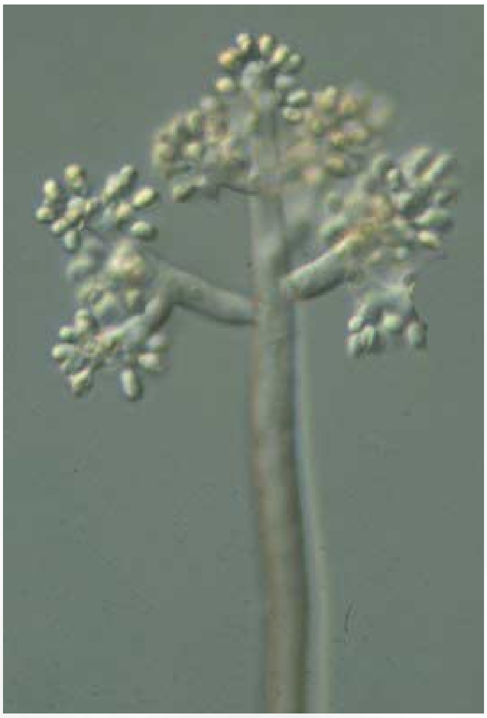


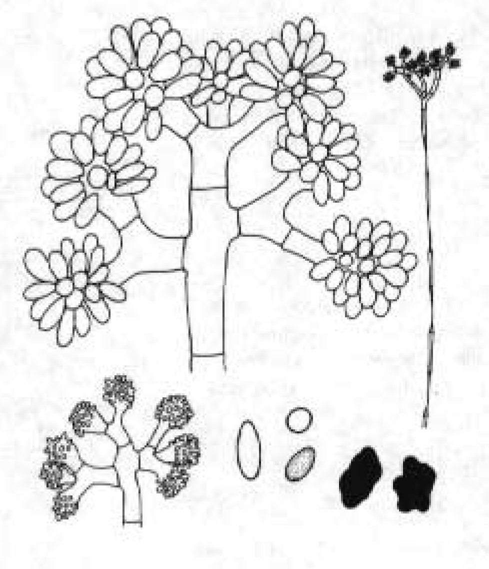
Bipolaris

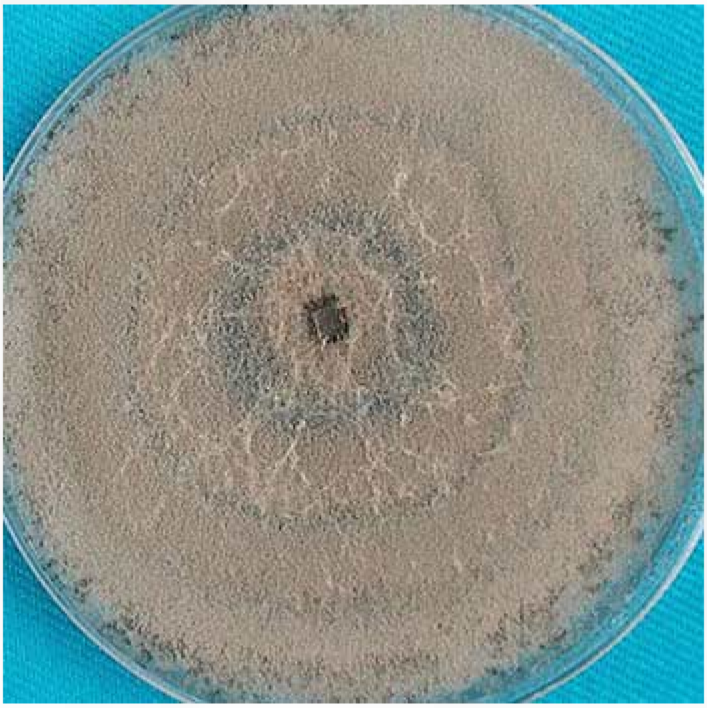
In species of *Bipolaris* the large, dark, multicellular spores are produced from pores along a gradually elongating, dark conidiophore. Often the cells of the spores appear to be very thick walled. Germination occurs only through the two end cells (and hence the generic name). *Drechslera* species differ in having spores that germinate through any cell. Species of *Curvularia* are similar, but the spores never appear very thick walled. Common on dead or dying plant material, especially grasses.

Classification: Pleosporaceae (Pleosporales).
Holomorph: *Cochliobolus*.
Ref: Ellis 1971, 1976 (with Drechslera).

Botrytis





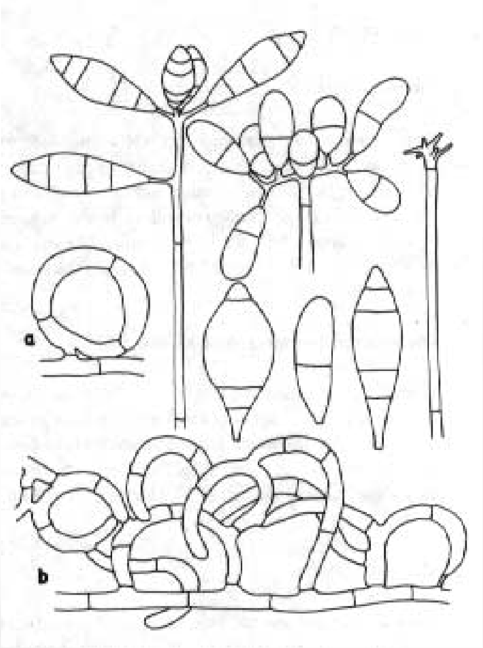


Botrytis cinerea

Species of *Botrytis* produce coarse, brown conidiophores with branched tops. The spores (conidia) cover the ultimate branches and are produced synchronously. As the colonies begin to dry, the cells of the conidiophore often flatten in alternate planes from each other. Many isolates produce black stone-like sclerotia. Often isolated from dead or living plants and frequently causing plant disease. Rotting of stored fruits and vegetables by *Botrytis* species is a major problem. Jarvis (1977) wrote an important overview of *Botrytis* that discusses many aspects of this economically important genus, although it cannot be used for identification of species.

Classification: Sclerotiniaceae (Sclerotiniales).
Holomorphs: *Botryotinia*, *Ciboria*, *Sclerotinia*.
Ref: Ellis 1971; Hennebert 1973.

Candelabrella

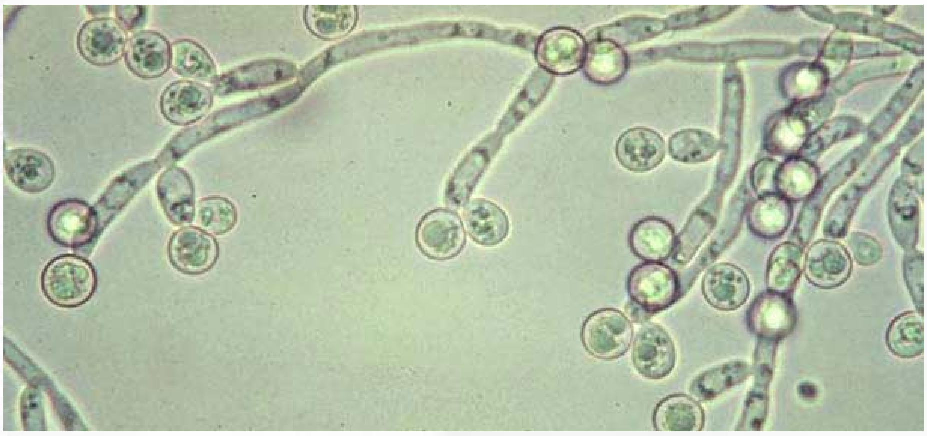


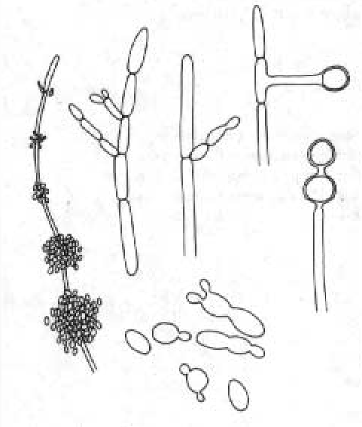
no image

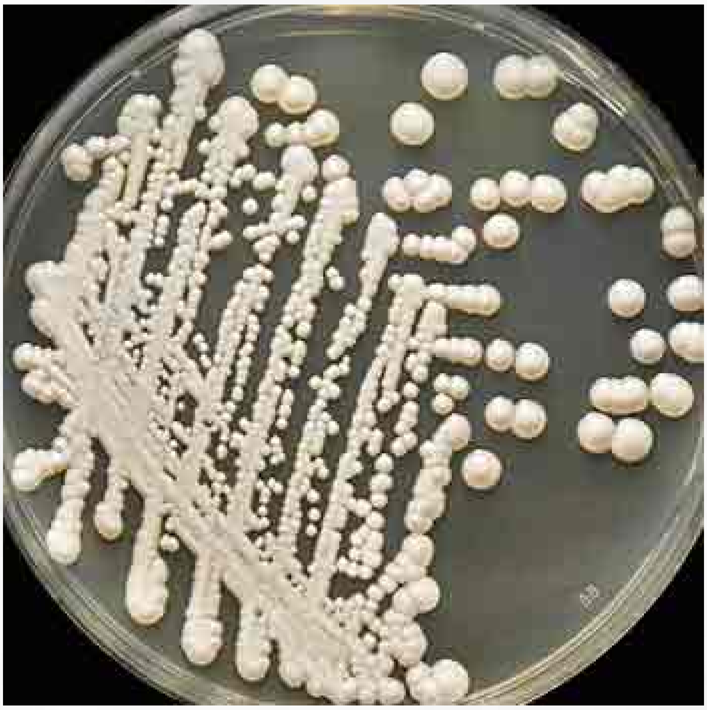
Conidiophores tall and bearing colourless 2- to 5-celled spores (conidia) at the tips of short apical branches. As the name implies, the branching is like that of a candelabrum. The species are predacious on eelworms and catch them in constricting rings (a) or sticky networks (b). *Arthrobotrys* species are similar but do not have conidiophores with branched tips. Some authors consider the two genera to be indistinguishable.

Classification: Orbiliaceae. Although the sexual stages resemble one of the inoperculate discomycetes, they may not be closely related. Dr Joey Spatafora, writing on The Tree of Life website assigns them to the Class Orbiliomycetes, a group of discomycetes distinct from both the Leotiomycetes and Pezizomycetes.
Holomorph unknown.
Ref: Cooke 1969; Rifai and Cooke 1966; Rubner, 1996.

Candida





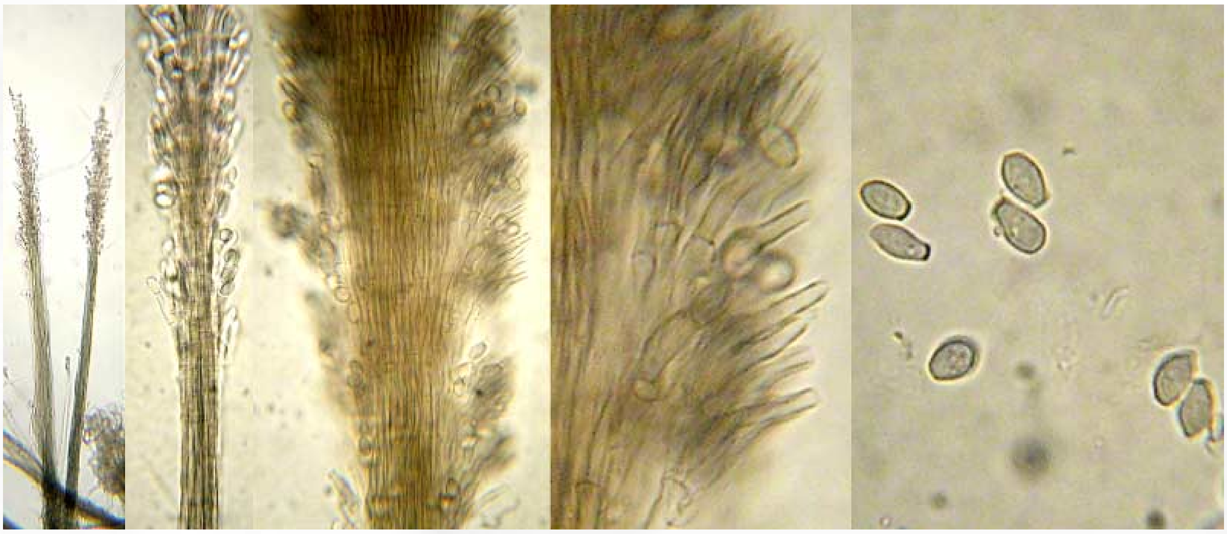


Candida albicans

Although often appearing to be mould-like, species of *Candida* are really yeast fungi, differing from filamentous fungi in some rather fundamental ways. The cells of their hyphae are usually rather loosely attached and will fragment when disturbed. The spores are produced along the "hyphae" and become so numerous that the filaments can be entirely obscured. The spores can reproduce themselves by "budding". The abundance of spores can give the colony a pasty or slimy appearance. Species of *Candida* are common in soil and organic debris and can also cause human disease. Although these organisms often live on the bodies of humans and other mammals causing little harm, if the immune system becomes compromised by immunosuppresant drugs or disease they can cause serious infections or even death. People infected with HIV are often at risk of contracting candidiasis, the name of the disease caused by *C. albicans*. Not all species of *Candida* cause disease in humans, many occur in association with plants or insects and never affect humans at all.

Classification: Saccharomycetales, one of the so-called Hemiascomycetes or yeasts.
Holomorphs: *Entelexis, Hyphopichia, Issatchenkia, Metschnikowia, Saccharomycopsis, Stephanoascus.*
Ref: Barnett and Pankhurst 1974; Lachance *et al*, 2011.

Cephalotrichum

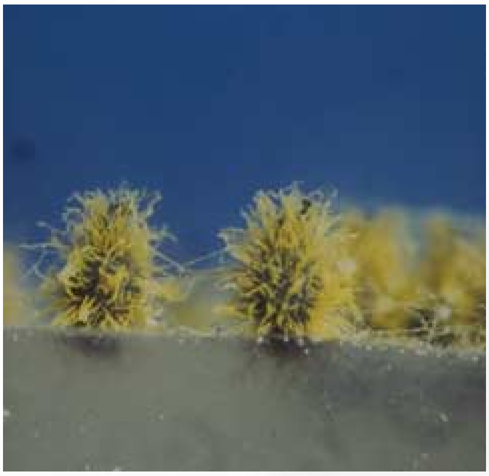


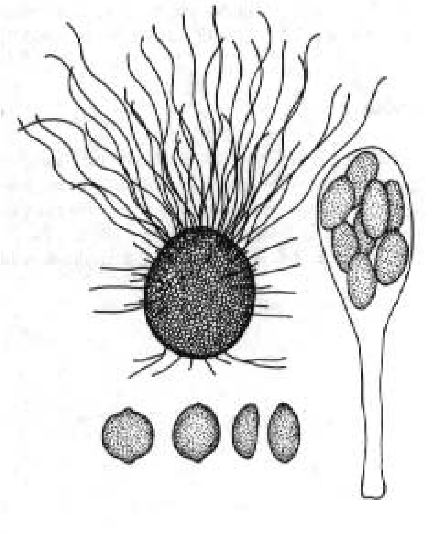
no image

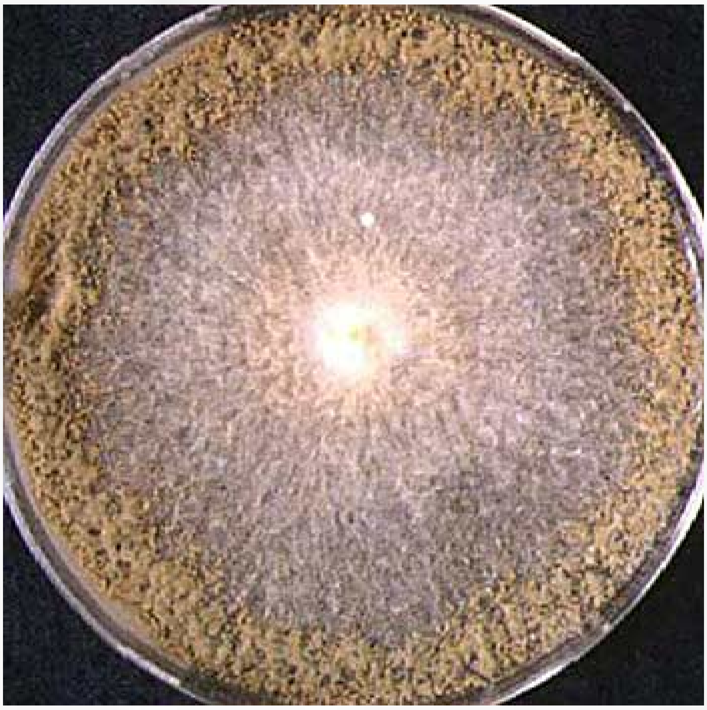
The dark brown conidiophores are united in a fascicle to form a long compound fruiting structure (synnema). The upper half of the synnema is covered with flask-shaped annellides giving rise to chains of grey-brown spores (conidia). In *C. stemonitis* there is an accessory *Echinobotryum* spore form arising from the stalks of the synnemata and on the surrounding hyphae. Other species, such as *C. microsporum*, pictured at right, have only one spore form. *Trichurus* species are similar, differing in having straight to coiled hairs arising among the annellides. Young synnemata of *Trichurus* species may not have well developed hairs and may be mistaken for a species of *Cephalotrichum*. Related to *Scopulariopsis*. Many of the species were placed in *Doratomyces* in the older literature. Common in soil, dung, and decaying plant materials.

Classification: Microascaceae.
Holomorph unknown.
Ref: Morton and Smith 1963.

Chaetomium





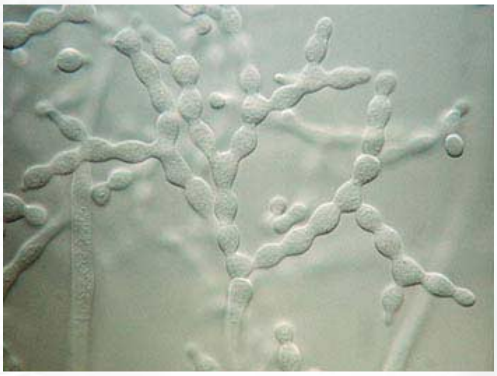


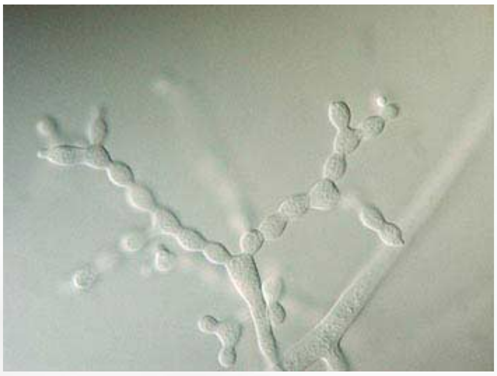
Chaetomium globosum

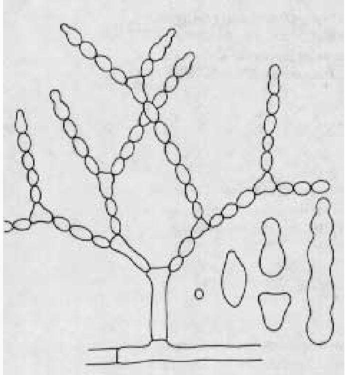
Characterized by densely hairy, egg-shaped fruiting bodies (perithecia) containing asci, which in turn enclose 4-8 brown spores (ascospores). The perithecial hairs can take a variety of forms, depending upon the species. The ascospores collect in a dense mass outside the perithecium. Most species are strong decomposers of cellulose and occur wherever this substrate is abundant, such as in soil, dung, or rotting plants.

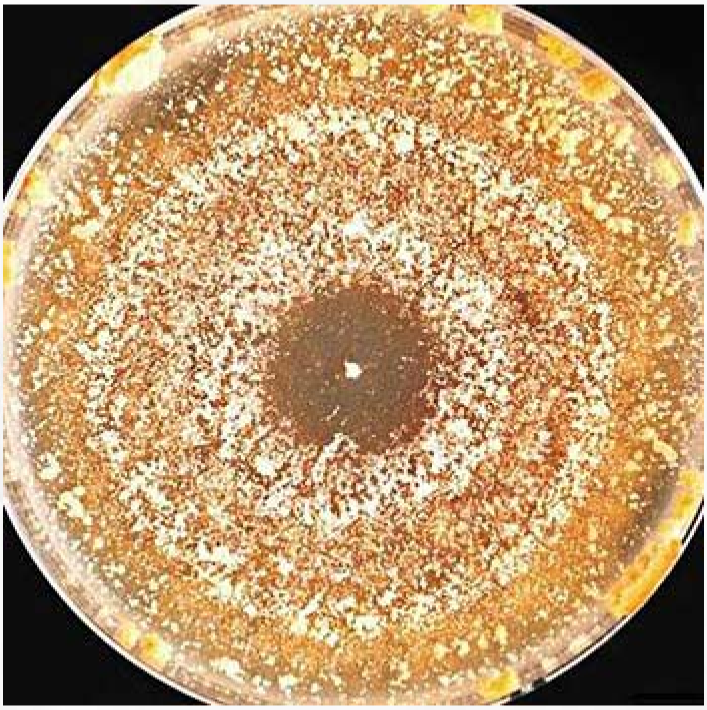
Classification: Chaetomiaceae (Sordariomycetidae).
Anamorphs: *Acremonium*, *Botryotrichum*, *Chrysosporium*, *Scopulariopsis*, *Trichocladium*, or lacking.
Ref: Ames 1963; Arx *et al.*, 1986; Seth 1970

Chrysonilia









Chrysonilia sitophila

Recognized by its branched chains of light or brightly coloured spores (conidia) arising from inconspicuous conidiophores. Spores are produced by "budding", with the youngest ones at the tips of the chains.

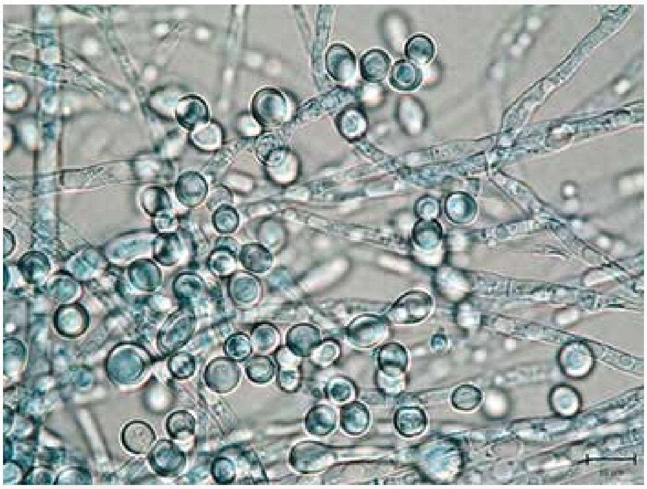
Species of *Chrysonilia*, including *C. sitophila*, the red bread mould, produce very fast growing pink colonies and numerous spores. The spores are dry and easily detached from one another. Because they combine rapid growth and prolific reproduction, species of *Chrysonilia* can contaminate other laboratory cultures very rapidly. In the school or university laboratory where many students may be cultivating fungi at the same time these fungi can cause lab-wide epidemics, ruining every culture they contact. The best strategy is to discard all rapidly growing, pink, powdery cultures without opening them.

Neurospora, the holomorph of *Chrysonilia* species, is widely used as an experimental organism. More is known about the physiology and genetics of *Neurospora* than any other fungus. The ascospores of *Neurospora* species resist germination until they encounter certain kinds of physical or chemical stimulant. In nature, the ascospores occur in soil and are activated by heat. Thus the species *Neurospora* and their associated *Chrysonilia* anamorphs can often be found on the surface of soil following forest or grass fires. They can also appear on the surface of soil that has been partially sterilized in the greenhouse. They can be isolated from soil by first treating the sample with alcohol or heat (see discussion of stress techniques in Chapter 4.

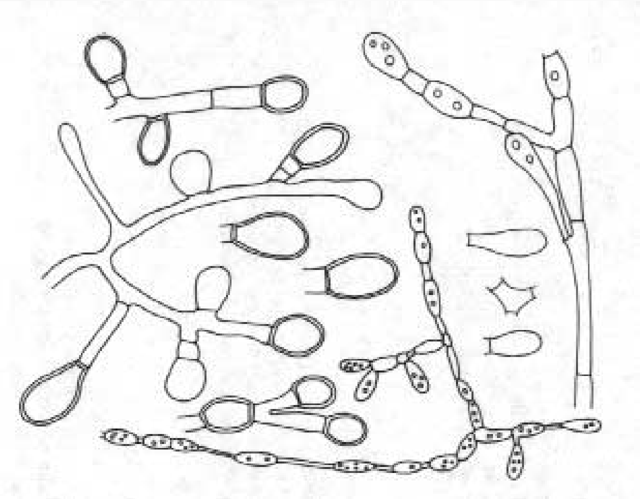
Many texts still treat *Chrysonilia* species in the genus *Monilia*. However, *Monilia* species are plant parasites, commonly causing a soft brown rot of stone fruits (peaches, apricots, etc.), and are not closely related to *Chrysonilia*. Common in soil, homes, fruits, and as a laboratory pest.

Classification: Sordariaceae (Sordariomycetidae).
Holomorph: *Neurospora*.
Ref: Samson *et al*, 2004.

Chrysosporium



Chrysosporium fastidium



Chrysosporium pannorum

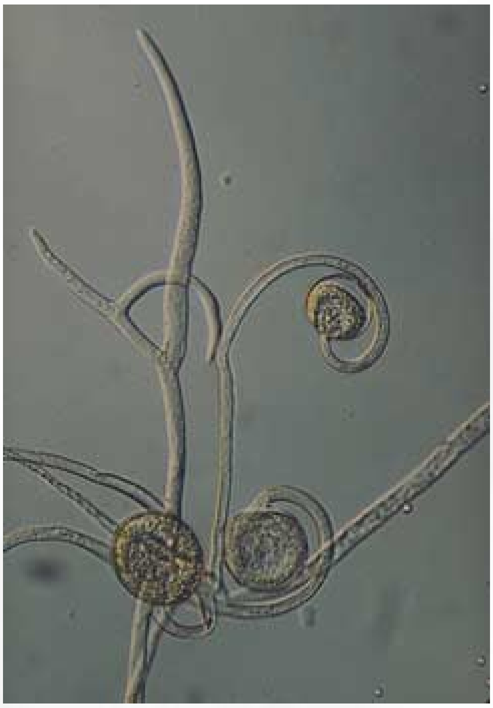
Spores (conidia) are produced along the vegetative filaments by a swelling of the wall and subsequent isolating by a cross-wall. The conidia can be terminal on the filament or at various sites along its length. Chains of conidia may occur and are sometimes separated by empty cells. Most species are entirely colourless to yellow.

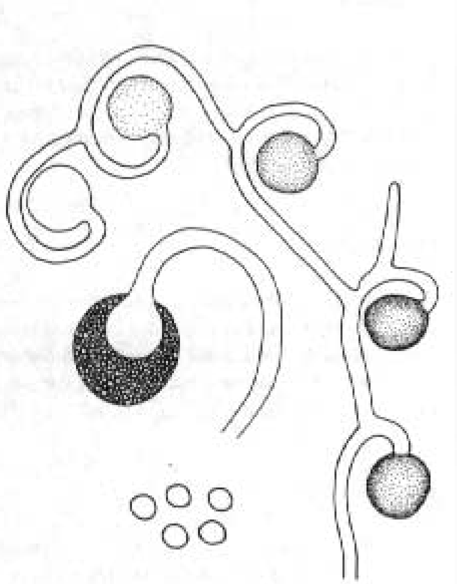
Species of *Chrysosporium* have been shown to be anamorphs of many different fungi (see below), suggesting that they are not a group with a unique ancestor but are instead polyphyletic. Their ecology reflects these diverse origins; some species are psychrotolerant (able to grow at low temperatures) while others, in contrast, are thermotolerant (able to grow at high temperatures). As well, some are osmotolerant (tolerating dryness or osmotic stress) while others are not. Although the species are often not physically complex or highly characteristic, their physiological diversity is a great help in their identification.

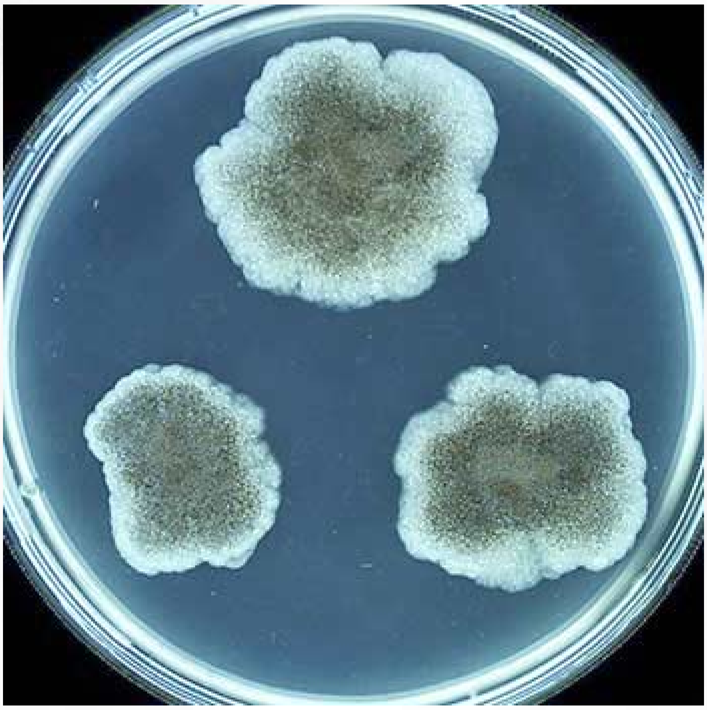
Growing in soil, dung, and decaying plant material. Some are able to decompose hair, hoofs, and leather.

Classification: Onygenaceae (Onygenales).
Holomorphs: *Aphanoascus*, *Apinisia*, *Arthroderma*, *Bettsia*, *Chaetomium*, *Gymnoascus*, *Pectinotrichum*, *Psathyrella*, *Renispora*, *Rollandina* and others.
Ref: Carmichael 1962; Van Oorschot 1980.

Circinella





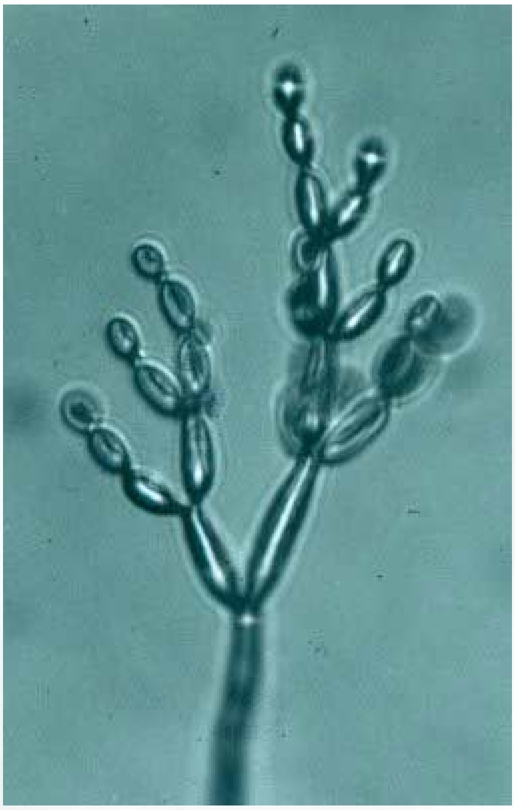


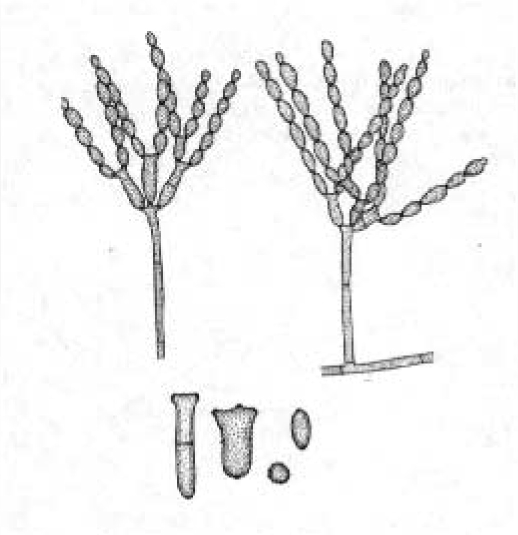
Circinella muscae

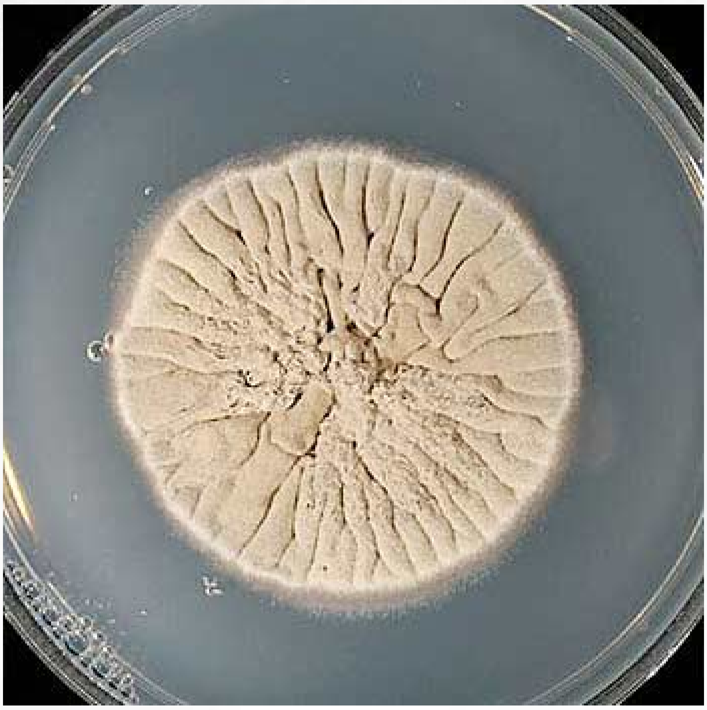
Colonies rather coarse and fast-growing. Spores produced within dark spherical sporangia that are borne along the length of sporangiophores on strongly curved or hooked branches. The filaments have few cross-walls and thus resemble long, hollow tubes. The most characteristic feature is the strongly hooked sporangial branch. Occurring in soil, dung, and decaying nuts.

Classification: Mucoraceae (Zygomycota).
Ref: Arambarri and Cabello, 1996; Hesseltine and Fennell 1955; Zycha and Siepmann 1970.

Cladosporium







Cladosporium herbarum

Colonies dark greenish to black, black in reverse, and relatively slow-growing. The dark spores are 1- or 2-celled and occur in long, branching chains that arise from a dark conidiophore. The youngest spore is at the top of the chain. The slightest movement will disrupt the chains, making microscope mounts of the whole structure nearly impossible. The best way to recognize the genus is by the prominent scars on the spores where the adjacent ones were attached. Very common on decaying plants and fungi; the fungus most commonly isolated from air, both indoors and outdoors.

It has always been difficult to identify species of *Cladosporium*. Most isolates from air and from habitats associated with humans have been referred to one of three species, distinguished by the following key:

1. Spores usually ellipsoidal in shape, only rarely spherical - 2.

1. Spores often nearly spherical -» *Cladosporium sphaerospermum*.

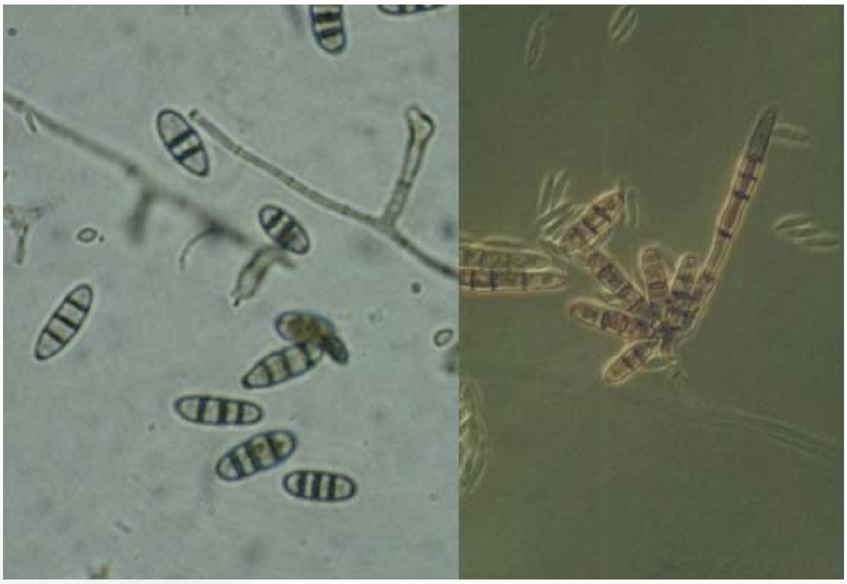
2. Spores smooth -» *Cladosporium cladosporioides*.

2. Spores warty -» *Cladosporium herbarum*.

Unfortunately the taxonomic reality is that there are many more species of *Cladosporium*, perhaps hundreds more, than these three. Many are known from specific plants or particular geographic areas. Many have not yet been grown in culture and many remain undescribed. The recent book on *Cladosporium* edited by Crous *et al* (2007) addresses this difficult genus in several ways and provides keys, descriptions and illustrations to aid in identification. It is a major advance in the taxonomy of *Cladosporium* and one that will undoubtedly stimilate further research.

Classification: Davidiellaceae (Capnodiales).
Holomorph: *Davidiella, Mycosphaerella* and *Venturia*.
Ref: Bensch *et al.*, 2012; Crous *et al*, 2007; Ellis 1971, 1976; de Vries 1952; Wang, 1990.

Dendryphiella



no image

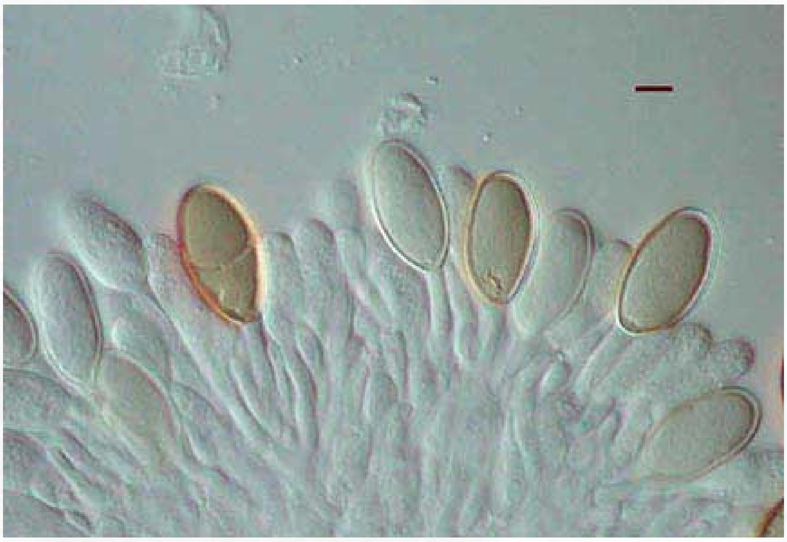
Dendryphiella species are not among the most common of fungi but any isolations from ocean beaches will turn them up in abundance. Two species are known in this habitat, *D. arenaria*, at left, and *D. salina*, at right. Both are common but often not overlapping in their ranges, with *D. salina* found in cool climates and *D. arenaria* in warm ones. Other species, including the type, occur on decomposing plants in terrestrial situations. Species of *Dendryphiella* are recognized by their sympodially developing conidiogenous cells producing dark poroconidia with several transverse septa.

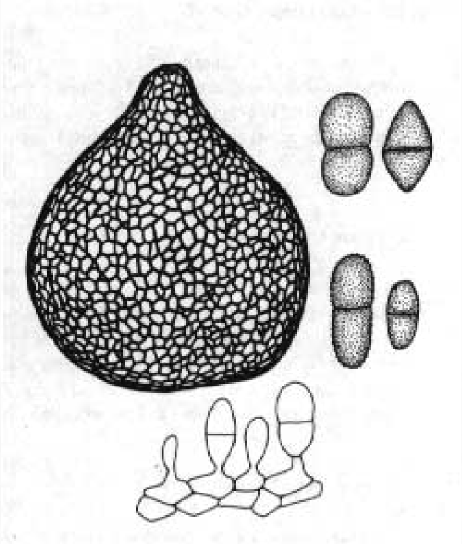
Mycologists have long debated whether the two marine species belong in the genus *Dendryphiella* or *Scolecobasidium*. They are very similar morphologically, so the distinction really boils down to some very obscure features. Dela Cruz *et al* (2006) finally laid the controversy to rest by presenting molecular evidence that *D. arenaria* and *D. salina* are closely related to one another and only very distantly related to species of *Scolecobasidium*. Of course there is one futher issue left to resolve; the genus *Dendryphiella* was typified (created specifically) for *Dendryphiella interseminata* (Berk. & Ravenel) Bubák, a species orginally described from *Phytolacca decandra* (=*Phytolacca americana*), American pokeweed and *Cicuta maculata*, Spotted cowbane. It is not yet known whether *D. interseminata* is closely related to the two marine species or not. If not, our two beach inhabitants will have to find a home in yet another genus.

Habitat: decaying stems and marine algae.

Classification: Pleosporaceae (Pleosporales).
Holomorphs unknown.
Refs.: Kohlmeyer and Volkmann-Kohlmeyer, 1991 (for marine species), Ellis, 1976 (as species of *Scolecobasidium*).

Diplodia



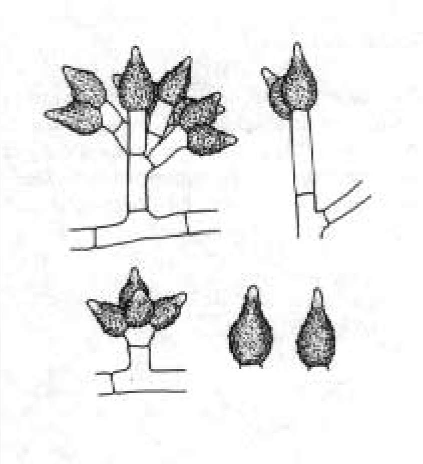


Diplodia mutila

The spores (conidia) are brown, 2-celled, and are borne within more or less round fruiting structures (pycnidia). Conidial production occurs (probably holoblastically) on short cells that line the inner walls of the pycnidium. There are a number of similar genera that are distinguished on the basis of pycnidial and spore structure. Most species occur on living or dead plants.

Classification: Botryosphaeriaceae (Botryosphaeriales).
Holomorphs: *Botryosphaeria*, *Cucurbitaria*, *Eutryblidiella*, *Massarina*, and others.
Ref: Sutton, 1980; Zambettakis 1954, 1955.

Echinobotryum

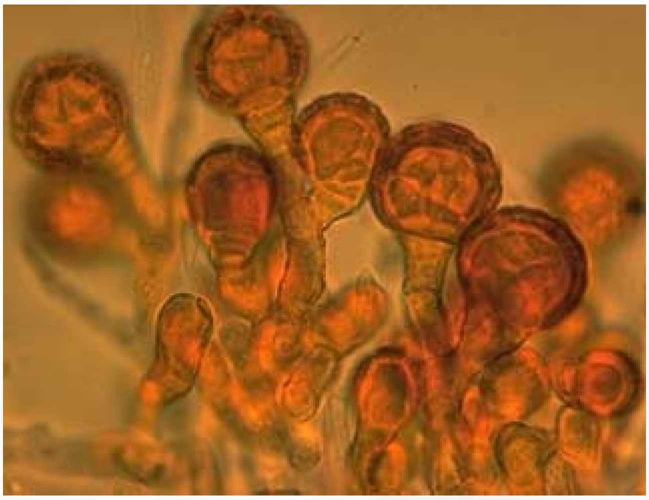


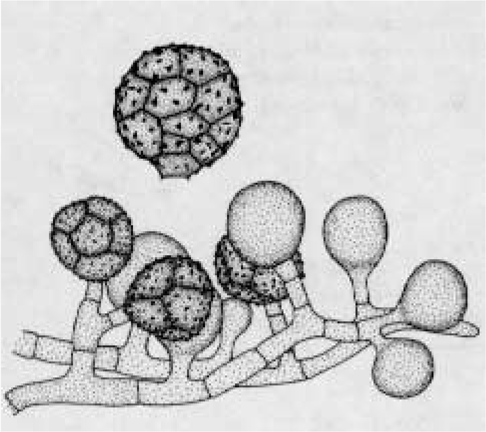
no image

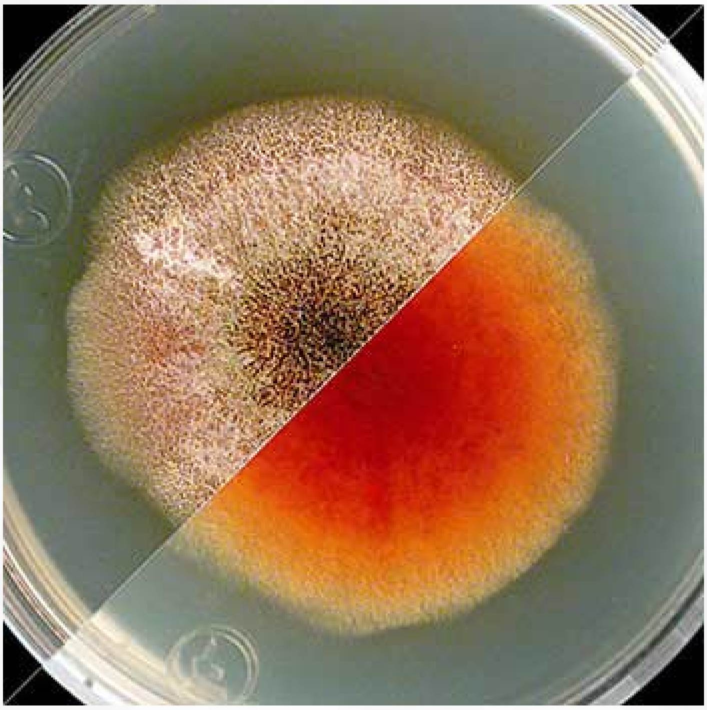
Characterized by small clusters of pear-shaped, beaked, roughened, brown spores (conidia) borne on short, branched or simple conidiophores. Usually occurring as an "accessory form" at the synnematal bases and surrounding hyphae of *Cephalotrichum stemonitis*. Fairly common on dung, soil, and plant debris.

Classification: Microascaceae.
Holomorph unknown.
Ref: Hennebert 1968

Epicoccum





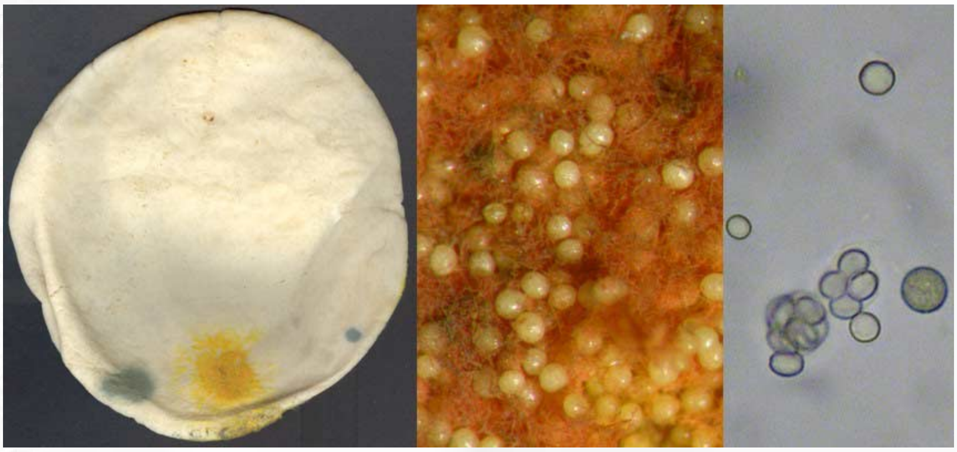


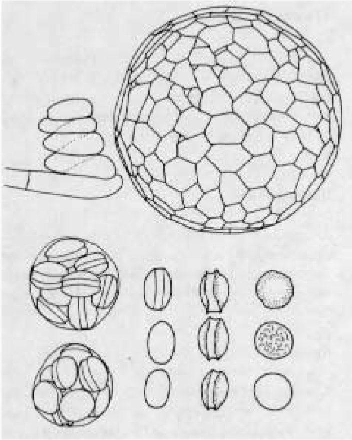
Epicoccum purpurascens - top/bottom

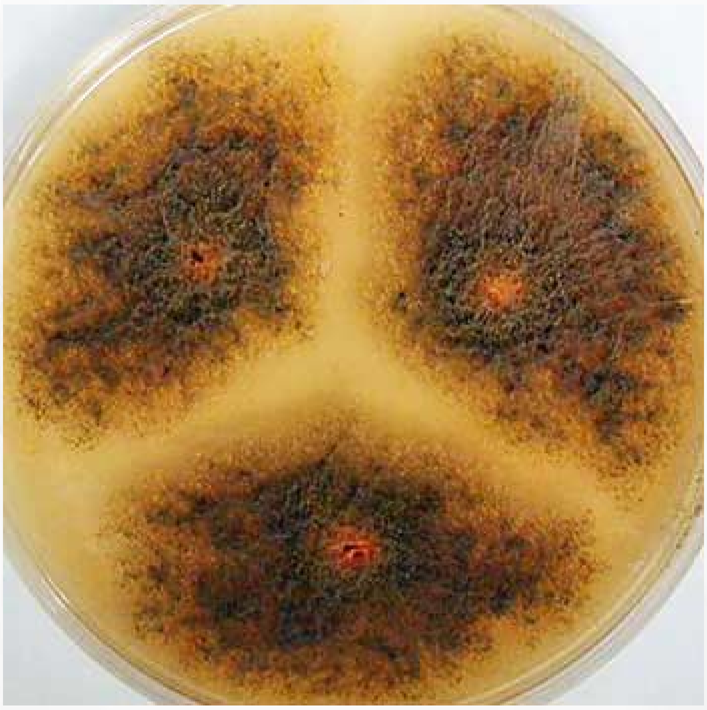
Easily recognized by its nearly spherical spores (conidia) that are several-celled and strongly roughened. The conidia are usually produced in dense masses from clustered conidiophores (sporodochia). Identification may be difficult at first because isolates often fail to produce conidia in culture. Experienced mycologists easily recognize it by its fast-growing, red, orange or yellow colonies. Heavily sporulating colonies are sometimes encountered but these are less common than the more lightly sporulating or non-sporulating strains. Very common on dead or dying plants; frequently isolated from both outdoor and indoor air.

Classification: Pleosporaceae (Pleosporales).
Holomorph unknown.
Ref: Schol-Schwarz 1959.

Eurotium







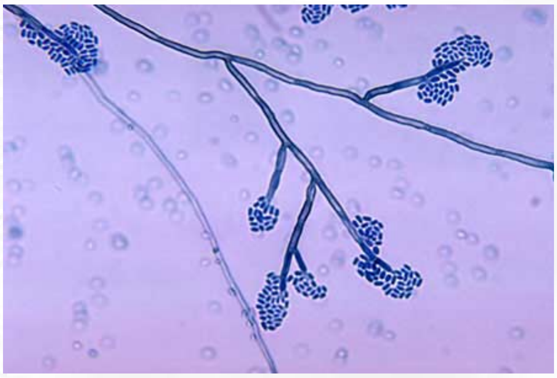
Eurotium rubrum

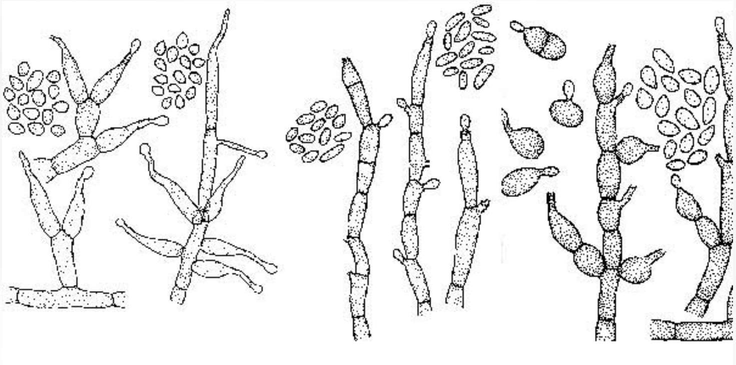
An ascomycete characterized by whitish to bright yellow spherical fruiting bodies (cleistothecia) containing spherical asci which in turn each enclose eight colourless ascospores. The ascospores are oblate (like a flattened sphere) and may have equatorial ridges, thus resembling pulleys. Species of *Eurotium* grow best in dry situations and are usually cultivated on media high in sucrose or glycerine. They are common in homes, stored grains, and rodent dwellings.

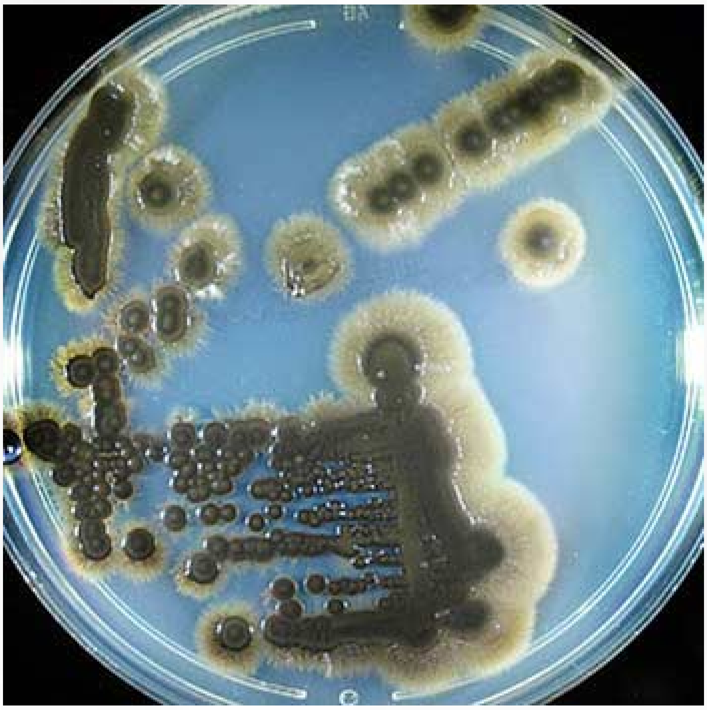
The three photographs at top are of a strain of *Eurotium rubrum* found growing on an old pita bread in a New Brunswick home. The bright yellow-orange colony is typical of *Eurotium* species where the bright yellow cleistothecia greatly outnumber the green masses of conidia. The green colony at left is a species of *Penicillium*, probably *P. chrysogenum*. The middle panel is an enlargement of the colony showing the yellow cleistothecia nestled among the red hyphae characteristic of *E. rubrum*. The right panel shows a group of spores. The darker, roughened spores at the right and top of the picture are conidia of the *Aspergillus* anamorph of the fungus. The rest of the spores are ascospores, which are shaped like minute hamburgers. In common with hamburgers, ascospores of *Eurotium* species tend to come to rest on a top or bottom rather than on a side. Thus most of the ascospores look circular. However, two of these are lying on their side and thus have the elliptical outline of a hamburger as viewed by someone about to bite into it. The group of ascospores that are slightly out of focus are still inside an ascus, although the ascal wall cannot be seen. All of these features can be seen more clearly in the drawing at right. The coiled structure in the drawing is an ascogonial coil, discussed in greater in the discussion of the Sordariomycetes.

Classification: Trichocomaceae (Eurotiales).
Anamorph: *Aspergillus*.
Ref: Blaser 1976; Klich and Pitt, 1985; Raper and Fennell 1965.

Exophiala







Exophiala dermatitidis

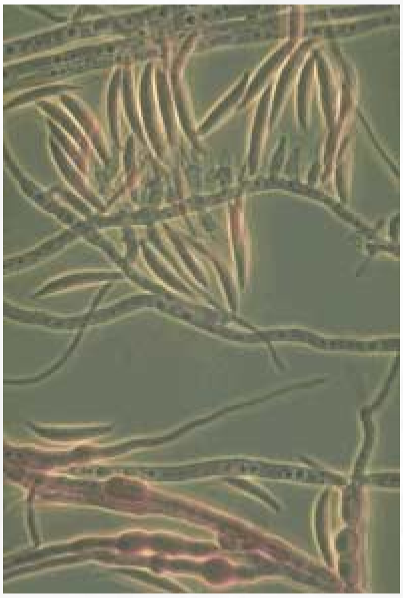
Exophiala species are usually included among the fungi called "black yeasts". Conidia are typically borne at the tips of short annellides produced along the vegetative hyphae. The annellides are often difficult to see and to determine that they actually *are* annellides. Species of *Phialophora* are similar but produce their conidia on phialides rather than annellides. Species of *Aureobasidium*, another genus of black yeasts, produce conidia holoblastically on minute peg-like extensions of short hyphal branches or directly along the hyphae themselves.

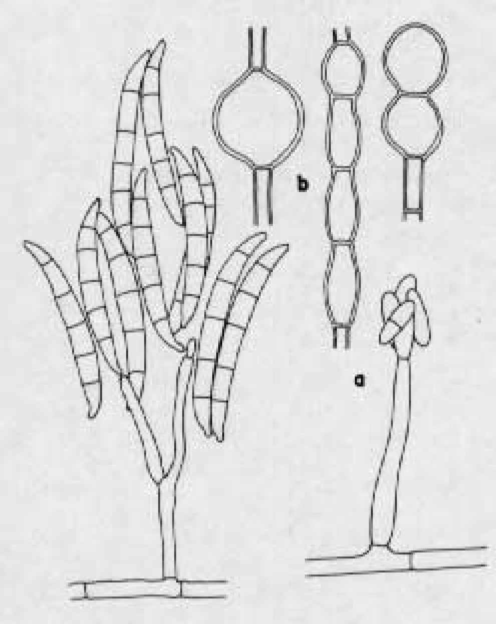
Some species of *Exophiala* are known to cause a subcuaneous disease in humans and other vertebrates. Although not normally life-threatening, these infections must be removed surgically or they may continue to grow for years. In handling these fungi, care must be taken not to accidentally inoculate oneself with contaminated instruments.

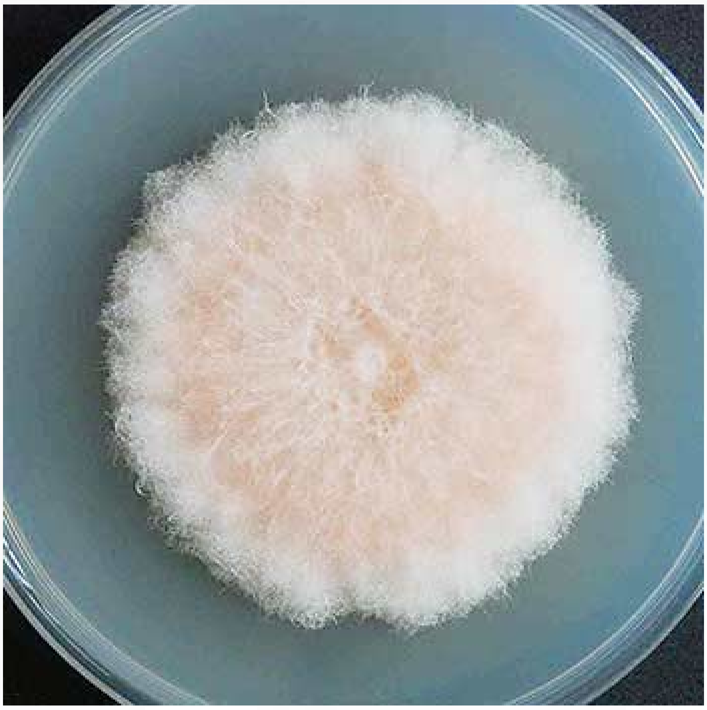
The natural habitats of *Exophiala* species are hard to pin down. They can be isolated from decaying plant material, wood, sewage sludge, soil, tree exudates and many other sources. They sometimes appear in unlikely places, such as in syrup-like solutions of polyvinyl alcohol. They are often most easily found by locating the small perithecia of the *Exophiala* holomorphs.

Classification: Herpotrichiellaceae (Eurotiomycetes).
Holomorph: *Capronia*.
Refs: Hoog and Hermanides-Nijhoff, 1977; Untereiner, *et al.,* 1995. The drawings used here are from the Ph.D. thesis of Wendy Undereiner.

Fusarium





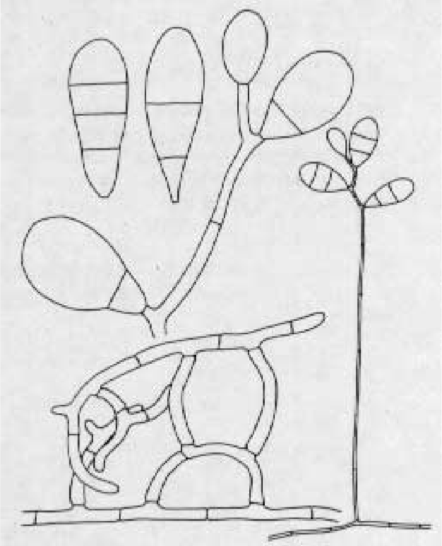


Fusarium equiseti

Most characteristic are the colourless spores (conidia), which are canoe-shaped in side view, have a distinct "foot cell" at the lower end, and are divided by several cross-walls. The conidiophores are often clustered to form sporodochia and produce large pasty masses of spores from tapered phialides. Two other spore forms may occur, microconidia (a) resembling spores and phialides of *Acremonium*, and chlamydospores (b), thick-walled swellings along the filaments. Cultures may be brightly coloured. Common in soil and dead or living plants; often causing plant disease.

Classification: Nectriaceae.
Holomorphs: *Albonectria*, *Coralomycetella*, *Gibberella*, *Haematonectria*, and possibly others.
Ref: Booth 1971b, 1977; Burgess, *et al*., 1988; Gerlach and Nirenberg, 1982; Nelson, *et al*., 1983.

Geniculifera

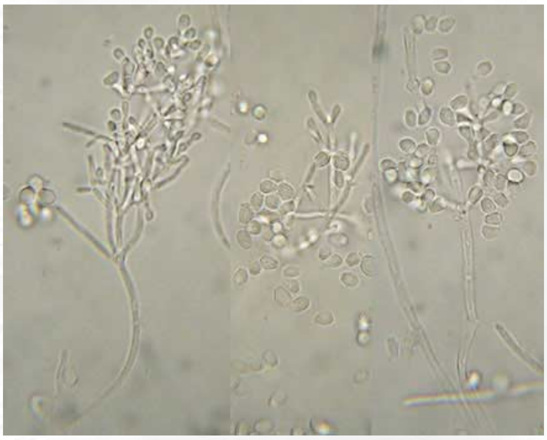


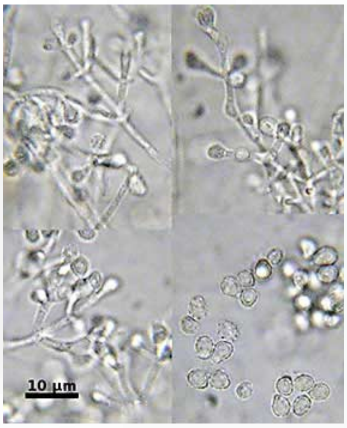
no image

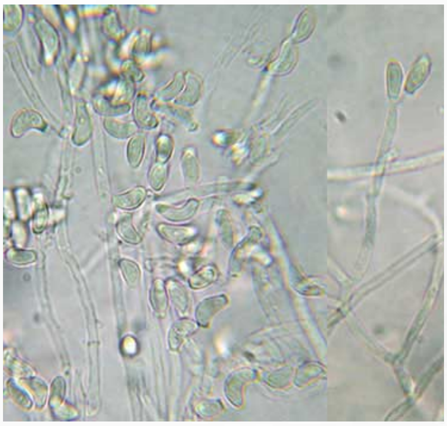
The 2- to 4-celled colourless spores (conidia) are produced at the "joints" of more or less zigzag or geniculate conidiophores. The youngest conidium is at the top and new growth of the conidiophore then originates just below it and pushes it to one side. Considered by some authors to be indistinguishable from *Arthrobotrys*. Predacious on eelworms, which they trap in sticky networks of loops. Occurring in soils high in organic material.

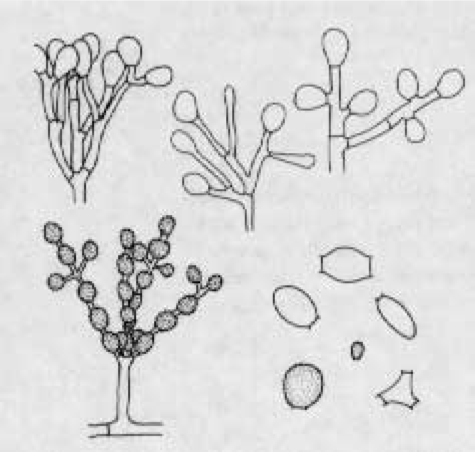
Classification: see *Arthrobotrys*.
Holomorph unknown.
Ref: Rifai 1975; Rifai and Cooke 1966; Rubner, 1996.

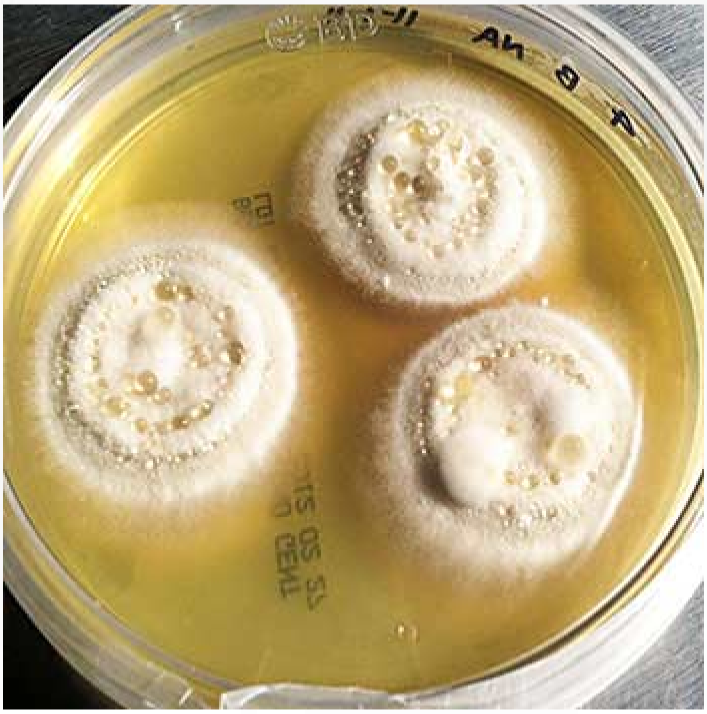
Geomyces











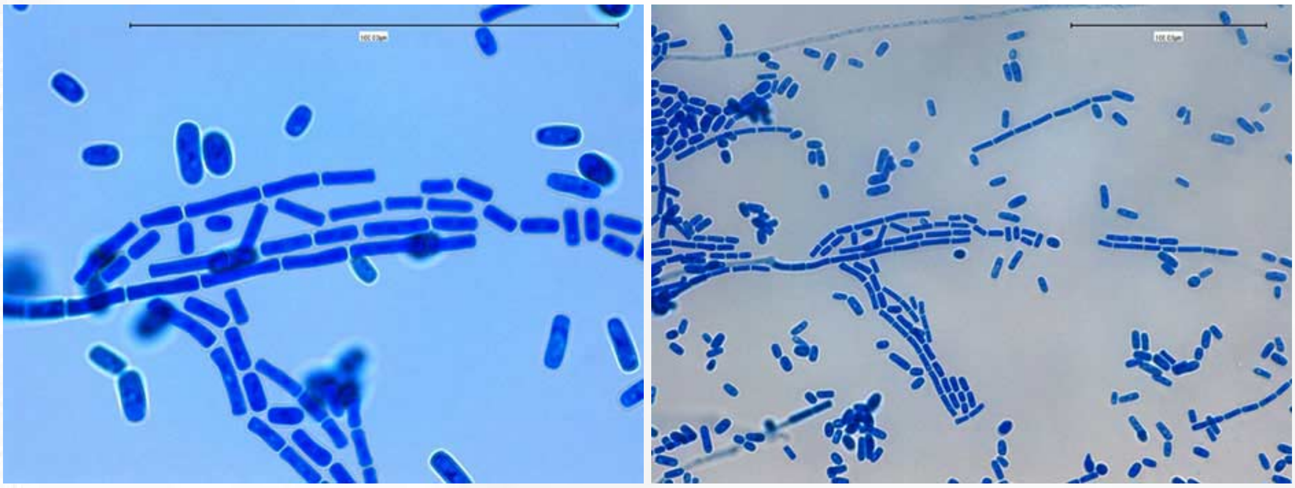
Geomyces destructans

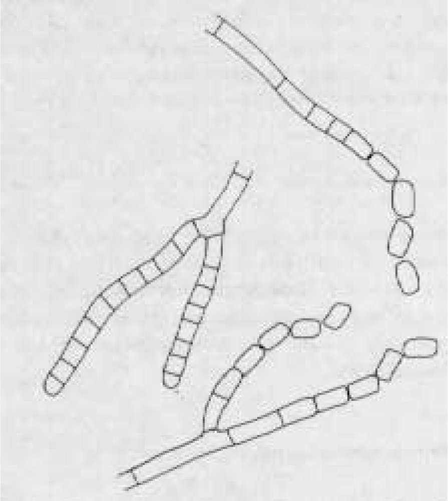
Characterized by short but distinct conidiophores that are branched above and which bear chains of spores formed directly from the cells of the branches. Often only the tips of the branches become converted into spores. The spores (conidia) are 1-celled and may be white or yellow.

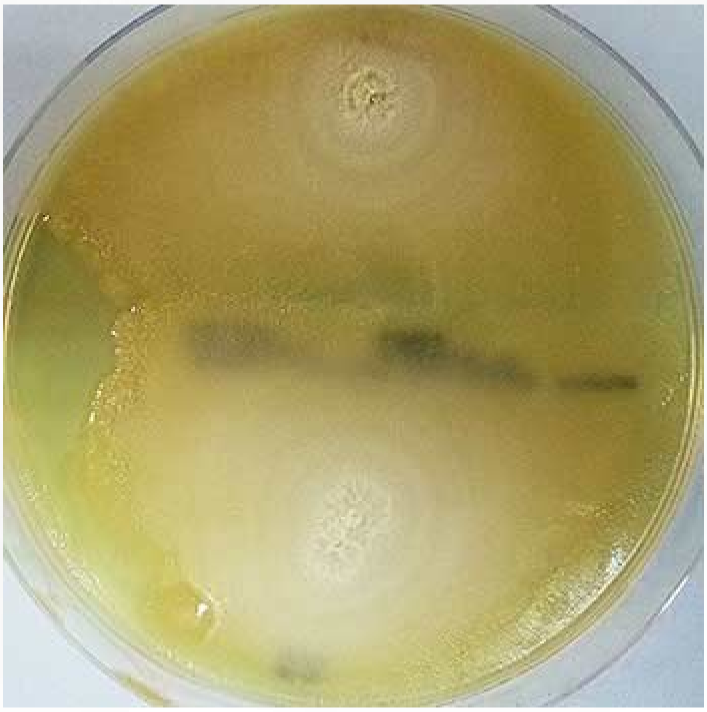
Species of *Geomyces* are generally found in relatively cool habitats, although many can grow well at room temperature. Some species are psychrophilic, that is they are adapted to cold conditions and cannot tolerate temperatures above the mid-teens celsius. These psychrophiles are often abundant in soils at high latitudes or in cold habitats such as mines and caves. *Geomyces destructans*, cause of white-nose syndrome in bats, thrives on hibernating bats in caves where the year-around temperature remains below 10 degrees C. The picture at right-middle shows the curved conidia characteristic of *G. destructans*. Occurring in soil, leaf litter and animal materials such as dung and decomposing tissues.

Classification: Myxotrichaceae (Myxotrichales).
Holomorph: Pseudogymnoascus.
Ref: Hayes 2012; Sigler and Charmichael 1976; Van Oorschot 1980.

Geotrichum





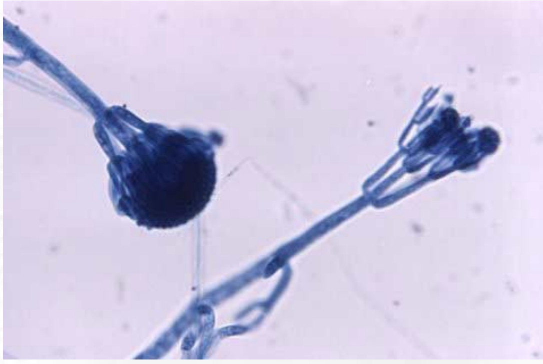


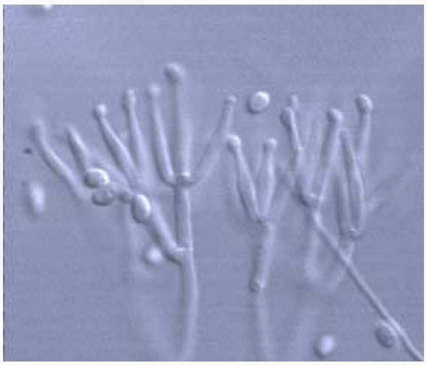
Geotrichum candidum

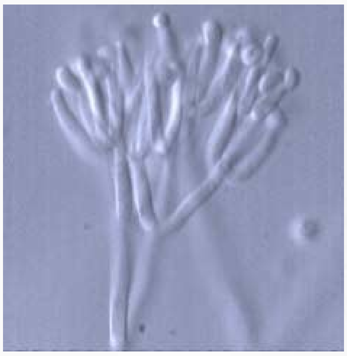
A very simple genus characterized by the formation of chains of colourless, slimy spores (conidia) through the segmentation of vegetative filaments. Some with strong odours. Common in dairy products, fruits, slime fluxes, and sometimes soil. Suh and Blackwell (2006) described three new species from the guts of living insects.

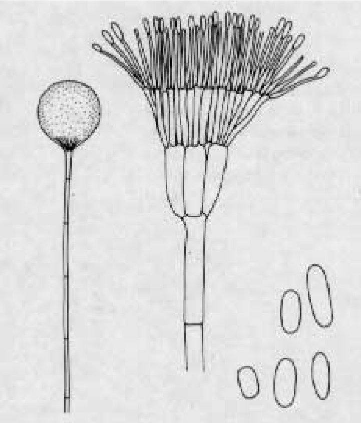
Classification: Dipodascaceae (Saccharomycetales), one of the so-called Hemiascomycetes or yeasts.
Holomorph: *Galactomyces*.
Ref: Carmichael 1957; Hoog *et al.*, 1986; Hoog and Smith, 2011; Sigler and Carmichael 1976.

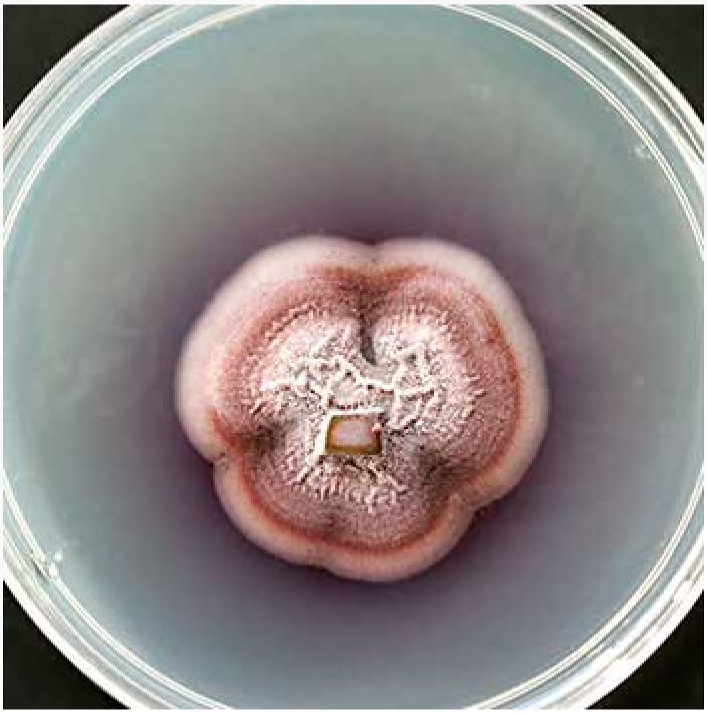
Gliocladium











formerly *Gliocladium roseum*

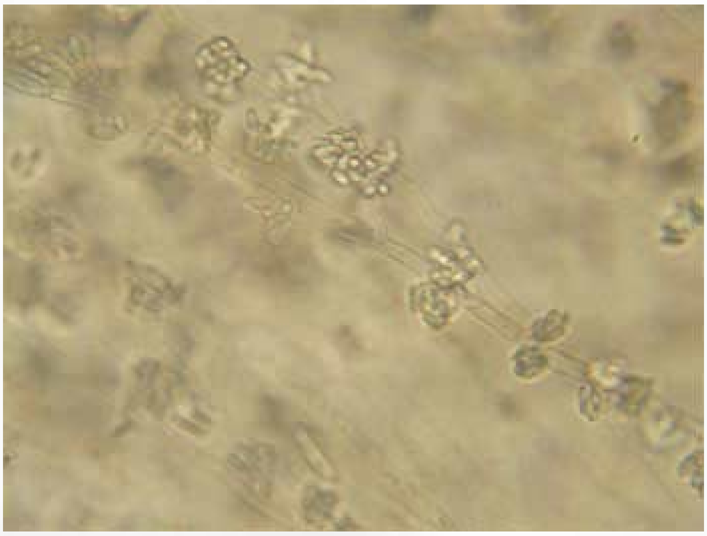
Conidiophores erect, terminated by a dense brush-like branching system bearing tapered phialides. The spores (conidia) are colourless, or green and are produced in a dense wet mass from the phialides. The spore-bearing structures are fairly large and complex as in the illustration of *G. penicillioides* at left. Species of *Gliocladium* are similar to those of *Penicillium* but with conidia collecting in wet rather than dry masses.

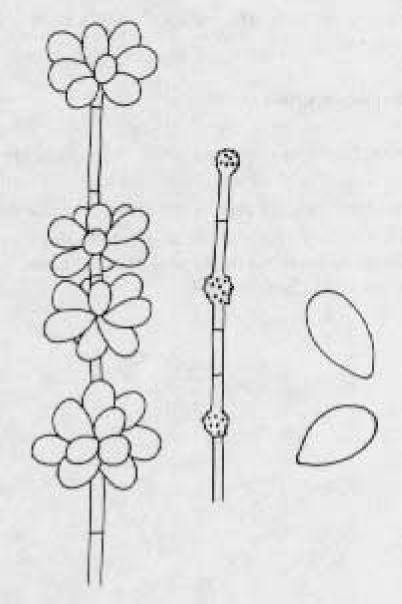
For many years *Clonostachys rosea* (two photos at right) was maintained in *Gliocladium* as *G. rosum* but is now known to be a member of the Bionectriaceae as an anamorph of *Bionectria* and *Roumegueriella* species.

Species of *Gliocladium* occur in soil or decaying plant matter where they frequently are reported as parasites of other fungi. Some can become pests in petri dish cultures, overrunning the colonies of other fungi.

Classification: Hypocreaceae.
Holomorphs: *Sphaerostilbella*, *Hypocrea* and other Hypocreales.
Refs: Domsch, Gams and Anderson, 1980; Morquer *et al.*, 1963; Raper and Thom, 1949.

Gonatobotrys



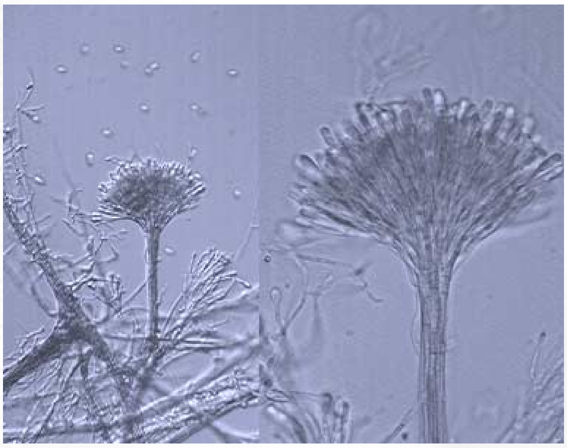


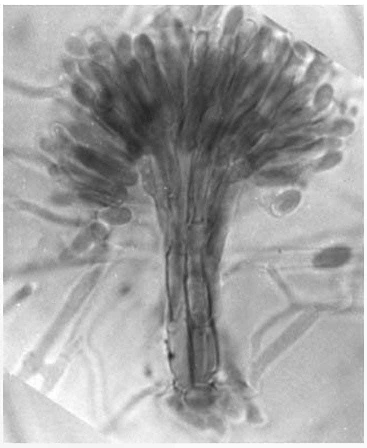
no image

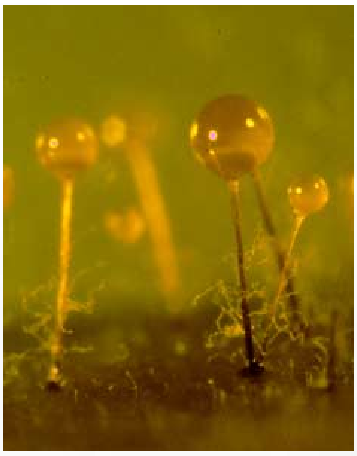
Consisting of an erect conidiophore with several roughened swellings along its length. The colourless 1-celled spores (conidia) are borne in grape-like clusters around each swelling. Similar to *Arthrobotrys* but the spores are never more than 1-celled. Parasitic on other fungi by means of small sucker-like structures called contact cells. Common on dead or dying plant parts, especially those not yet fallen to the ground.

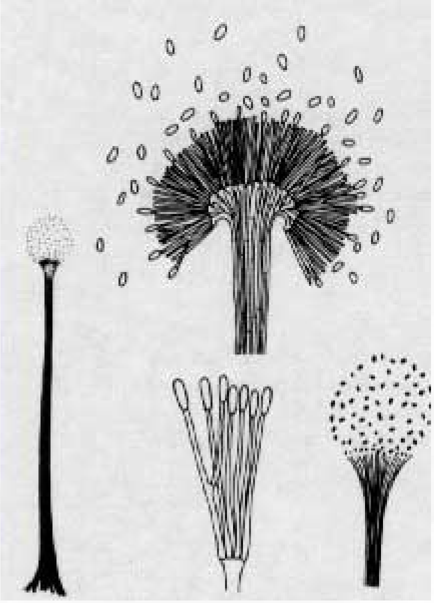
Classification: Ceratostomataceae (Hypocreales).
Holomorph: possibly *Melanospora*.
Refs: Matsushima 1975; Sutton 1973.

Graphium









Graphium ulmi

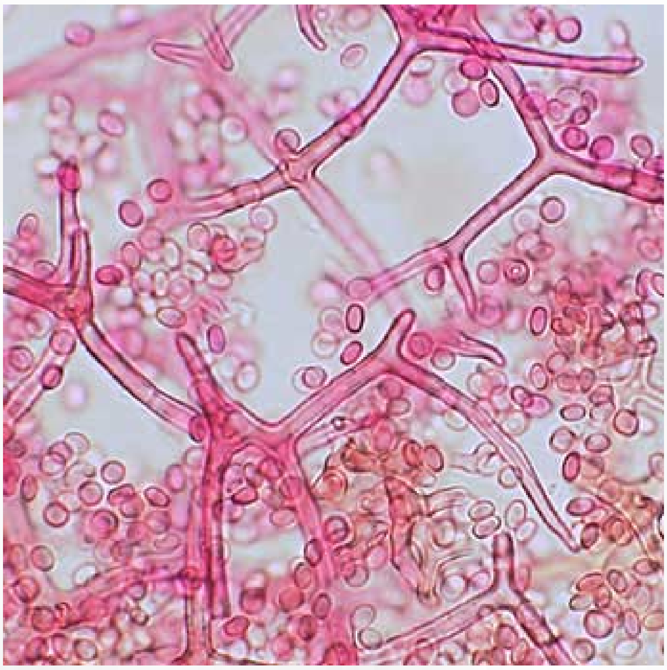
Fruiting structure a synnema, composed of fused dark conidiophores terminating in a droplet of liquid containing conidia. The colourless 1-celled spores are produced continuously from annellides, phialides or sympodially occurrring holoblastic loci, and collect in a large drop of fluid. The synnemata can be quite stout and up to 5 mm high.

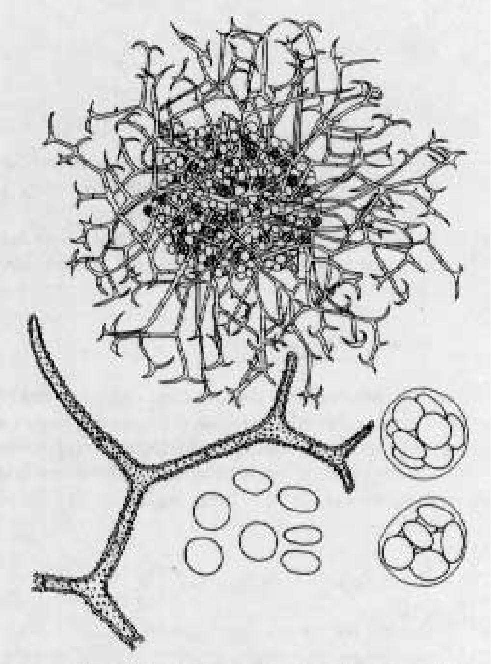
The two panels in the leftmost photo were taken from a culture isolated from seeds of canola, an edible rapeseed. It is a typical *Graphium* anamorph of *Kernia*, *Microascus*, *Petriella* and *Pseudallescheria*, all members of the ascomycete family Microascaceae. A few non-synnematous (mononematous) structures can be seen in the photograph at left; strictly speaking, these should be called *Scedosporium* because they are not synnematous. However, many strains are highly synnematous when first isolated but become mononematous after a few transfers. Some species of *Scedosporium* cause disease in humans and should be handled with great care. The second photo is the *Graphium* anamorph of *Kernia pachypleura*. This species produces distinct but much smaller synnemata with more compact annellides. The picture at right-middle is a macrophoto of synnemata growing on an agar surface.

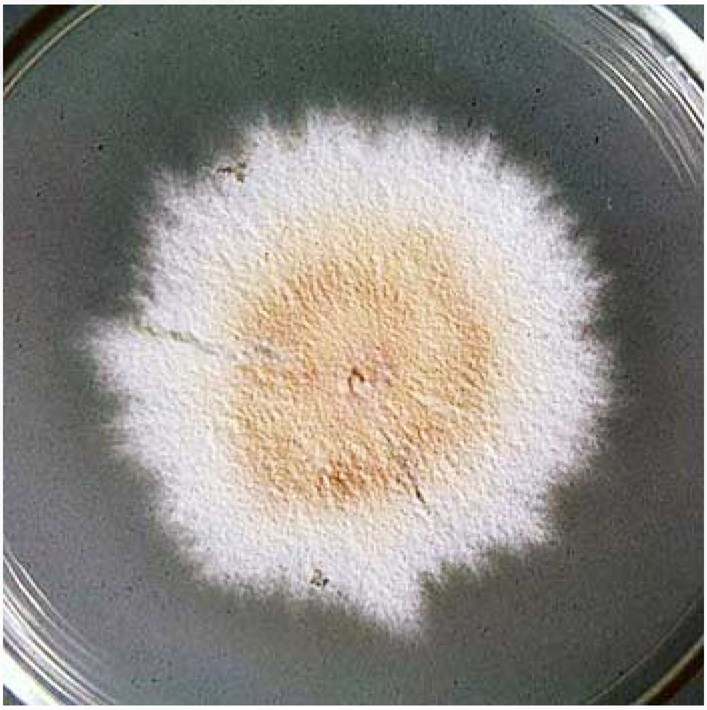
Occurring on wood, dung, seeds, and plant debris.

Classification: Microascaceae.
Holomorphs: *Kernia*, *Microascus*, *Petriella*, and *Pseudallescheria*.
Ref: Ellis 1971; Seifert and Okada, 1993.

Gymnoascus







Arthroderma gypseum (syn. *Gymnoascus gypseus*)

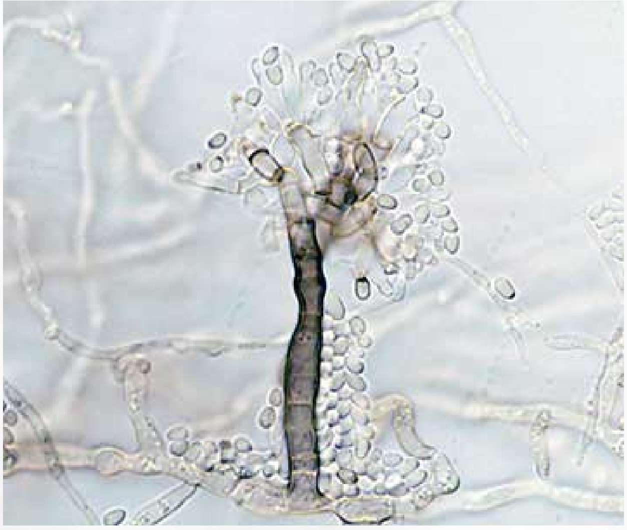
An ascomycete characterized by loose, light-coloured, bramble-like fruiting structures (gymnothecia) containing spherical asci which in turn each enclose eight spores (ascospores). The ascospores are colourless to yellow, smooth, and oblate (a flattened sphere). The gymnothecia usually bear some sort of hooked or recurved spines.

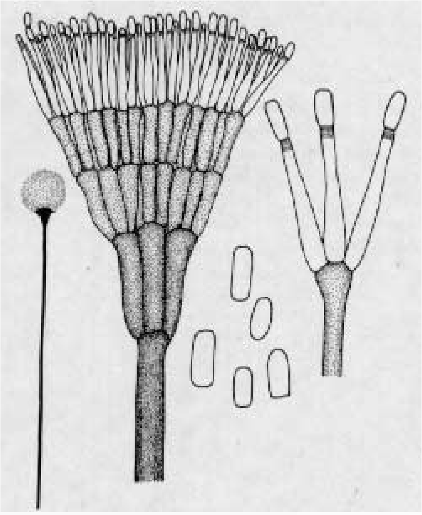
Several other genera of ascomycetes, all treated and discussed by Currah (1985, 1988), are similar to *Gymnoascus*. *Gymnoascus* species differ from all of these in having a combination of oblate, smooth ascospores and gymnothecia composed of distinctive hyphae forming a complete network around the mass of ascospores.

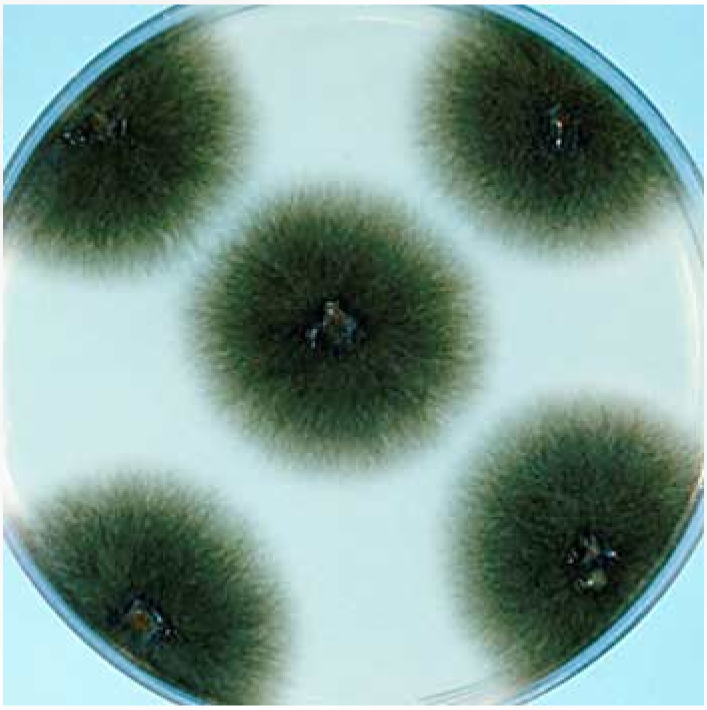
Occurring in soil, dung, or other habitats where hair or feathers are decaying.

Gymnoascaceae (Onygenales).
Anamorph: lacking.
Ref: Currah, 1985, 1988; Orr, Kuehn, and Plunkett 1963.

Leptographium





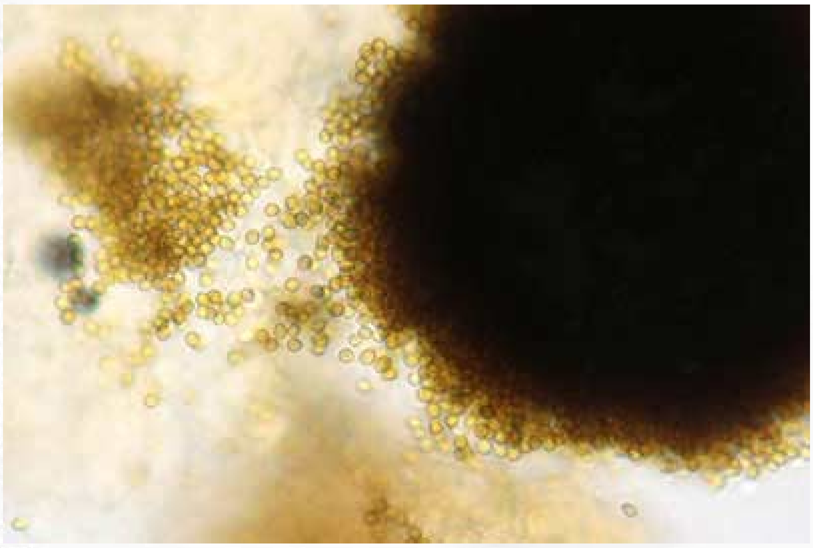


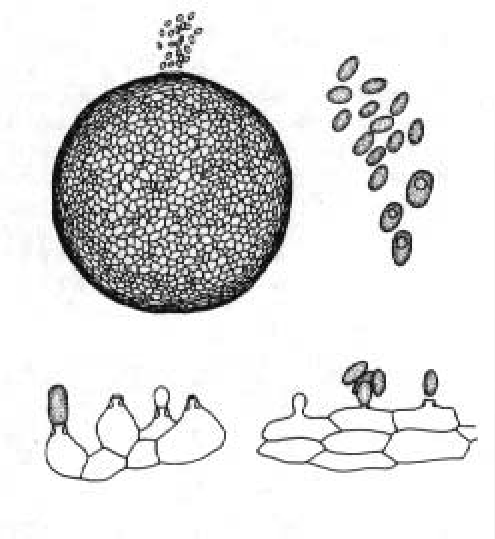
Leptographium procerum (syn. *Gymnoascus gypseus*)

Conidiophores very dark and stout, bearing a brush-like apical branching structure that is terminated by tapered annellides. The colourless 1-celled spores (conidia) are produced continuously from the tips of the annelides and collect in a large drop of fluid. *Phialocephala* species are related but differ in having phialides. Species of *Thysanophora* are similar but have conidiophores with short swollen branches bearing phialides in a manner strongly reminiscent of *Penicillium* species. On wood and conifer needles.

Ophiostomataceae (Ohiostomatales, Sordariomycetidae).
Holomorph: *Grossmannia*, *Ophiostoma*.
Ref: Ellis 1971.

Microsphaeropsis



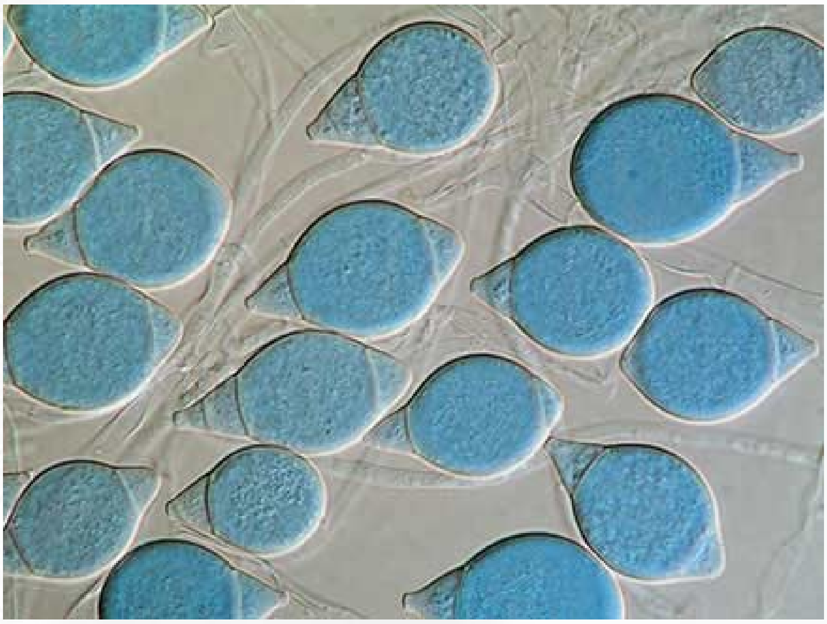


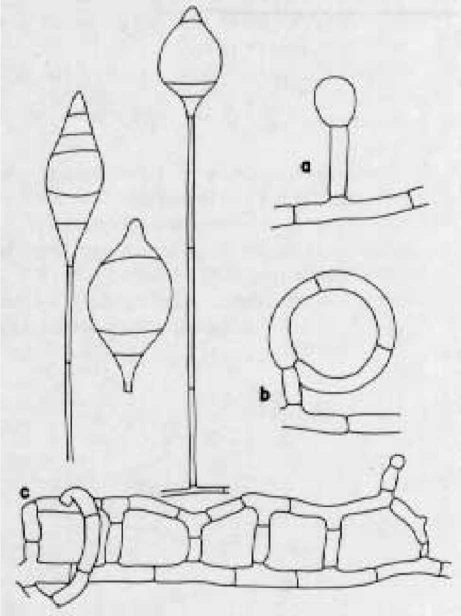
no image

The dark spores (conidia) are borne within cellular, more or less round fruiting structures (pycnidia) and are produced on small flask- or peg-like cells (annellides). Usually the spores are extruded through an opening at the top of the pycnidium and collect in a droplet of fluid. The species occur on living or dead plants.

Classification: Pleosporales.
Holomorphs: *Cucurbitaria*, *Didymosphaeria*, *Leptosphaeria*, *Pleospora*, and related genera.
Ref: Bestagno *et al.*, 1958; Sutton, 1980.

Monacrosporium



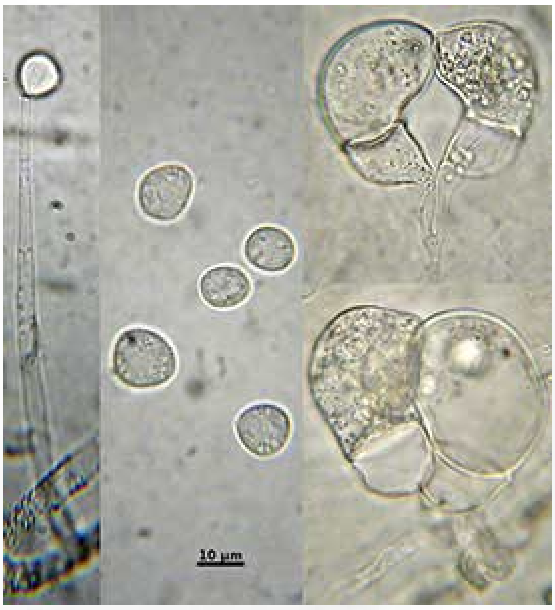


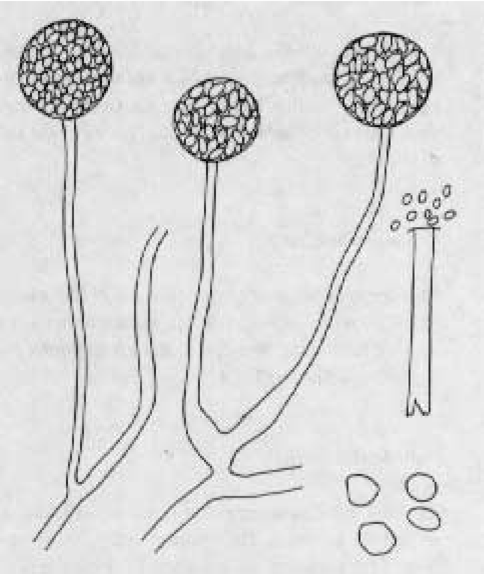
no image

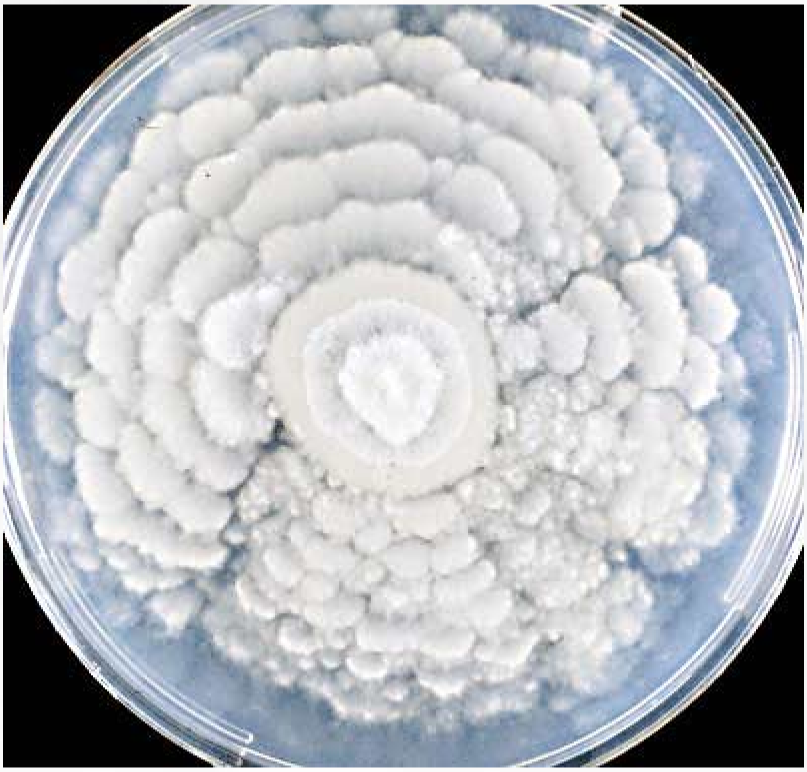
Conidiophores colourless, erect, bearing a single terminal spore (conidium). The conidia have 2 to several cells, are colourless, and have one cell larger than the others. Because of the large cell, the conidia are strongly spindle-shaped. Rubner (1996) recognized 39 species. Predacious on eelworms, which they catch by means of sticky knobs (a), rings (b), or adhesive networks (c). Closely related or possibly synonymous with *Arthrobotrys*. Occurring in soil, dung, and decaying plant matter.

Classification: see *Arthrobotrys*.
Holomorphs unknown.
Ref: Cooke 1967; Cooke and Dickenson 1965; Cooke and Godfrey 1964; Rubner, 1996.

Mortierella







Mortierella wolfii

Mortierella colonies are relatively fast-growing and often spread in overlapping "waves" or lobes. Some have a peculiar odour suggesting garlic. Many species produce a white oily substance in large drops among the aerial hyphae. One group of species, characterized by velvety, odourless colonies, is included with *Mortierella* in the older literature but is now segregated into the separate and unrelated genus *Micromucor*. The spores (sporangiospores) of *Mortierella* species are produced inside spherical sporangia at the tips of sporangiophores and are colourless to brownish. A columella is usually lacking or very poorly developed (compare with *Mucor* for this feature).

The photograph at left illustrates a species of *Mortierella*, possibly *M. verticillata*, isolated by museum technician Karen Vanderwolf from the surface of a hibernating bat in a New Brunswick cave. The leftmost panel shows a sporangiophore with a single spore at its apex. In fact, the sporangial wall had already broken and the spore is one of three or four that were originally there. The middle panel depicts several sporangiospores from broken sporangia. Typical of *Mortierella* species the spores are irregular in size and shape. The rightmost panel illustrates two pairs of gametangia in the midst of mating. The contents of one will move into the other, where the nuclei of the two will fuse, producing temporarily diploid nucei (zygotes). The gametangium containing the diploid nuclei will dvelop into a zygosporangium.

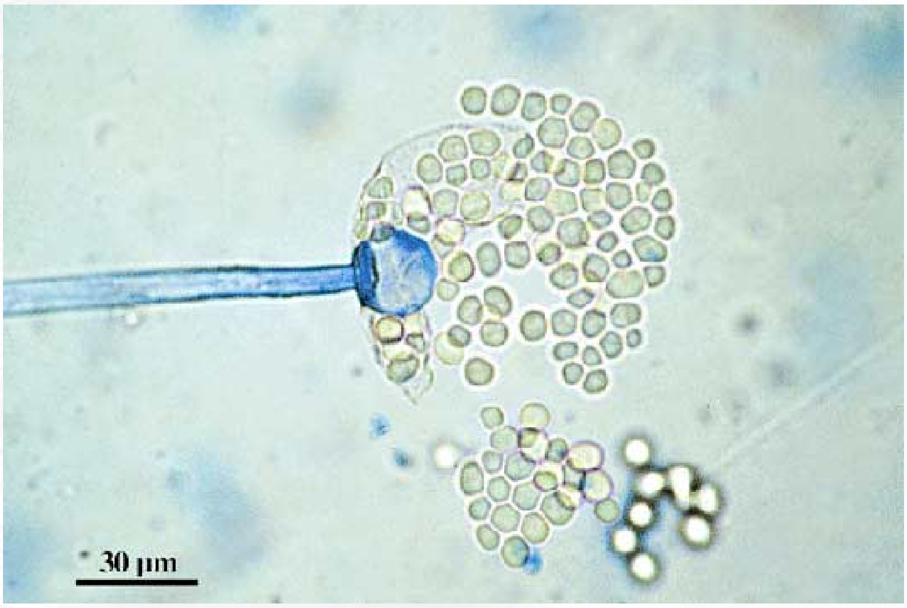
Mortierella species often fail to reproduce under normal laboratory conditions. We have obtained good sporulation by growing the colonies on water agar (agar media containing no nutrients) and incubating at 5-10°C. Growth is slow but sporangia are often abundant. Apparently cold and starvation triggers reproduction.

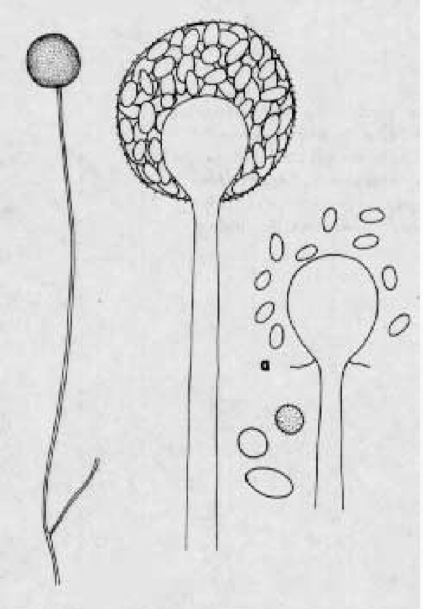
Some species, such as *M. polycephala*, produce spherical "chlamydospores". These spores can be large in some species and may be variously roughened. In culture, the chlamydospores may be more conspicuous than the sporangia; in fact sporangia may be absent at first. Similar spores are produced by *Histoplasma capsulatum*, cause of a serious disease in humans, and by species of *Sepedonium*.

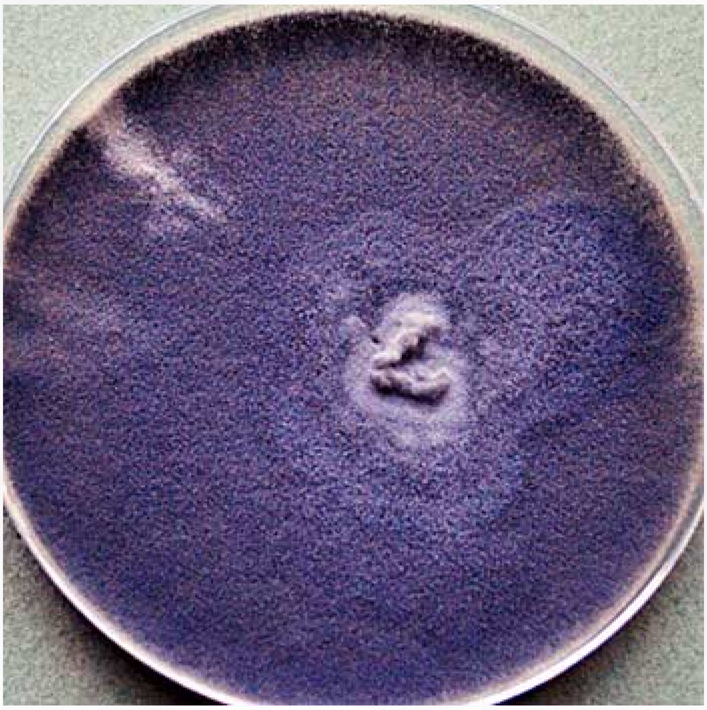
Common in soil and dung.

Classification: Mortierellaceae (Mucorales, Zygomycota).
Ref: Gams 1969, 1977; Zycha and Siepmann 1970.

Mucor





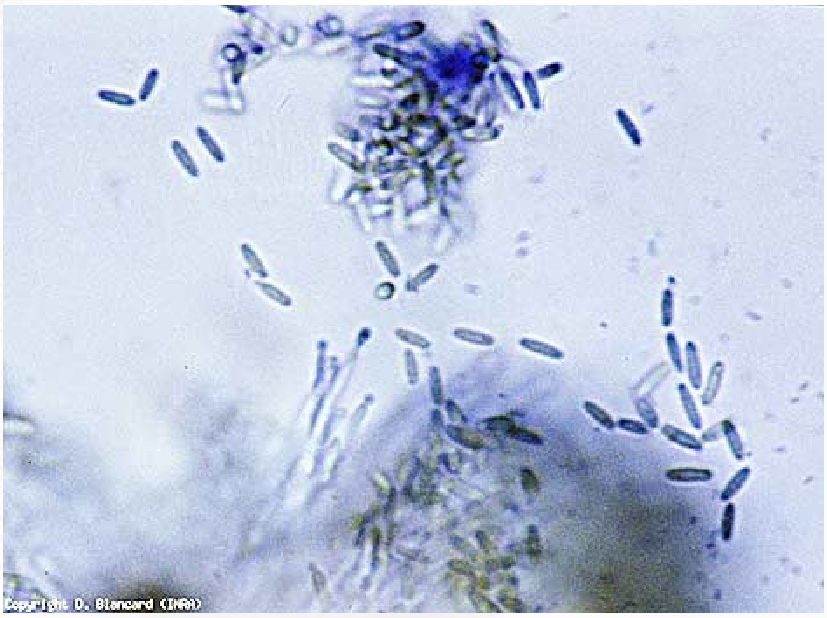


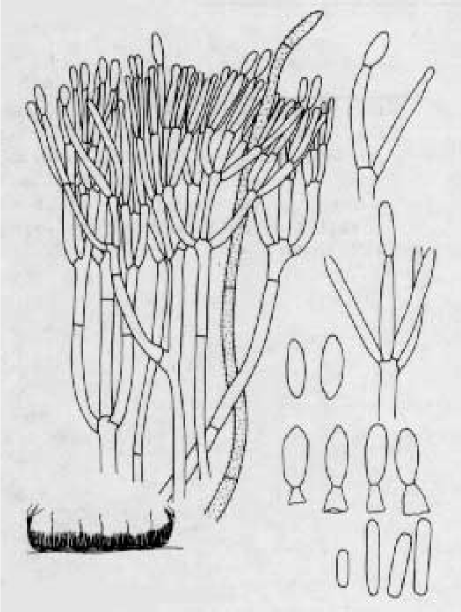
Mucor circinelloides

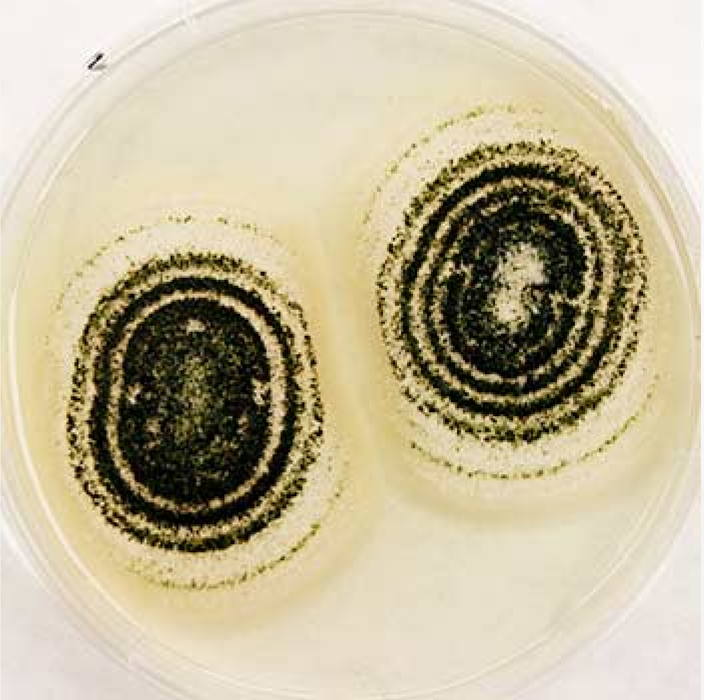
Colonies fast-growing, whitish to greyish, usually thick owing to the abundant upright sporangiophores. Spores (sporangiospores) produced inside spherical sporangia at the tips of the sporangiophores, brownish. Always with a large columella that remains after the sporangial wall is broken (a). Large dark zygospores may be produced. Common almost everywhere fungi occur.

Classification: Mucoraceae (Mucorales, Zygomycota).
Ref: Schipper 1978.

Myrothecium





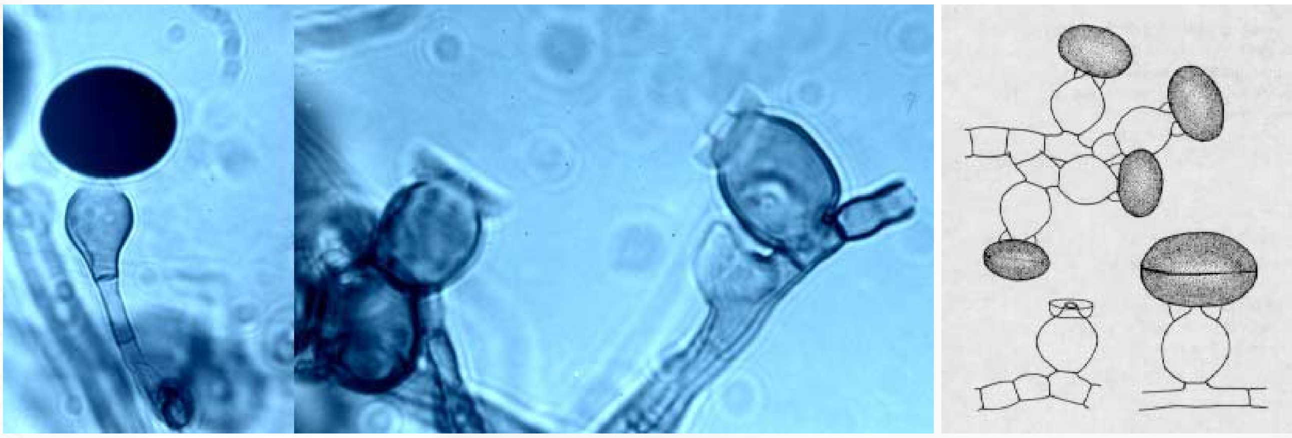


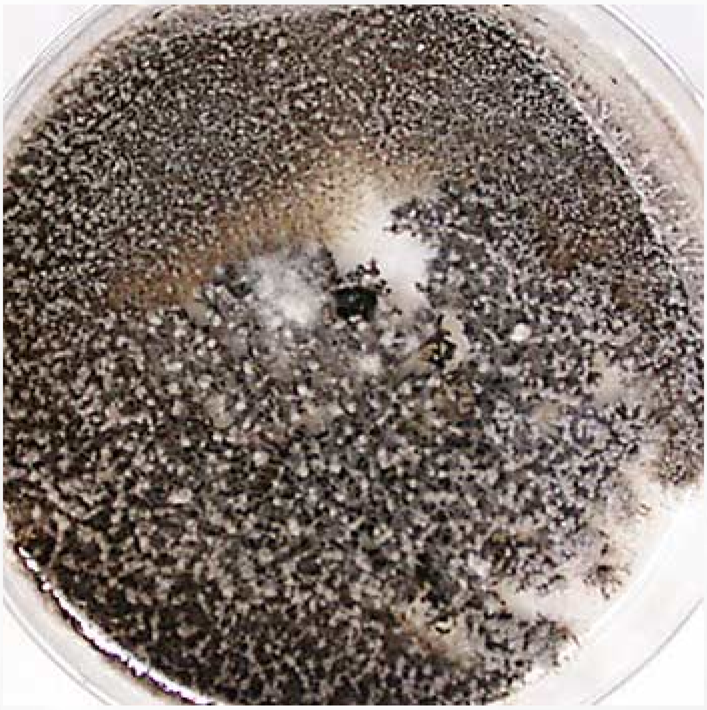
Myrothecium roridum

The conidiophores are united together to form fruiting structures (sporodochia) which are usually flat but may be on a stalk. The spores (conidia) are borne from the tips of the long phialides which are in turn borne on densely branched and brush-like conidiophores. The mass of dark green conidia collect in large green to blackish wet drops. In soil and decaying plant debris.

Classification: Hypocreales (Hypocreomycetidae), but its family placement is still unclear.
Holomorphs: unknown.
Ref: Domsch *et al.*, 1980; Tulloch 1972.

Nigrospora



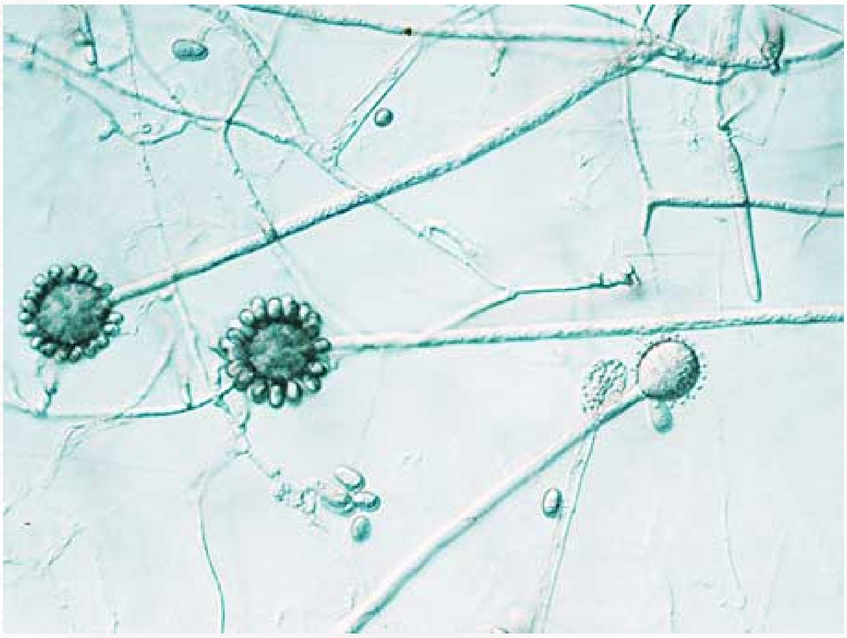


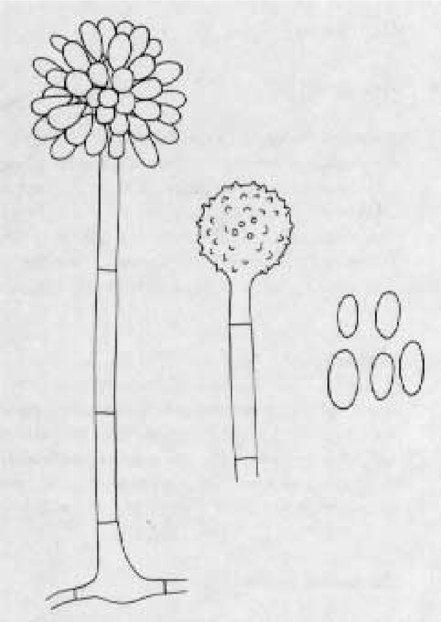
Nigrospora

The white woolly colonies grow fairly rapidly. Spores (conidia) are produced singly on swollen urn-shaped conidiophores and are egg-shaped to flattened-spherical, black, and often have an equatorial colourless line or germ slit. Occurring as parasites on living grasses but also present on dead ones; easily isolated from dead lawn grass in the autumn.

Classification: Trichosphaeriales (Sordariomycetidae).
Holomorph: *Khushkia*.
Ref: Ellis 1971.

Oedocephalum



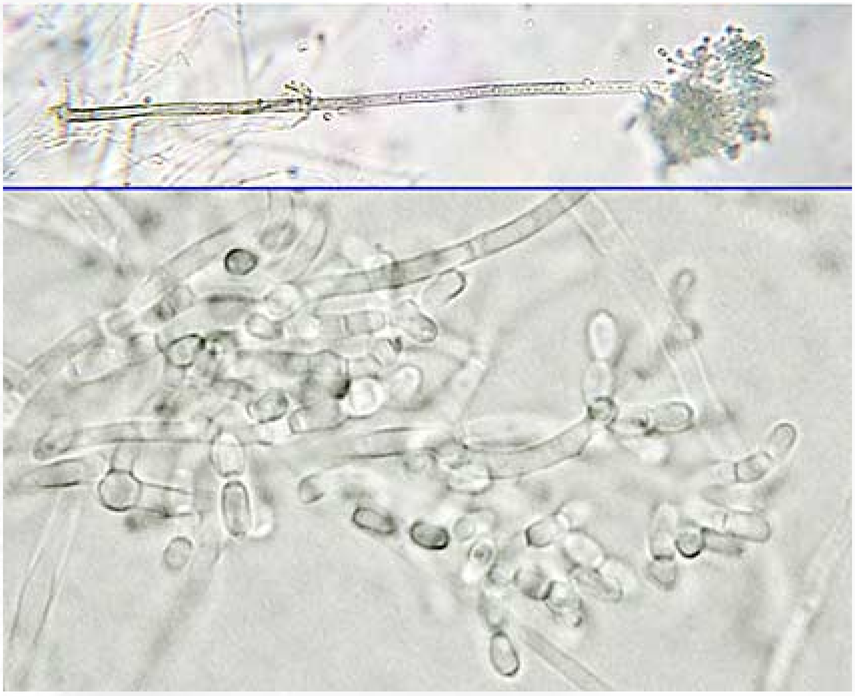


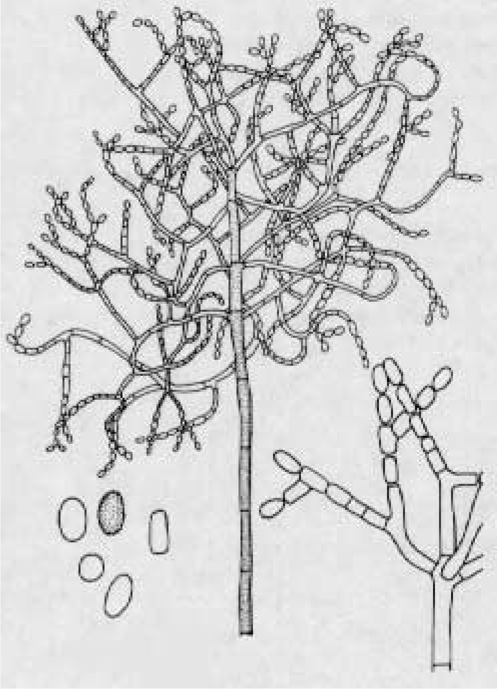
no image

Characterized by erect colourless conidiophores with a terminal swelling or vesicle. The spores (conidia) are colourless, 1-celled, and are borne in a single layer on the surface of the vesicle. Isolated from dung, wood, soil, and decomposing plant matter.

Classification: Pezizaceae.
Holomorphs: *Iodophanus*, *Peziza*.
Ref: Stalpers 1974.

Oidiodendron



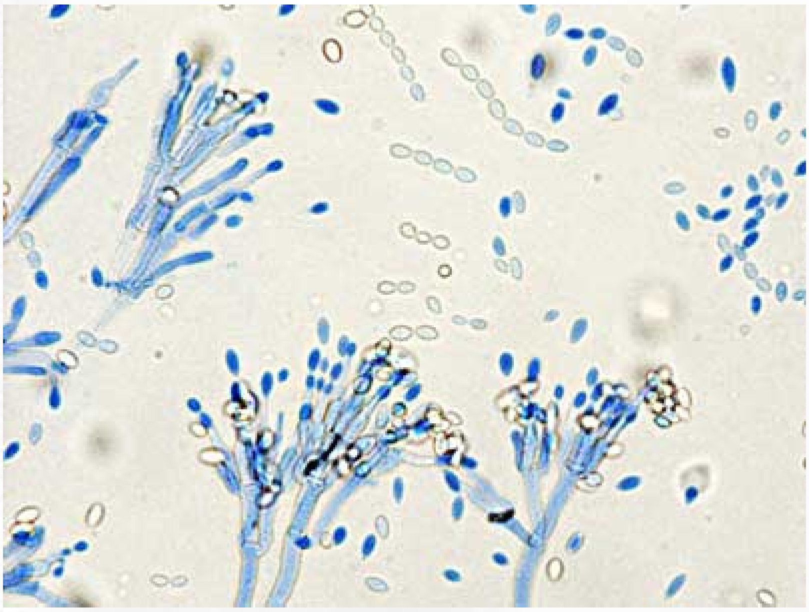


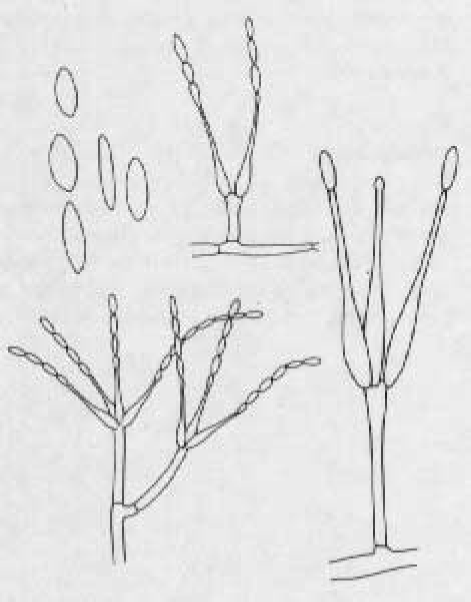
no image

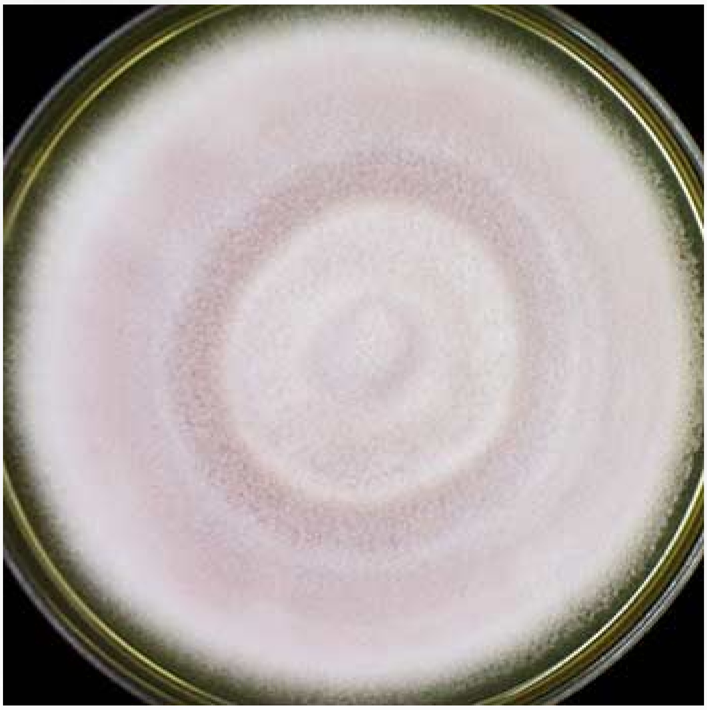
The dark conidiophores are erect, usually tall, and are terminated by a rather irregular system of tree-like branches. The brown to colourless spores (conidia) are produced by the fragmentation of the conidiophore branches. Occurring in soil and organic debris.

Classification: Myxotrichaceae (*Myxotrichales*).
Holomorphs: *Byssoascus*, *Myxotrichum*.
Ref: Barron 1962; Morrall 1968; Rice and Currah, 2005; Tokumasu 1973.

Paecilomyces





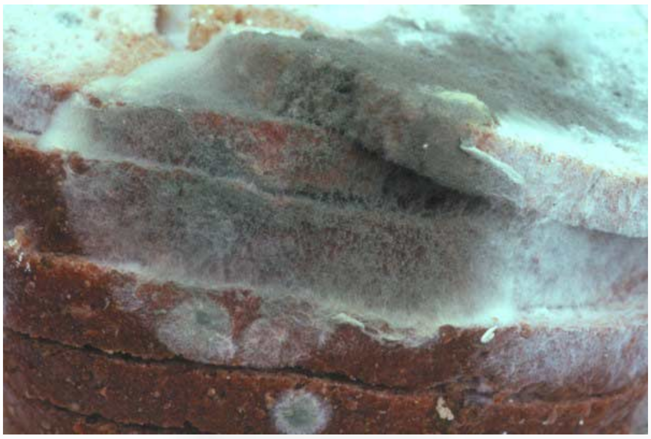


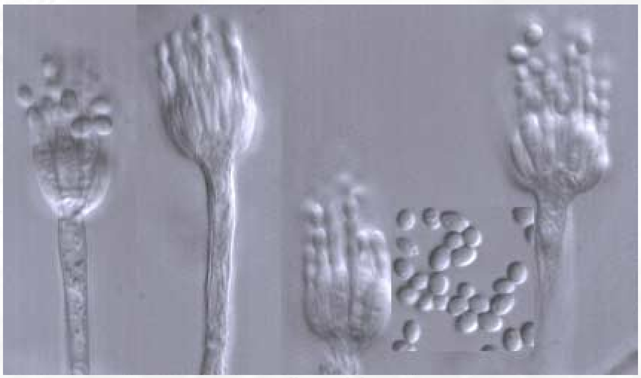
Paecilomyces lilacinus

Colonies with more or less well developed, colourless, simple or branched conidiophores bearing two to several phialides. The phialides are characteristically swollen at the base and gradually narrowed into a long beak. The spores (conidia) are produced in chains from the tips of the phialides, are colourless or brightly pigmented, and are usually rather narrow. Similar to *Penicillium*, but the chains of spores tend to be widely divergent in *Paecilomyces* and more parallel in *Penicillium*.

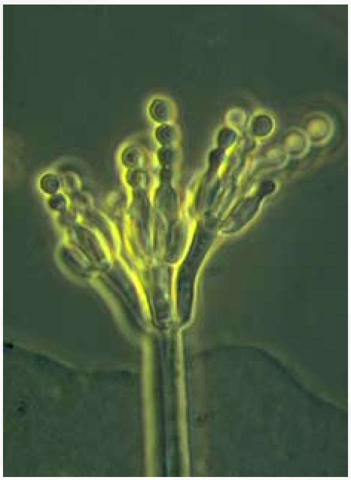
Classification: Thermoascaceae (Eurotiales).
Holomorphs: *Byssochlamys*, *Talaromyces*, *Thermoascus*.
Ref: Bissett 1979; Samson 1974.

Penicillium

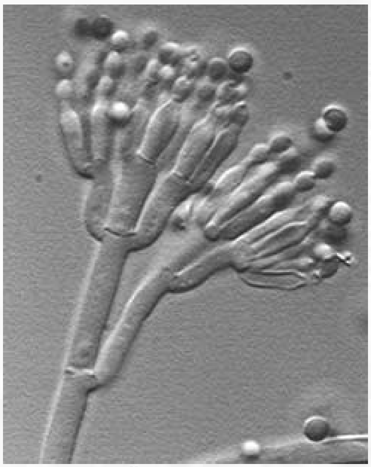




Penicillium glabrum



Penicillium



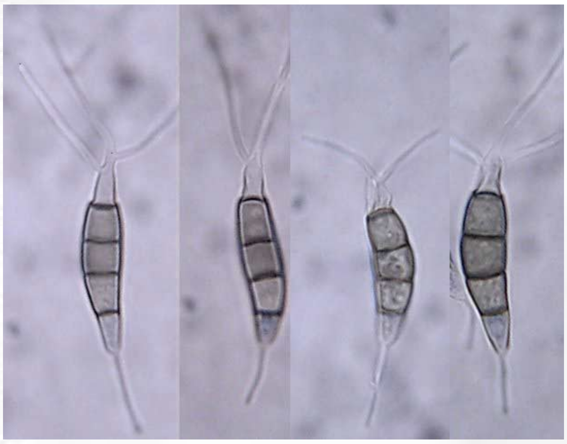
Penicillium atramentosum

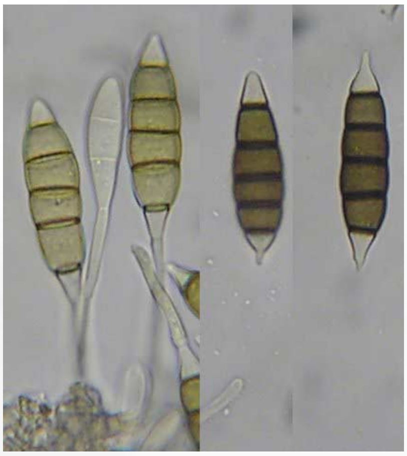
Species of *Penicillium* are recognized by their dense brush-like spore-bearing structures. The conidiophores are simple or branched and are terminated by clusters of flask-shaped phialides. The spores (conidia) are produced in dry chains from the tips of the phialides, with the youngest spore at the base of the chain, and are nearly always green. Branching is an important feature for identifying *Penicillium* species. Some, such as *Penicillium glabrum* at left, are unbranched and simply bear a cluster of phialides at the top of the stipe. Others (middle photo) may have a cluster of branches, each bearing a cluster of phialides. *Penicillum atramentosum*, at right, represents a third type haing branches that bear a second order of branches, bearing in turn a cluster of phialides. These three types of spore bearing systems (penicilli) are called monoverticillate, biverticillate and terverticillate respectively. *Penicillium* is a large and difficult genus encountered almost everywhere, and usually the most abundant genus of fungi in soils.

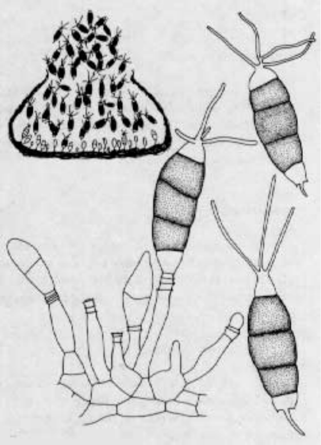
The common occurrence of *Penicillium* species in food is a particular problem. Some species produce toxins and may render food inedible or even dangerous. It is a good practice to discard foods showing the development of any mould. On the other hand some species of *Penicillium* are beneficial to humans. Cheeses such as Roquefort, Brie, Camembert, Stilton, etc. are ripened with species of *Penicillium* and are quite safe to eat. The drug penicillin is produced by *Penicillium chrysogenum*, a commonly occurring mould in most homes.

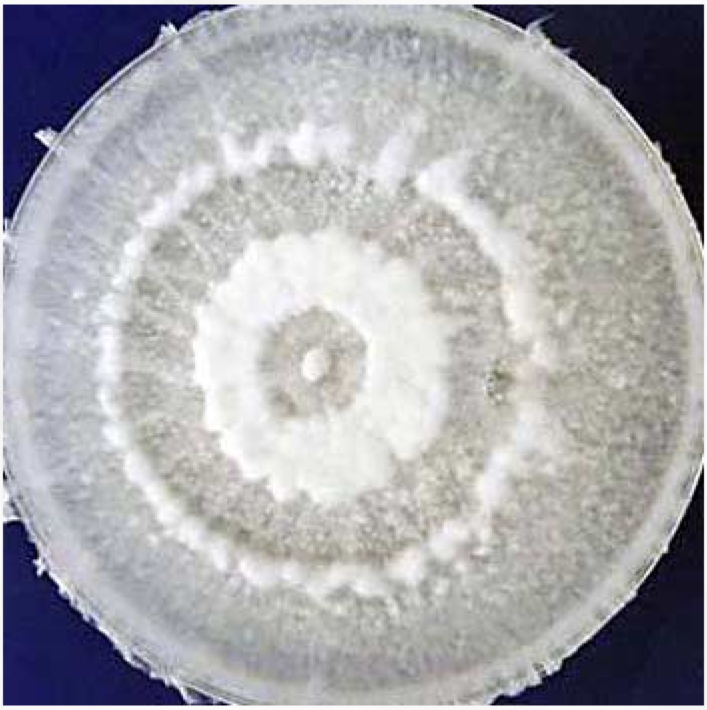
Classification: Aspergillaceae (Eurotiales).
Holomorphs: *Eupenicillium*, *Hamigera*, *Talaromyces*, *Trichocoma*.
Ref: Kulik 1968; Pitt, 1980, 1985; Raper and Thom 1949; Ramirez, 1982; Samson and Frisvad, 2004; Samson and Houbraken, 2011; Samson, Stolk, and Hadlok 1976; Stolk and Samson, 1972, 1983.

Pestalotiopsis









Pestalotiopsis microspora

Conidiophores (annellides) produced within compact fruiting structures (aecervuli or pycnidia). Spores (conidia) 4- to 5-celled, with the two or three central cells dark brown, and with two or more apical appendages or hairs; collecting in a wet mass outside the aecervulus.

Pestalotiopsis is just one of a complex group of fungi. For example the photo at top-center is of *Seiridium abietinum*, a species found on dead branches of balsam fir in Atlantic Canada. It differs from species of *Pestalotiopsis* in having conidia with a single apical appendage rather than several. The following key may be some help in distinguishing these difficult genera. However, anyone seriously interested in identifying a member of this group should consult the monumental work on coelomycetes with appendaged conidia by T. R. Nag Raj (Nag Raj, 1993).

Simplified key to *Pestalotiopsis* and related genera

1. Conidia with a single apical branched or unbranched appendage 2.

1. Conidia with appendages arising at more than one point on the apical cell 10.

2. (1) Basal appendages always lacking 3.

2. Basal appendage present in some of the spores 6.

3. (2) Apical appendage laterally branched, comb-like -» *Labridella*.

3. Apical appendage unbranched or with branches regularly produced on more than one side 4.

4. (3) Apical cell with a single unbranched appendage produced at a nearly right angle to the axis of the spore -» *Bleptosporium*.

4. Apical cell with appendage(s) branched or arising at several points 5.

5. (4) Branches of the apical cell arising at one point or nearly so -» *Hyalotiella*.

5. Branches of apical appendage arising at several points -» *Truncatella*.

6. (2) Conidia without appendages commonly occuring among those with appendages -» *Seimatosporium*.

6. Conidia consistently appendaged 7.

7. (6) Basal appendage arising from the basal septum of the conidium, often visible inside the conidiogenous cell before the conidium has broken off 8.

7. Basal appendage arising from the lateral wall of the basal cell, usually visible alongside the conidiogenous cell before the conidium has broken off 9.

8. (7) Conidia with four or five cells, euseptate, with normally thickened or relatively thin septa -» *Monochaetia*.

8. Conidia with six cells, disto-septate, with inner walls greatly thickened and often with conspicuous septal pores -» *Seiridium*.

9. (8) Apical appendage lateral, branched -» *Doliomyces*.

9. Apical appendage unbranched -» *Sarcostroma*.

10. (1) Conidia disto-septate, with inner walls greatly thickened and often with conspicuous septal pores -» *Pestalotia*.

10. Conidia euseptate,with normally thickened or thin septa 11.

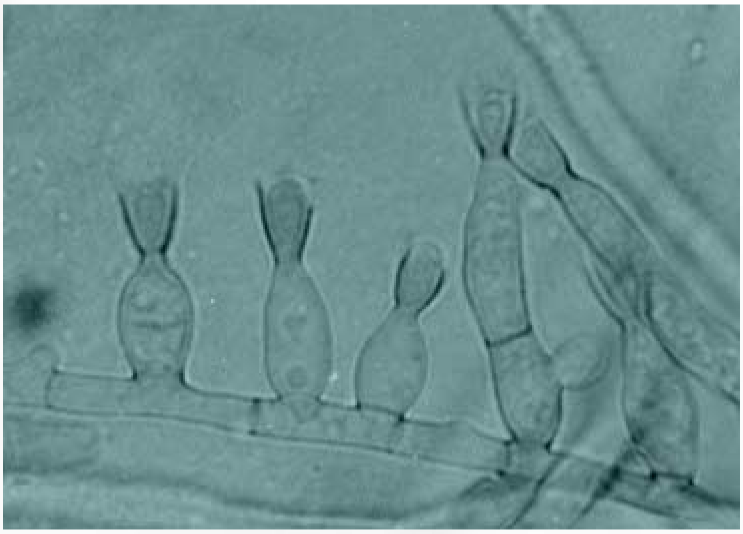
11. (10) Median (coloured) cells of the conidia thin, smooth-walled and pale, occasionally nearly colourless; apical appendages consist of one obliquely bent terminal appendage giving the spore a hummingbird-like appearance and one or more lateral appendages borne on the convex side of the apical cell -» *Zetiasplozna*.

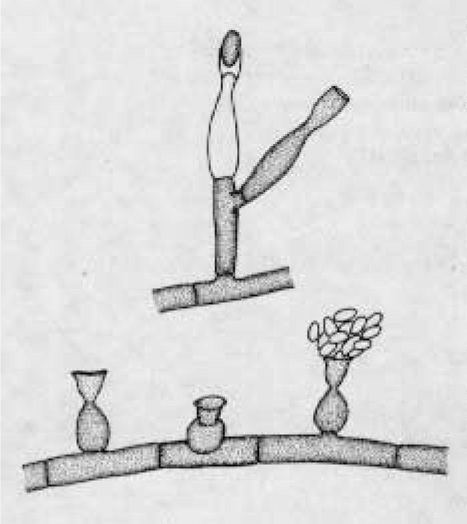
11. Median cells of the conidia thick-walled, dark and sometimes roughened; apical appendages less regular in configuration -» *Pestalotiopsis*.

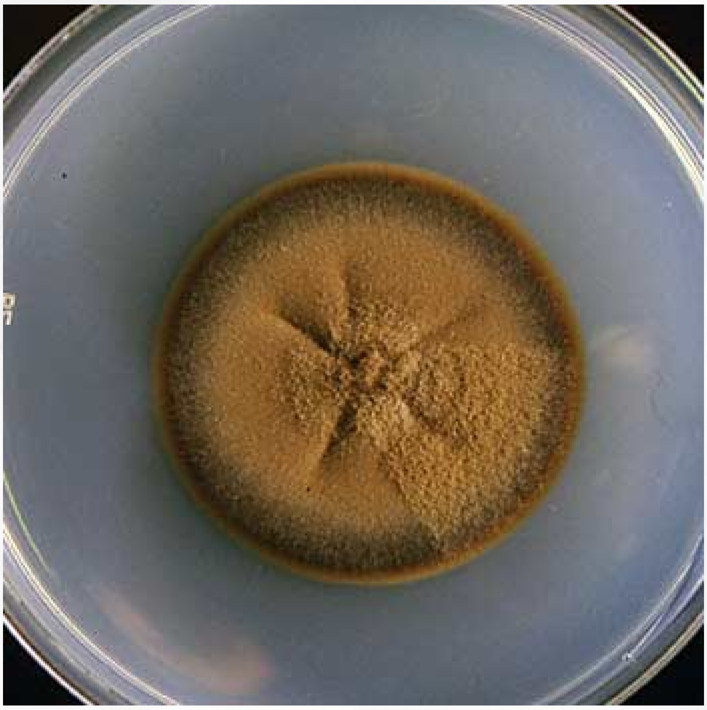
Parasitic or endophytic on living leaves and twigs but are often isolated from dead plant matter and even soil.

Classification: *Pestalotiopsis* species, and those of related genera, are anamorphs of members of the ascomycete family Amphisphaeriaceae (Sordariomycetidae). Members of the Amphisphaeriaceae and their anamorphs include *Amphisphaeria* (*Bleptosporium*), *Blogiascospora* (*Seiridium*), *Broomella* (*Pestalotia* and *Truncatella*), *Discostroma* (*Seimatosporium*), *Ellurema* (*Hyalotiopsis*), *Griphosphaerioma* (*Labridella*), *Lepteutypa* (*Seiridium*), *Neobroomella* (*Pestalotia*), and *Pestalosphaeria* (*Pestalotiopsis*). *Doliomyces*, *Monochaetia*, *Sarcostroma* and *Zetiasplozna* have not yet been found associated with a holomorph.
Ref: Guba 1961, Kang, *et al* 1999, Nag Raj, 1993.

Phialophora







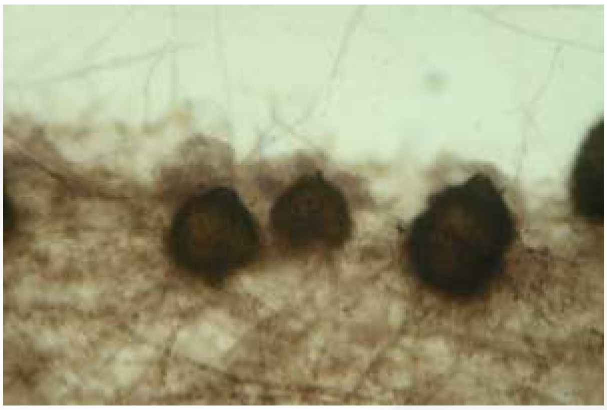
Phialophora verrucosa

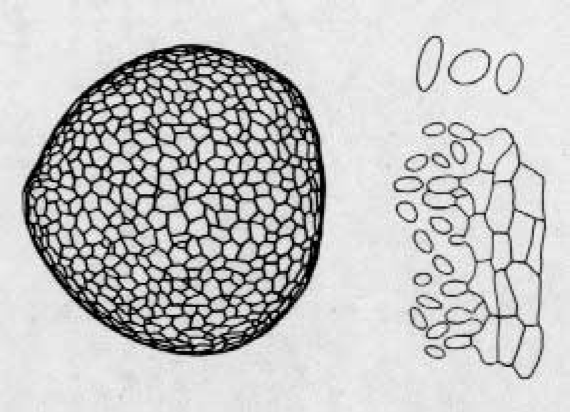
Characterized by brown to black colonies bearing phialides directly on the vegetative filaments or on short branches. The phialides are dark, flask-shaped, and have a collar-like or flared apex. The colourless to brown 1-celled spores (conidia) are produced successively from the apex of the phialides. Some species may produce dark brown holoblastic conidia along the vegetative hyphae or at the tips of short branches. Species of *Exophiala* are similar and are separated from those of *Phialophora* mainly on the basis of producing annellides rather than phialides. The differences between the two are subtle in some instances. There are numerous other fungi not closely related to *Phialophora* as strictly defined. Seifert *et al.* provide a key written by the eminent Dutch mycologist Dr. Walter Gams to 36 genera that could be confused with *Phialophora*.

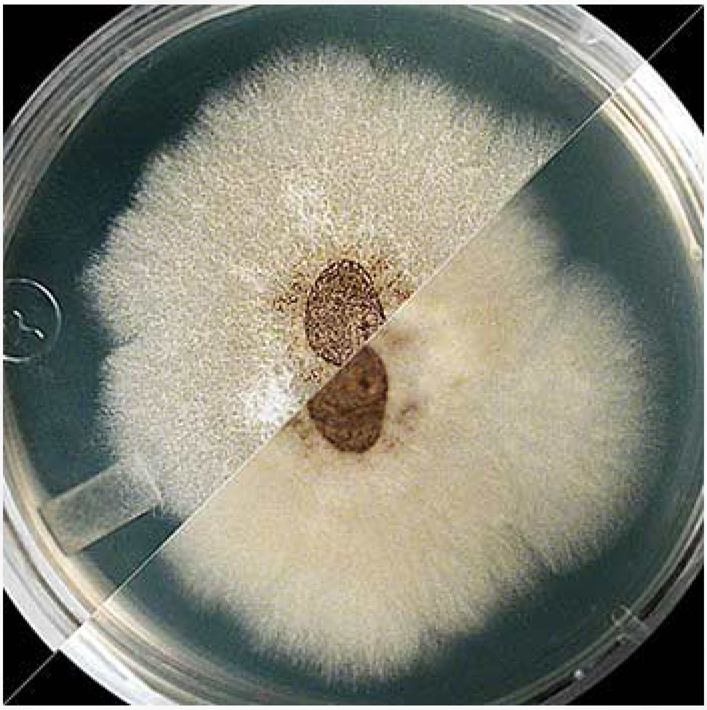
Phialophora species have been isolated from soil, water, dung, wood and plant debris.

Classification: Herpotrichiellaceae (Eurotiomycetes).
Holomorphs: *Capronia*.
Ref: Cole and Kendrick 1973; Ellis 1971, 1976; Schol-Schwarz 1970; Wang, 1990.

Phoma







Phoma glomerata

Recognized by its cellular and more or less round fruiting structures (pycnidia) containing masses of 1-celled colourless to yellow or pink spores (conidia). The conidia are borne from inconspicuous peg-like phialides lining the inner wall of the pycnidium. Species of *Phoma* having spines or setae on their pycnidia are sometimes confused with those of *Pyrenochaeta.* However, the two genera can be distinguished on the basis of their conidium-bearing structures: conidia of *Phoma* species are produced from simple phialides while those of *Pyrenochaeta* arise from phialides ocurring along the sides of elongated conidiophores.

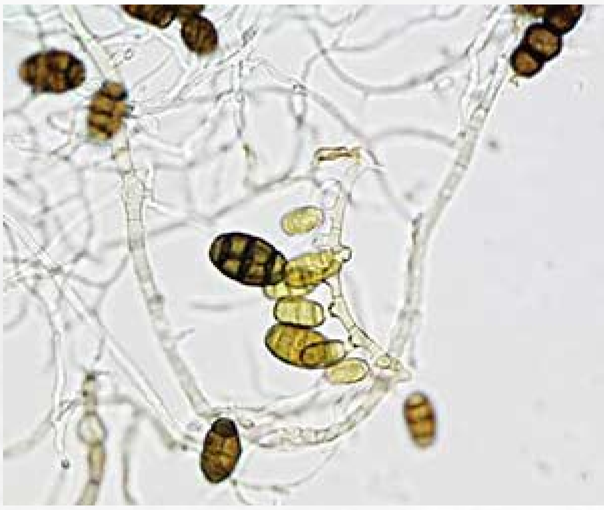
Phoma is a taxonomically difficult genus and is still under study. Species identification is often difficult. Much of our present knowledge has come from the work of Dr. G.H. Boerema and his colleagues in The Netherlands. Boerema (in Aa, *et al.*, 1990) divided *Phoma* into five sections, extended in 2004 (Boerema *et al.*, 2004) to nine in a comprehensive identification manual.

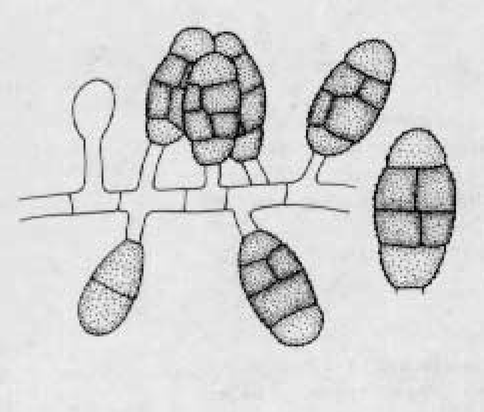
Aveskamp *et al.*, (2010) have studied the genetic relationships of fungi referrable to *Phoma* and have found, as Boerema himself suspected, that the genus is highly polyphyletic; that is, its species belong to a number of distinct families within the *Pleosporales.*, including the Cucurbitaceae, Didymellaceae, Leptosphaeriaceae, Phaeosphaeriaceae, Pleosporaceae, and Sporormiaceae. While these authors agree that Boerema's classification is useful for practical identification the sections do not really reflect natural relationships.

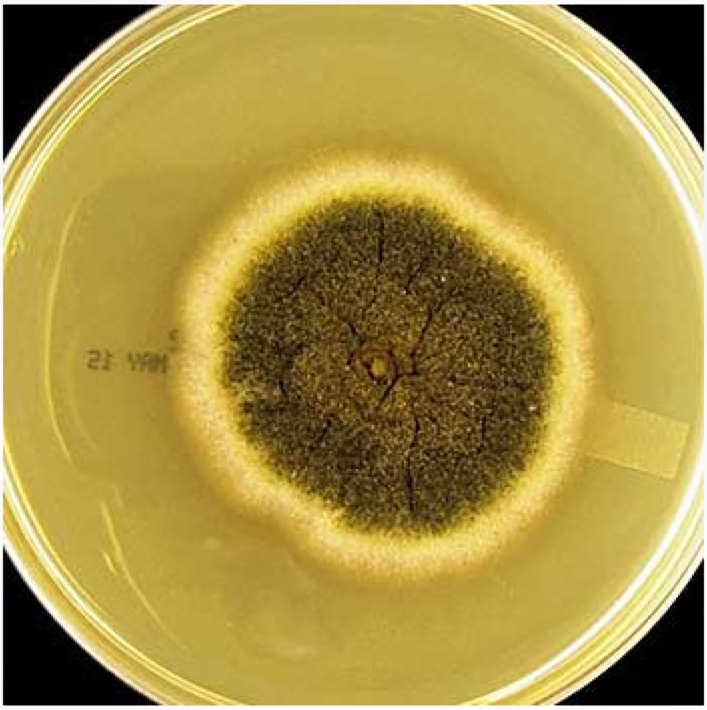
Species of *Phoma* are frequently encountered in indoor environments. In fact, in an intensive study of the dust in 369 homes in western Ontario, Dr. James Scott found the species *Phoma herbarum* to be in nearly 30% of the homes and to be the 14th most common mould overall (Scott, 2001). This study is available online at Dr. Scott's Sporometrics website. *Phoma herbarum* is the type species of the genus *Phoma*, meaning that it is the species upon which the genus is based. It is therefore undisputedly a 'good' species of *Phoma*. Beside being found in indoor environments species of *Phoma* are common in soils, dung, and both living and dead plants.

Classification: In the true genetic sense, based on its type species *P. herbarum*, *Phoma* belongs in the Didymellaceae (Pleosporales). In a broader and less evolutionary sense it can be located in all of the families listed above.
Holomorphs: many genera of ascomycetes, for example, *Didymella* and *Leptosphaeria*.
Ref: Aa *et al*, 1990; Aveskamp *et al.*, 2010; Boerema, 1993; Boerema *et al.*, 1994; Boerema *et al.*, 2004; Boerema and Dorenbosch 1973; Dorenbosch 1970; Gruyter and Noordeloos, 1992.

Pithomyces







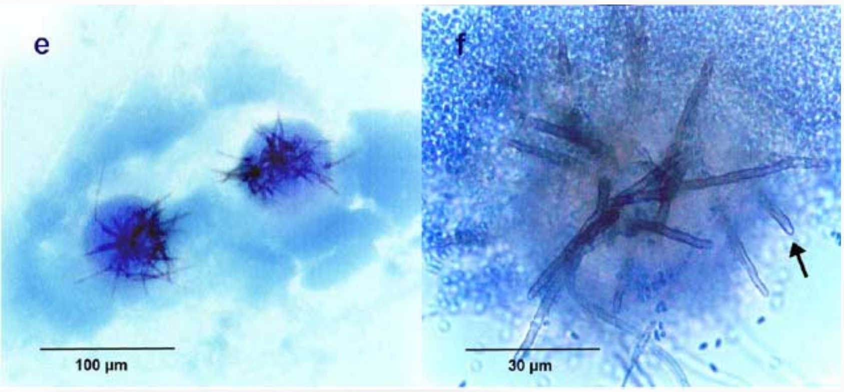
Pithomyces

Spores (conidia) produced at the apex of short side branches of the vegetative filaments, dark brown, 2- to several-celled. When the spores are released they retain a small portion of the cell that produced them. The spores of *P. chartarum*, the most commonly isolated species, have both longitudinal and transverse walls.

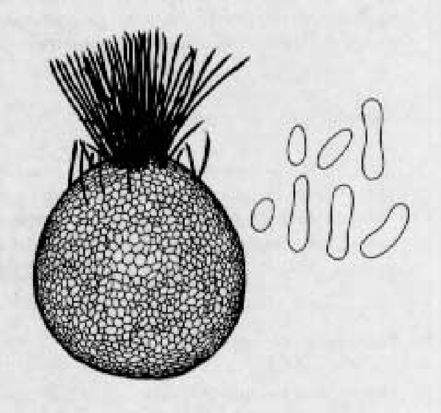
Growing on decaying plants, especially grasses.

Classification: Pleosporaceae (Pleosporales).
Holomorph: *Leptosphaerulina*.
Ref: Ellis 1971, 1976.

Pyrenochaeta



Pyrenochaeta unguis-hominis

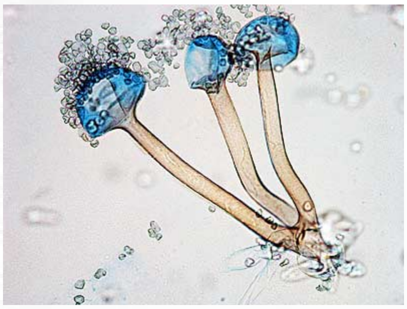


Pyrenochaeta lycopersici

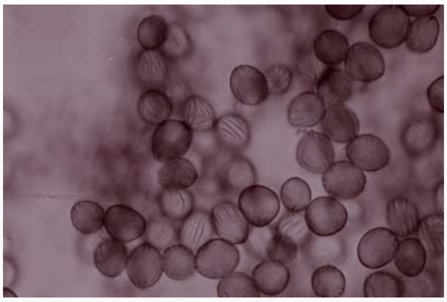
Fruiting structures (pycnidia) more or less round and ornamented, at least on the upper part, with stiff spines. The colourless to yellowish 1-celled spores (conidia) are borne from phialides produced along the length of elongated conidiophores lining the inner walls of the pycnidium. Some species of *Phoma* also have pycnidial spines, but differ in having simple phialides borne dirctly from the walls of the pycnidium. Isolated from soil and plant debris.

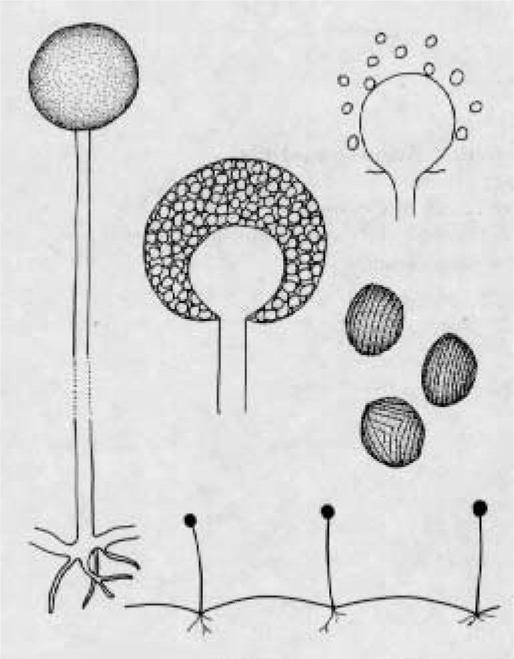
Classification: Cucurbitariaceae (Pleosporales) according to Gruyter *et al.*, (2010).
Holomorphs: *Cucurbitaria*, *Herpotrichia*.
Ref: Dorenbosch 1970; Gruyter *et al.* 2010; Schneider 1979.

Rhizopus



Rhizopus microsporus var. *rhizopodiformis*



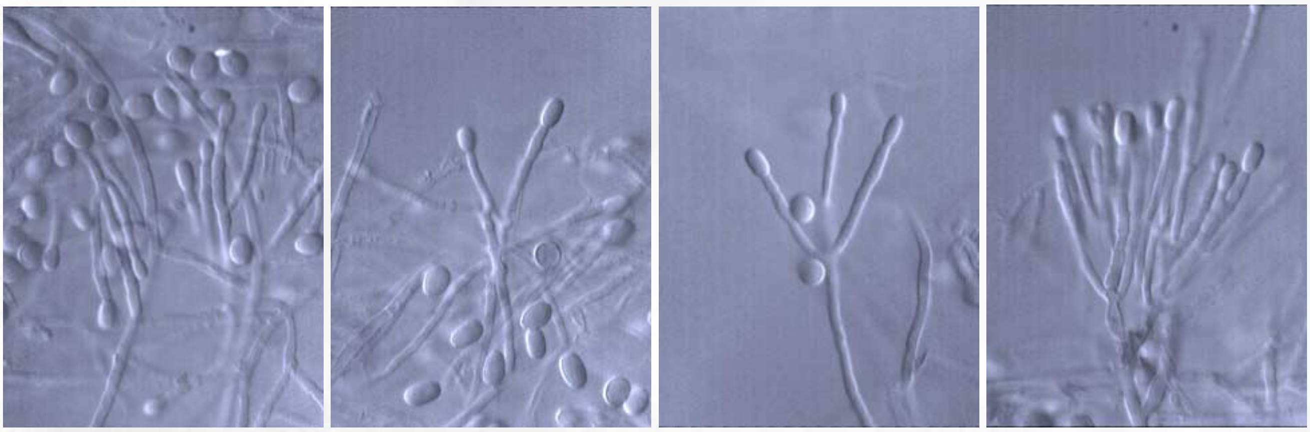


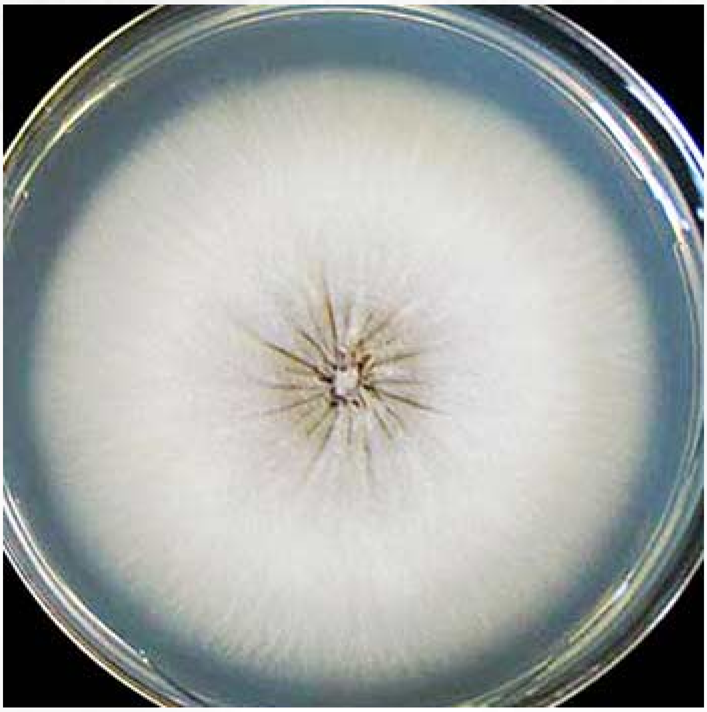
Rhizopus oryzae

Colonies very fast growing and coarse. Characterized by dark sporangia containing dark to pale spores and a large columella. At the base of the sporangiophores are root-like rhizoids. Often spreading by means of aerial, creeping stolons. *Rhizopus* species are often a pest in the laboratory. Because of their rapid growth and dry, easily airborne spores they can take over all the cultures in the lab in a few days. One species is capable of transforming soy beans into edible products and is much used in some Asian countries. Common on decaying fruits, soil, and house dust.

Classification: Mucoraceae (Mucorales, Zygomycota).
Refs.: Schipper, 1984; Schipper and Stalpers, 1984.

Scedosporium





Scedosporium prolificans

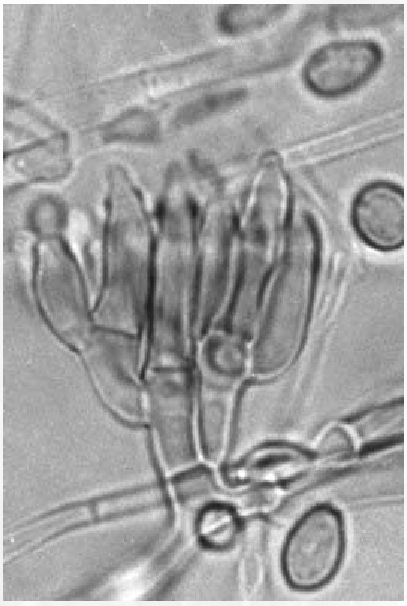
Spore-bearing cells may be solitary or united into more complex brush-like structures. Conidia are borne at the apices of cells with irregularly elongated necks and widely separated annellations. The conidia are generally flattened at the point of attachment and occur in wet masses. The spore-bearing structures are sometimes united into complex synnemata referrable to the genus *Graphium*.

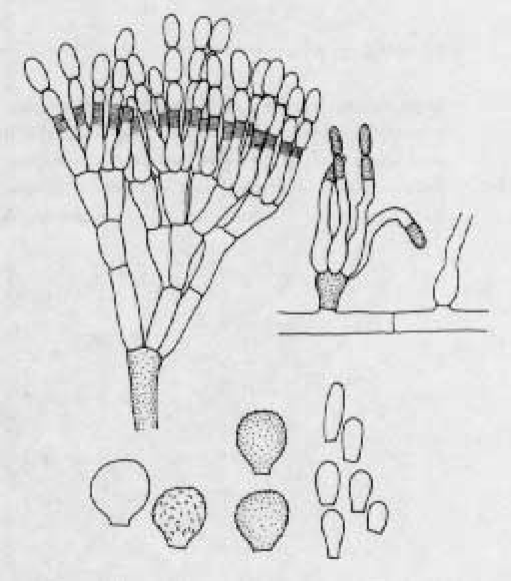
Species of *Scedosporium* can cause a variety of diseases in humans. Mostly they affect people with compromised immune systems, but healthy individuals may also become infected. Cultures of all *Scedosporium* species should be treated with caution.

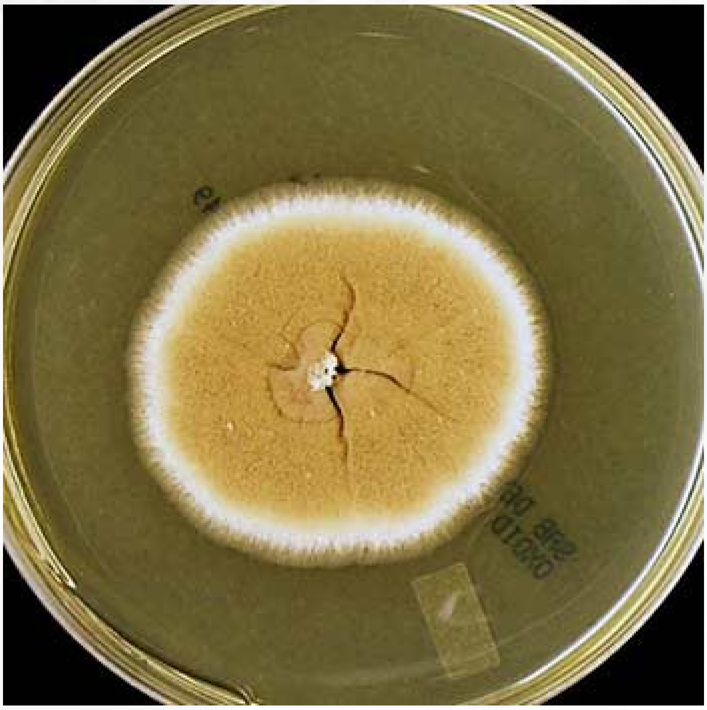
The species occur in soil, decaying plant matter or dung. They can become exceedingly abundant in some situations, such as in piles of feed-lot manure.

Classification: Microascaceae.
Holomorphs: *Petriella* and *Pseudallescheria*.

Scopulariopsis





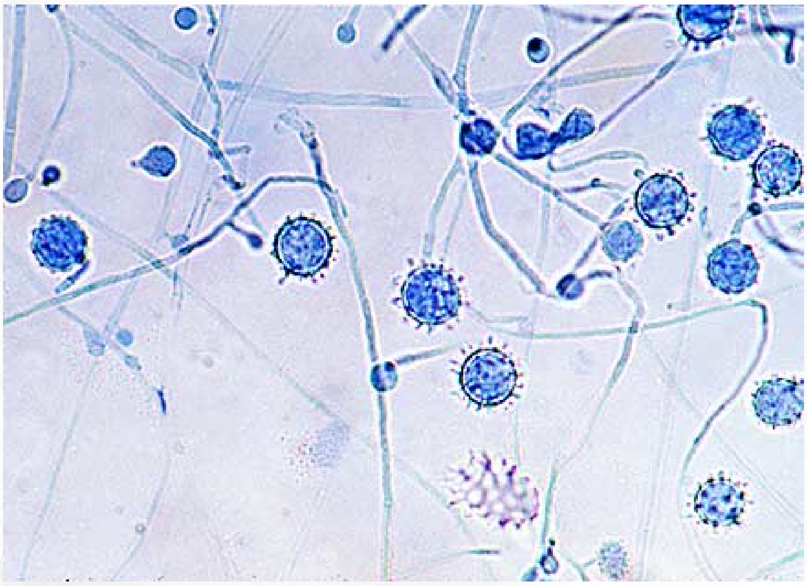


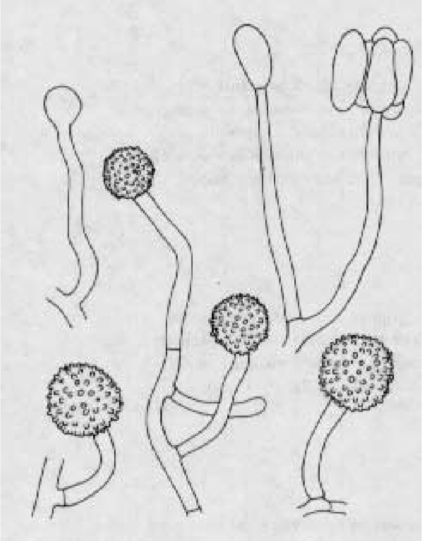
Scopulariopsis brevicaulis

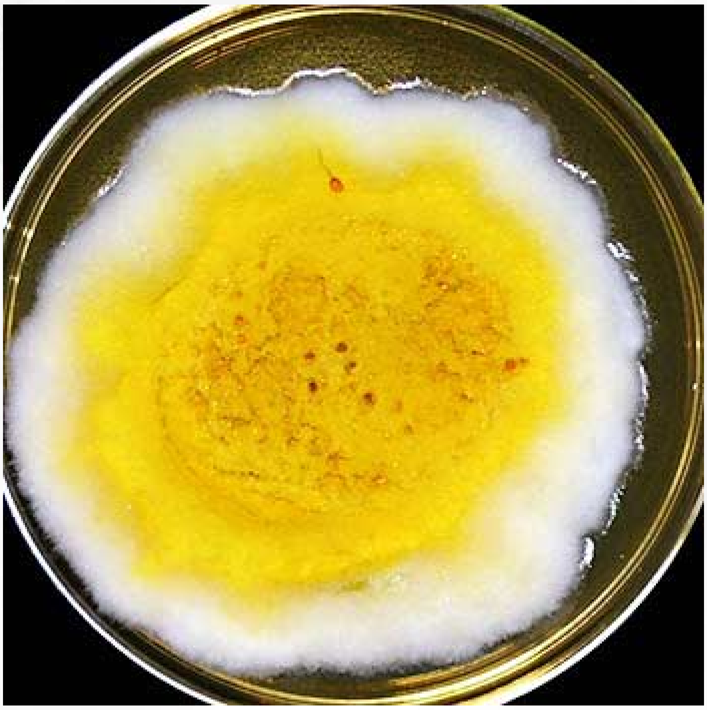
Conidiophores dark, usually highly branched and terminating in a brush-like complex bearing flask-shaped annellides. The colourless to dark 1- or 2-celled spores (conidia) are borne in chains from the tips of the annellides and usually have a flattened base where they were originally connected. Occurring in soil, dung, decaying plant debris, and house dust.

Classification: Microascaceae.
Holomorphs: *Kernia*, *Microascus*, *Petriella*.
Ref: Domsch *et al.*, 1980; Morton and Smith, 1963.

Sepedonium





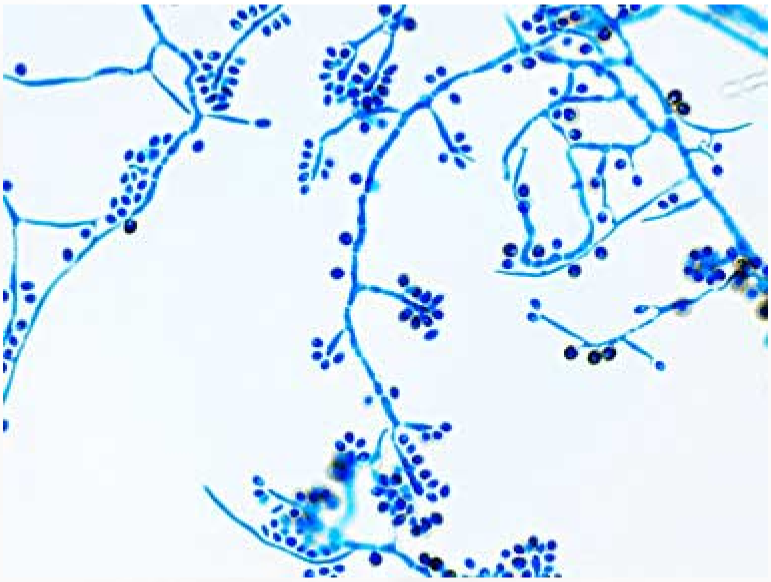


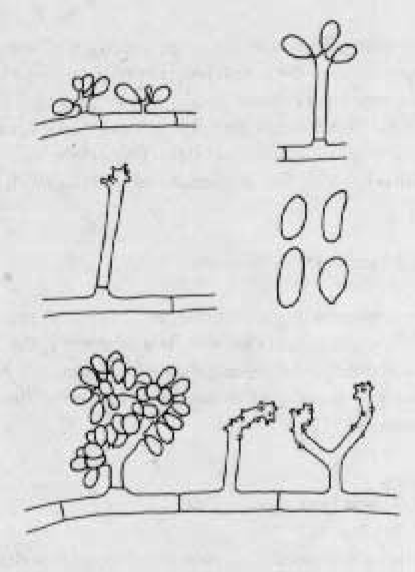
Sepedonium

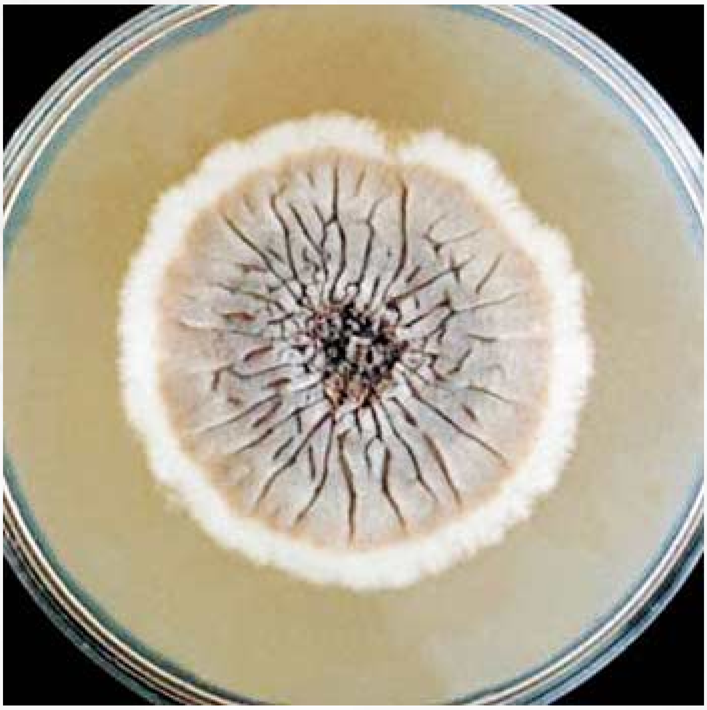
Most easily recognized by the spores, which are colourless to yellow, spiny, round, 1-celled, and produced singly at the ends of short filaments. Sometimes phialides of the Acremonium or *Gabarnaudia* type may also occur. A few species of Mortierella, as well as the human pathogen Histoplasma capsulatum, produce spores resembling those of *Sepedonium*. Isolated from soil, but most commonly parasitized boletes.

Classification: Hypocreaceae.
Holomorph: *Hypomyces*(*Apiocrea*).
Ref: Gilman 1957.

Sporothrix







Sporothrix schenckii

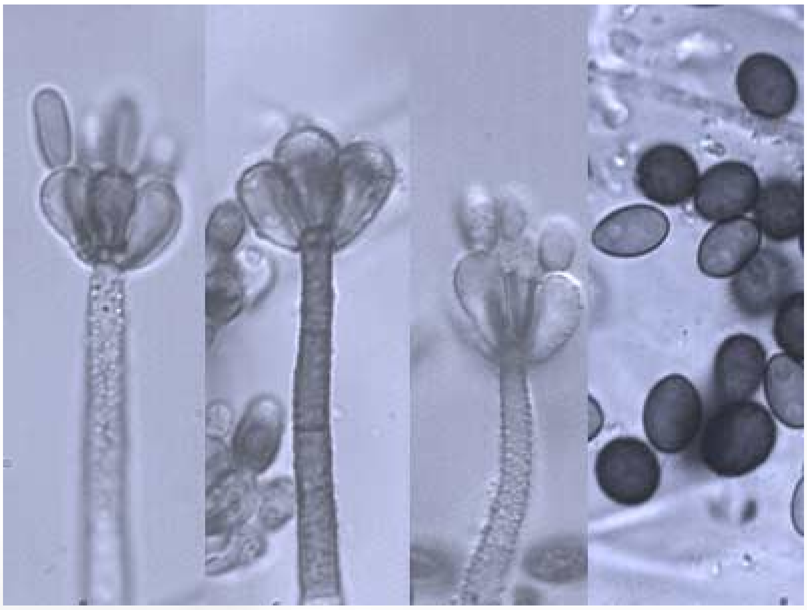
The 1-celled colourless spores (conidia) are produced on short roughened or toothed branches of the vegetative filaments. Occasionally more distinct conidiophores may develop.

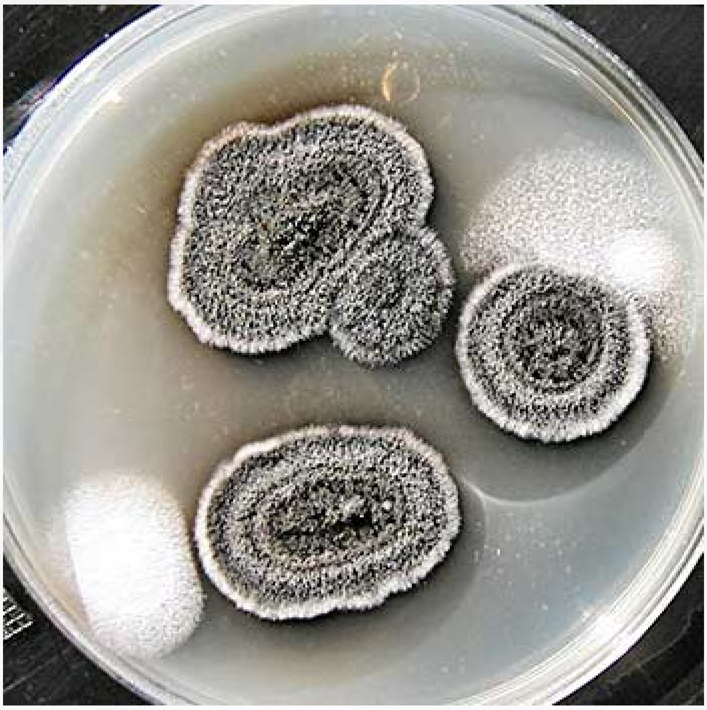
According to de Hoog (1993), species of *Sporothrix* have been reported as anamorphs of both ascomycetes and basidiomycetes. However, he believes the name should be restricted to those with ascomycetous relationships and refers the basidiomycetous ones to the genus *Cerinosterus*. Unfortunately, distinguishing *Sporothrix* from *Cerinosterus* with certainty requires an electron microscope or advanced biochemical techniques.

Isolated from soil, decaying plant materials, other fungi, insects, and air. Sometimes causing human disease.

Classification: Ophiostomataceae (Sordariomycetidae) in a strict sense, but found in other families of ascomycetes as well.
Holomorphs: *Cephaloascus*, *Ophiostoma*, *Valsonectria*, and others.
Ref: de Hoog 1974, 1993.

Stachybotrys





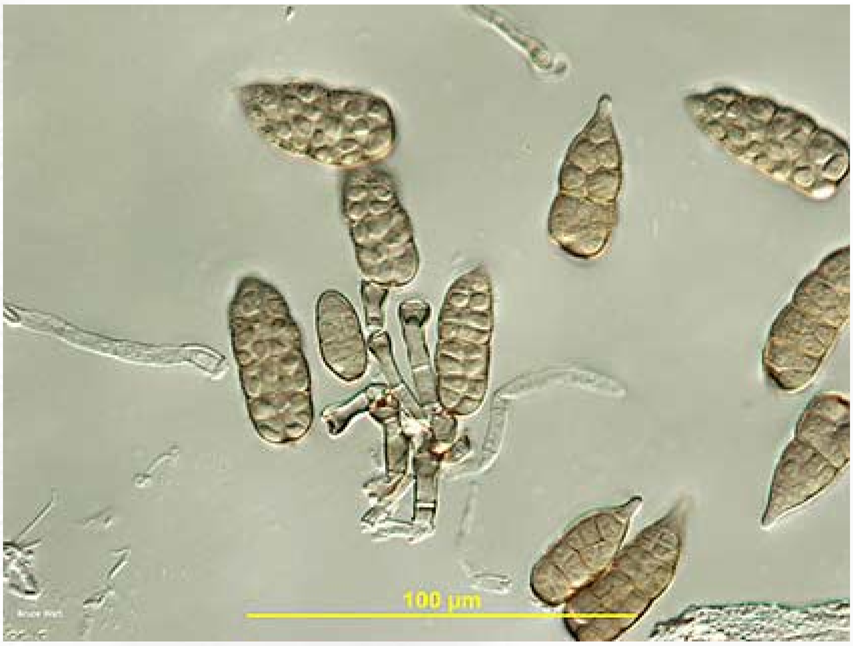
Stachybotrys

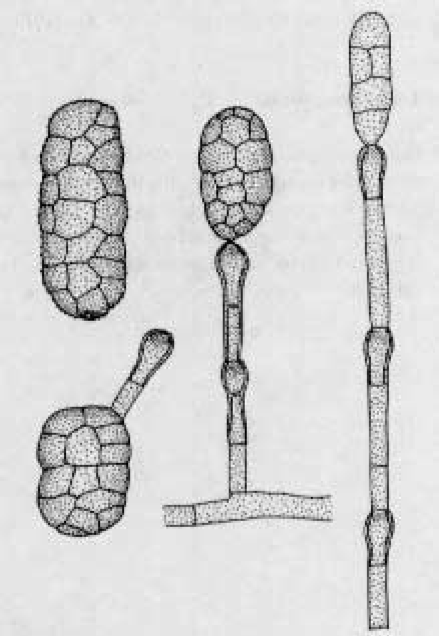
Characterized by clusters of colourless to brown swollen phialides at the tips of colourless to brown, sometimes branched, conidiophores. The dark brown 1-celled spores (conidia) are produced successively from the tips of the phialides and collect in wet masses. Species with spores in chains are referred to *Memnoniella*. A strong decomposer of cellulose and thus usually associated with decaying plant materials.

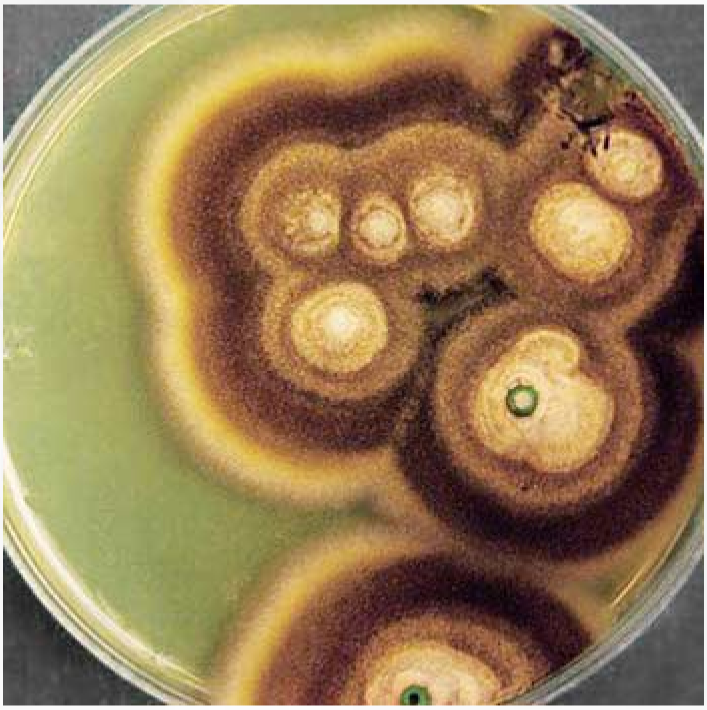
Species of *Stachybotrys* have earned a considerable notoriety in recent years due to their production of potent toxins in indoor environments. They have been linked to some cases of infant death in mouldy buildings. Rarely pathogenic for man.

Classification: Chaetosphaeriaceae (Hypocreomycetidae).
Holomorph: *Melanopsamma*.
Ref: Ellis, 1971; Jong and Davis 1976.

Stemphylium





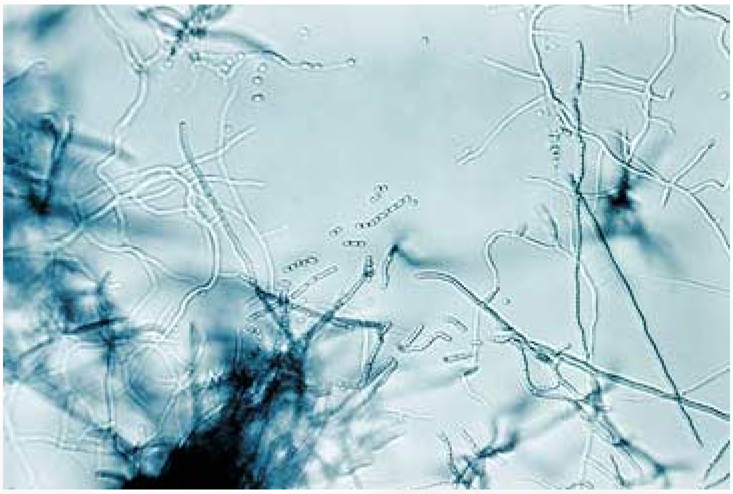


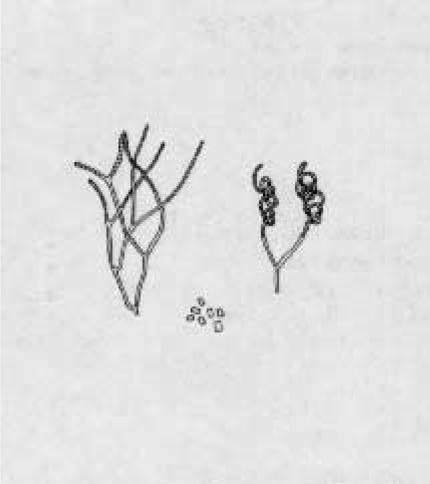
Stemphylium botryosum

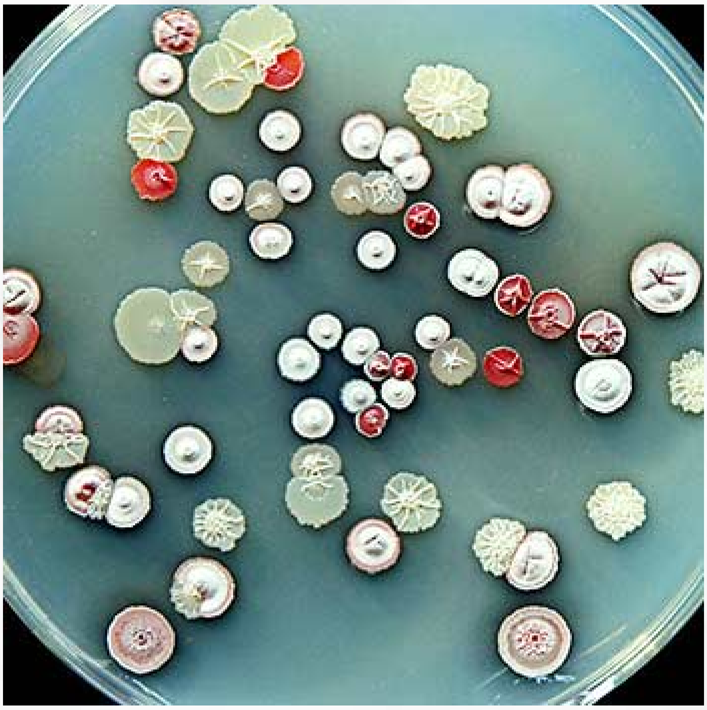
The dark conidiophores produce a single apical spore (conidium) through a pore and then continue to grow through the pore, thus dislodging the spore. Successive periods of spore production and regrowth give the conidiophore a noded appearance. The spores are dark brown and are divided by several longitudinal and transverse walls. Occurring on decaying and living plants and in soil.

Classification: Pleosporaceae (Pleosporales).
Holomorphs: *Pleospora*.
Ref: Ellis 1971.

Streptomyces





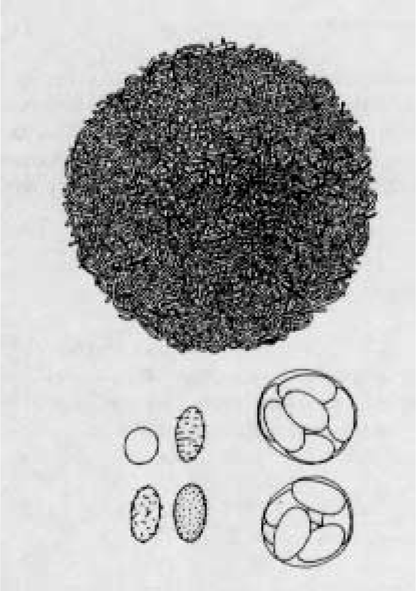


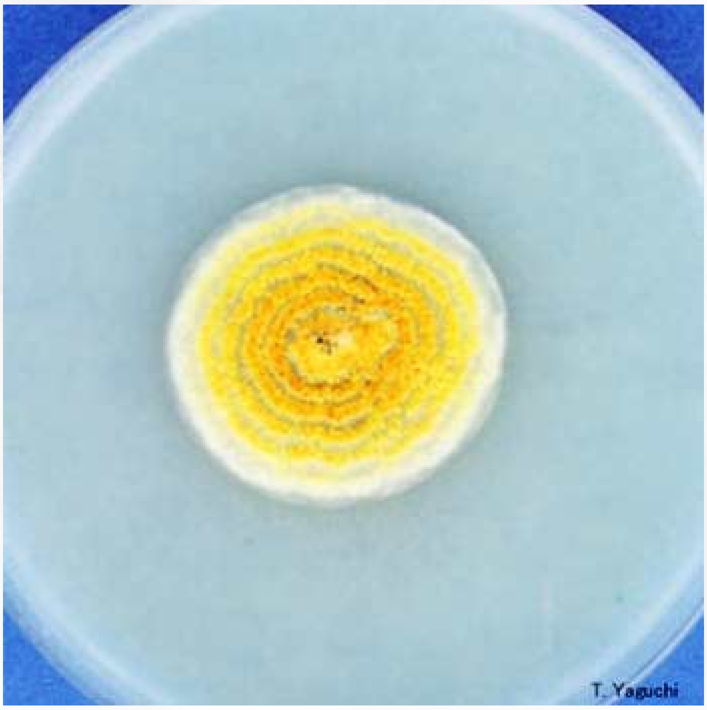
Streptomyces coelicolor

Streptomyces species are filamentous Gram-positive bacteria (actinobacteria), not fungi, and are thus out of place here. However, they occur in the same habitats as fungi and are superficially similar. The filaments and spores are very small (usually 1 µm or less in diameter). The spores are formed by the fragmentation of the filaments and are borne in straight, wavy, or helical chains. The colonies are slow-growing and often have a soil-like odour. Common in soil, plant debris, dung, house dust, and many other habitats.

Classification: Streptomycetaceae.
Ref: Buchanan and Gibbons 1974; Holt, 1994; Waksman 1961.

Talaromyces



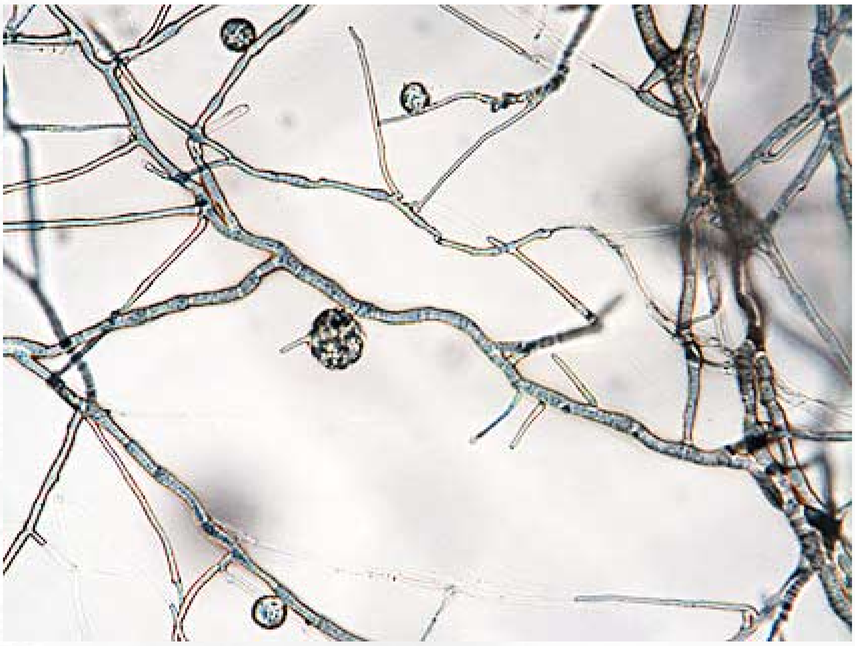


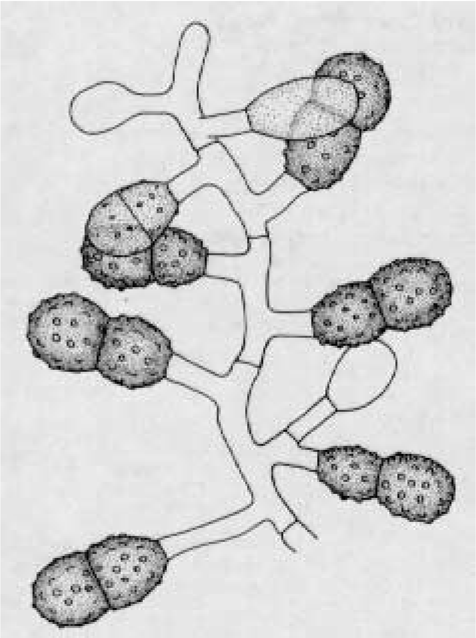
Talaromyces wortomannii

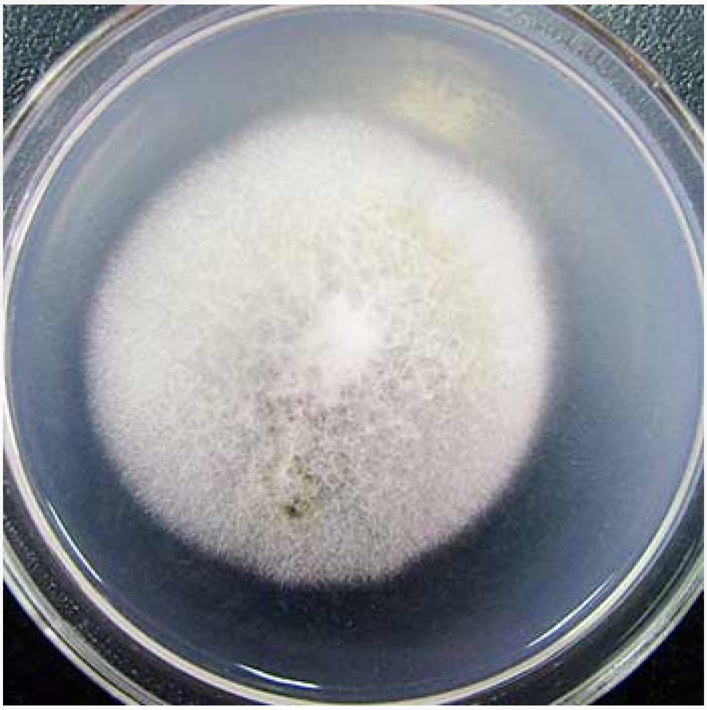
Ascomycetes characterized by loose hyphal fruiting bodies (gymnothecia) containing spherical asci, which in turn each enclose 8 ascospores. The ascospores are colourless to yellow, spherical to disc-shaped, and 1-celled. The whole fungus is either colourless or brightly coloured. Anamorphs are strongly like those of *Penicillium* and are often difficult to distiguish from them. Their most characteristic features are highly symmetrical spore-bearing structures (penicilli) and elongated and rather lance-like phialides. Conidia are often sharply fusoid. In soil, dung, or decaying plant material. The species can be quite aggressive in culture with other fungi, often completely overrunning other colonies, suggesting some level of parasitism may be involved.

Classification: Trichocomaceae (Eurotiales).
Anamorphs: *Penicillium*-like.
Refs: Pitt, 1980, 1985; Samson and Houbraken, 2011; Stolk and Samson, 1972.

Trichocladium





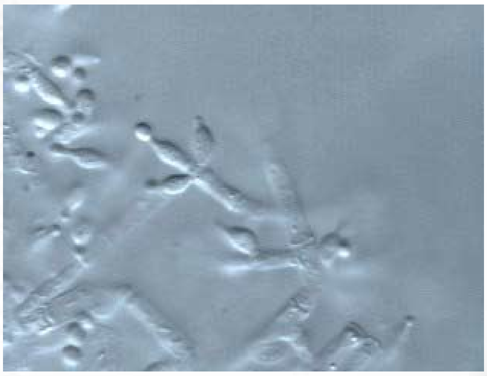


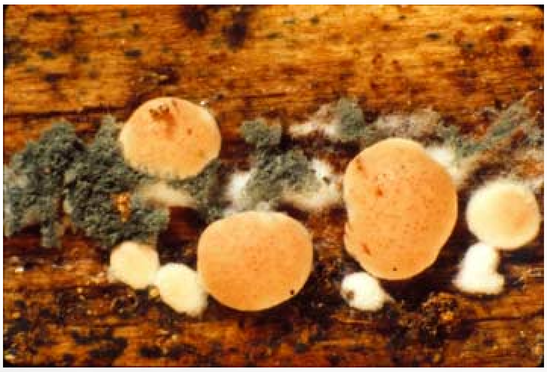
Trichocladium

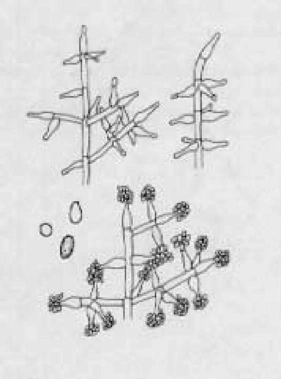
The dark brown 2- to several-celled spores (conidia) are produced by the swelling and subsequent delimitation of the terminal portion of short branches of the vegetative filaments. The most common species, *T. asperum*, has 2-celled, roughened spores. In soil and plant debris, including wood.

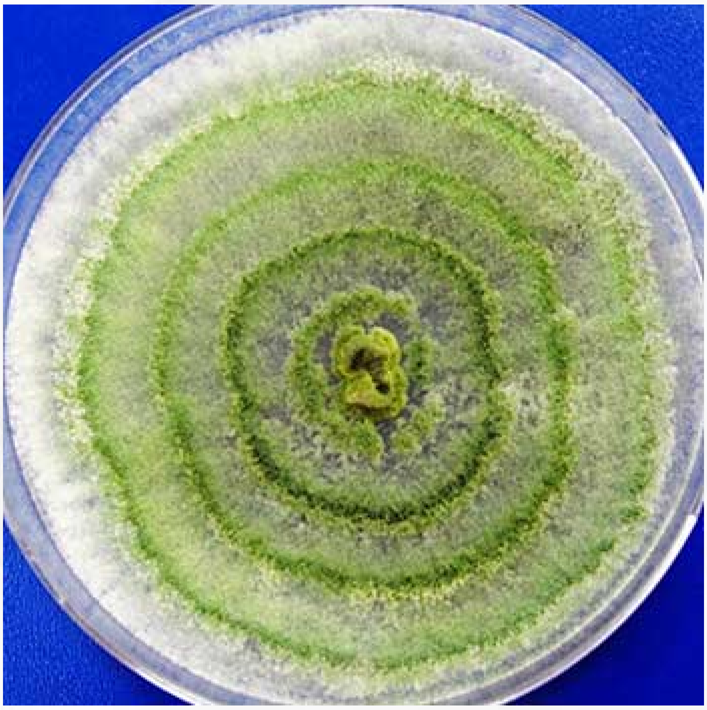
Classification: Chaetomiaceae (Sordariomycetidae).
Holomorph: *Chaetomium*.
Ref: Ellis 1971.

Trichoderma









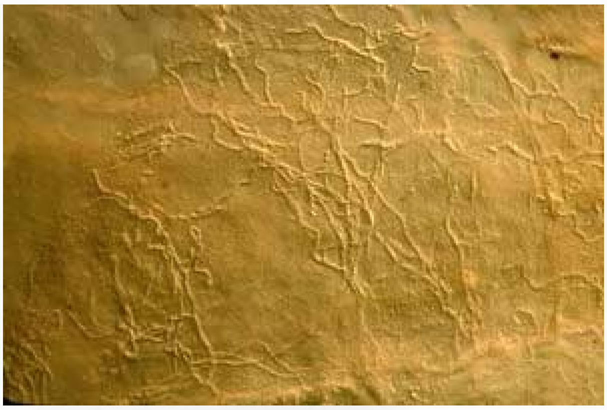
Trichoderma viride

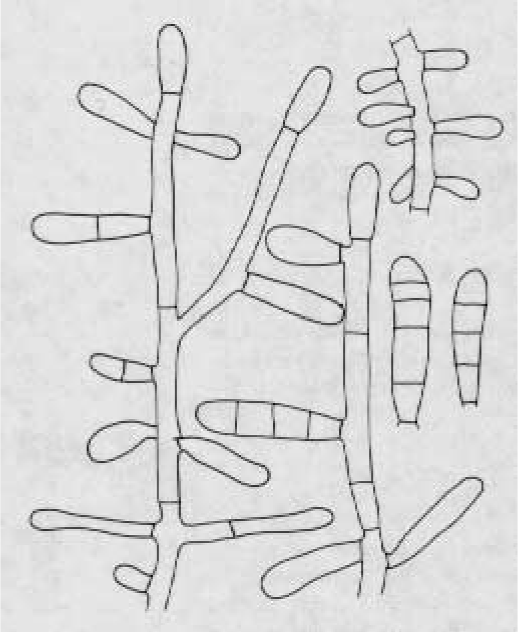
Usually recognized by fast-growing colonies producing white, green, or yellow cushions of sporulating filaments. The fertile filaments or conidiophores produce side branches bearing whorls of short phialides. The 1-celled spores (conidia) are produced successively from the tips of the phailides and collect in small wet masses. The photograph at left, and the drawing, show a species of *Trichoderma* as seen with a microscope, but *Trichoderma* species are also very conspicuous in the field, especially under the dead bark of trees. The photo at top-center shows a species of *Trichoderma* producing its green conidia among the nearly mature cushion-shaped stromata of its teleomorph.

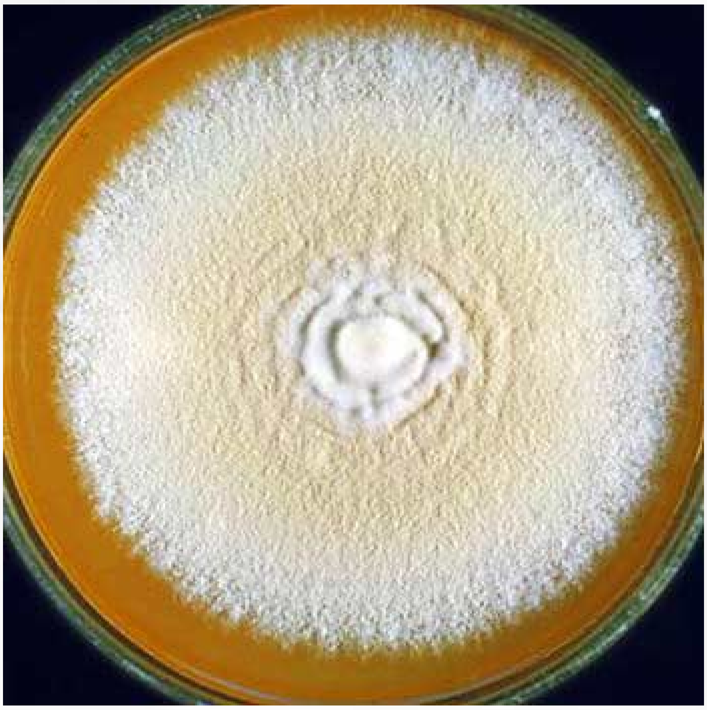
Trichoderma species are strongly antagonistic to other fungi. The exact nature of this relationship is still not clear, but it appears that they kill other fungi with a toxin and then consume them using a combination of lytic enzymes. This suggests they are actually microbial predators. This antagonistic behaviour has led to their use as agents of biological control of some fungi causing plant disease. On the other hand, they can be serious pests in cultivated mushroom beds. Species of *Trichoderma* are common in soil (especially water-logged soil), dung, and decaying plant materials.

Classification: Hypocreaceae.
Holomorphs: *Hypocrea*, *Podostroma*.
Ref: Bissett, 1984, 1991a,b,c; Chaverri and Samuels, 2003; Gams, 2006; Rifai 1969; Samuels *et al.*, 1998.

Trichophyton





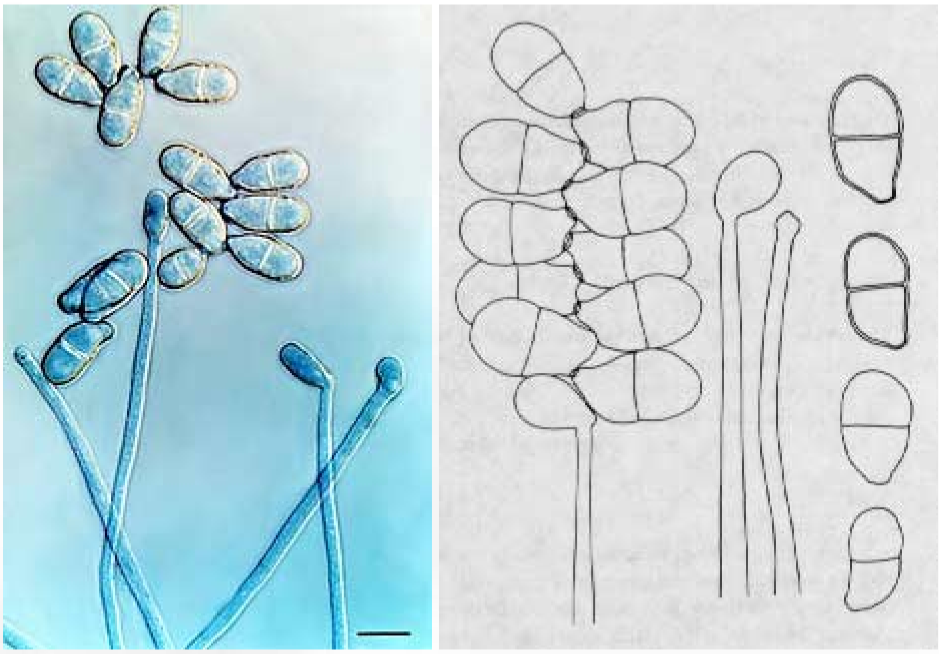


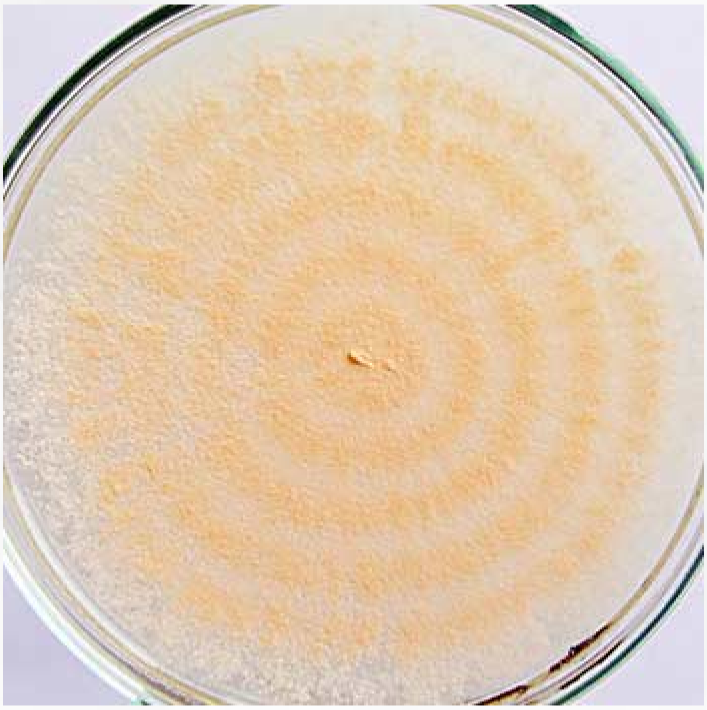
Trichophyton mentagrophytes

Characterized by colourless spores (conidia) that are nearly sessile and usually produced at right angles to the fertile filament, or as terminal swellings. Most conidia are 1- or 2-celled (micro-conidia) but at least a few are more than 2-celled (macroconidia). Similar to *Chrysosporium*. Usually occurring as a skin parasite on man and animals but occasionally isolated from soil, leather, feathers, etc. The picture at top-left shows hyphae of *T. rubrum* growing within a flake of dead skin scraped from an infected patient. The picture at top-right shows conidia as they are seen in pure culture.

Classification: Arthrodermataceae (Onygenales).
Holomorph: *Arthroderma*.
Ref: Ajello, 1968; Ajello, Georg, Kaplan, and Kaufman 1963; Beneke 1958; Rebell and Taplin 1970.

Trichothecium



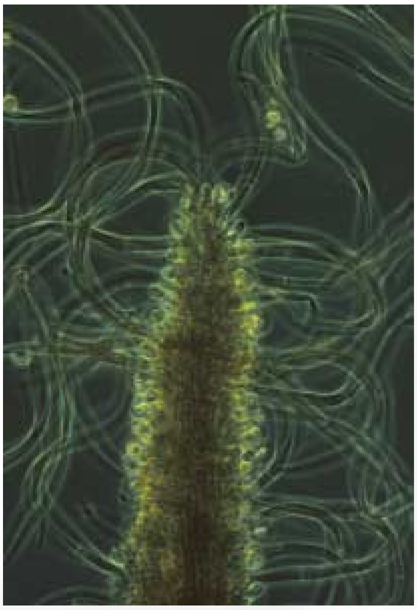


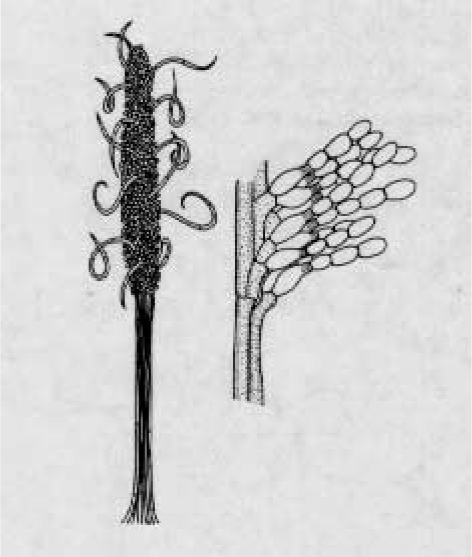
Trichothecium roseum

The 2-celled colourless to pink spores (conidia) are bilaterally symmetrical and are produced retrogressively in long chains from the unbranched conidiophores. The youngest spore is at the bottom of the chain and is always attached at an oblique angle to the conidiophore. Occurring in soil and decaying plant materials, often found as an epiparasite on black knot of cherry.

Classification: Bionectriaceae (Hypocreales).
Holomorph: *Hypomyces*.
Ref: Rifai and Cooke 1966.

Trichurus





no image

The brown conidiophores are united to form large complex cylindrical structures (synnemata) bearing a dense layer of annellides on the upper half. Curved to straight sterile hairs project out from among the annellides. The spores (conidia) are colourless to brown and are produced in chains from the tips of the annellides. Similar and possibly congeneric with Cephalotrichum.

Shoemaker and Kokko (1977) discussed four species and Udagawa *et al* (1985) added a fifth, *T. dendrocephalus*. These species can be distinguished with the following key:

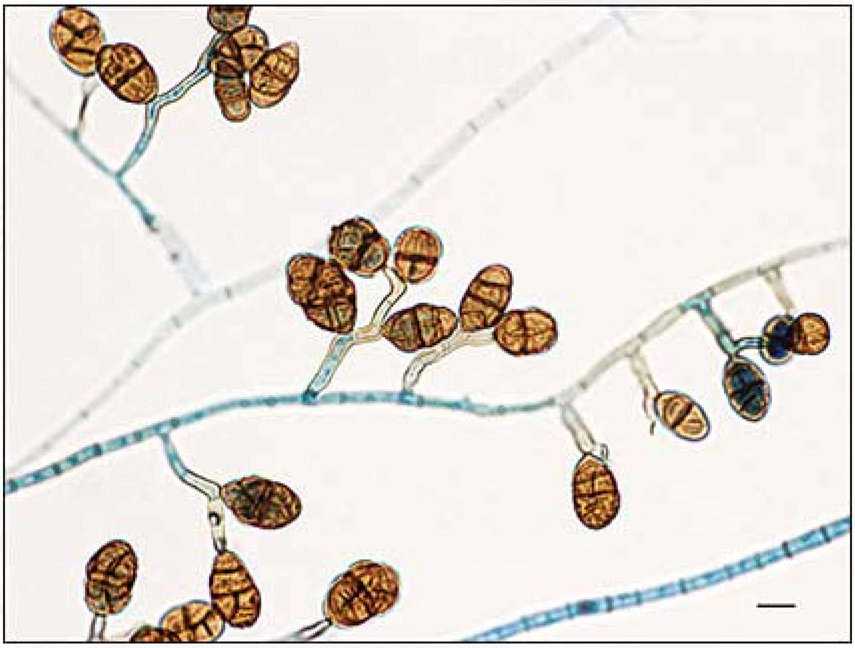
1. Sterile hairs straight - 2.
1. Sterile curved or definitely wavy - 3.
2. Sterile hairs usually unbranched. Spores 4-9 x 3 µ - *Trichurus cylindricus*.
2. Sterile hairs forked. Spores 3.0-6.0 x 2.0-3.5 µ - *Trichurus terrophilus*.
3. Sterile hairs branched - *Trichurus dendrocephalus*.
3. Sterile hairs unbranched - 5.

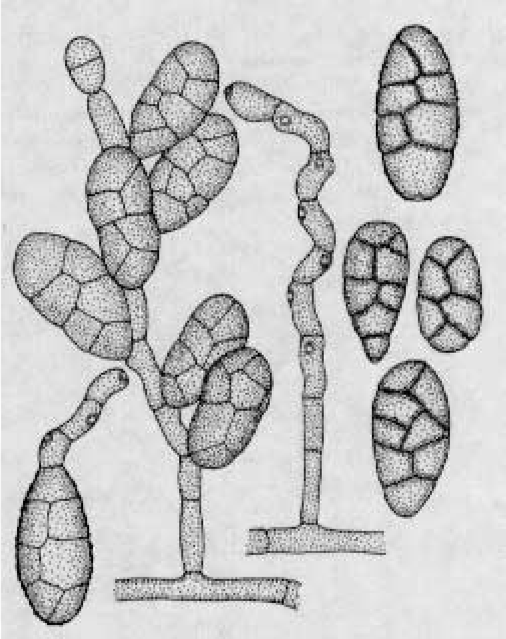
4. Spores ashy grey in mass - *Trichurus gorgonifer*.
4. Spores yellow-brown in mass - *Trichurus spiralis*.

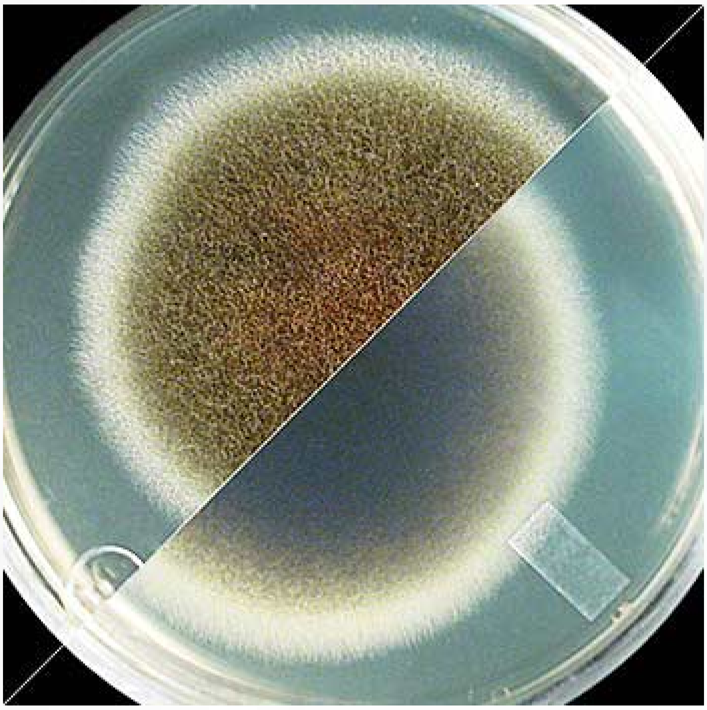
Occurring in soil, dung, and plant debris.

Classification: Microascaceae.
Holomorph unknown.
Ref: Ellis 1971; Shoemaker and Kokko 1977; Swart 1964; Udagawa *et al* 1985.

Ulocladium





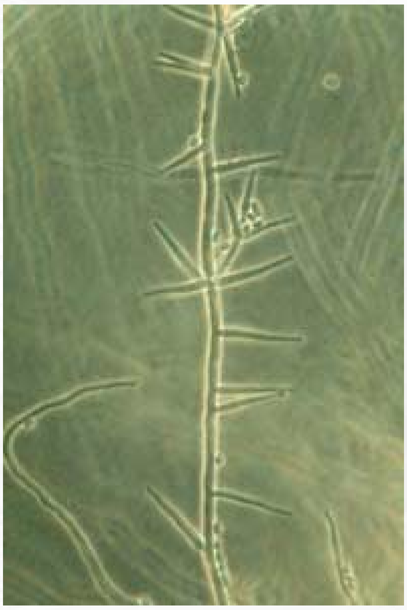


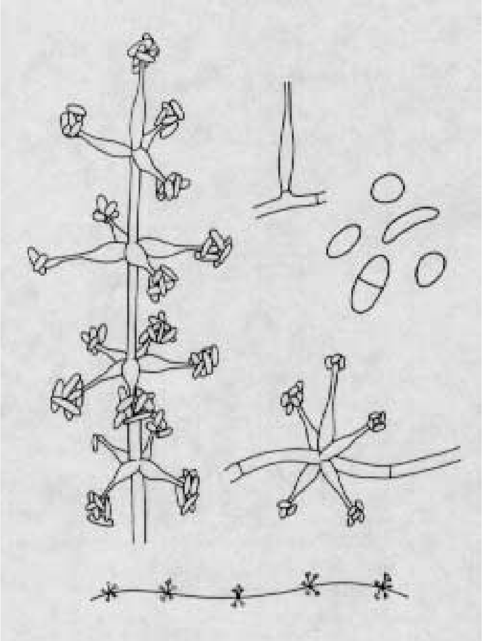
Ulocladium chartarum

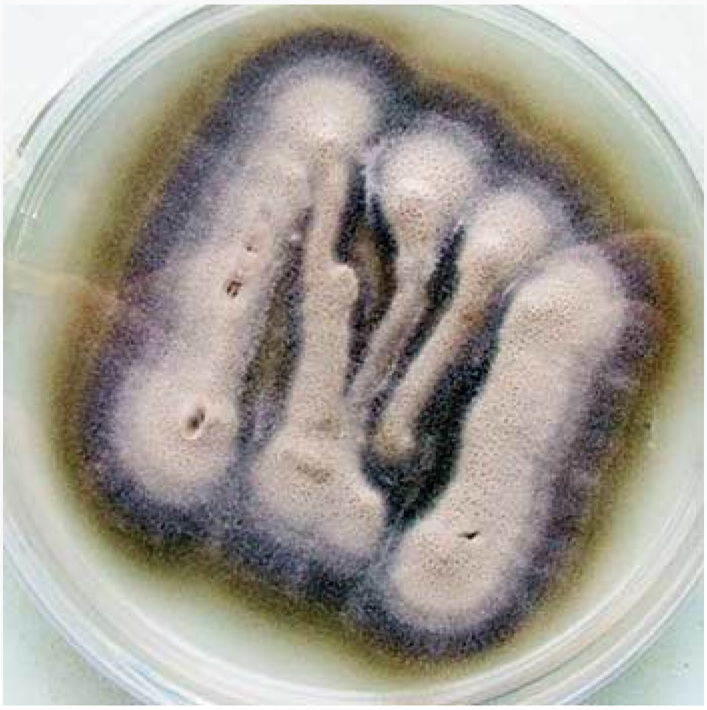
Characterized by dark conidiophores bearing conidia through a pore at several points along their length. The conidia are dark brown, more or less egg-shaped to cylindrical, and divided into several cells by transverse and longitudinal walls. Occurring in soil and dead or dying plants.

Classification: Pleosporaceae (Pleosporales).
Holomorph: Although no teleomorphs in the Pleosporaceae have been linked to species of *Ulocladium*, Dr. Lee Bonar, a pioneering California mycologist, published evidence that *Lasiobotrys affinis*, a member of the Venturiaceae (Pleosporales) produced a *Ulocladium* anamorph in culture (Bonar, 1928). He had made this observation on several occasions and published excellent illustrations. His evidence seems credible and should be examined further.
Ref: Ellis 1971, 1976; Simmons 1967.

Verticillium





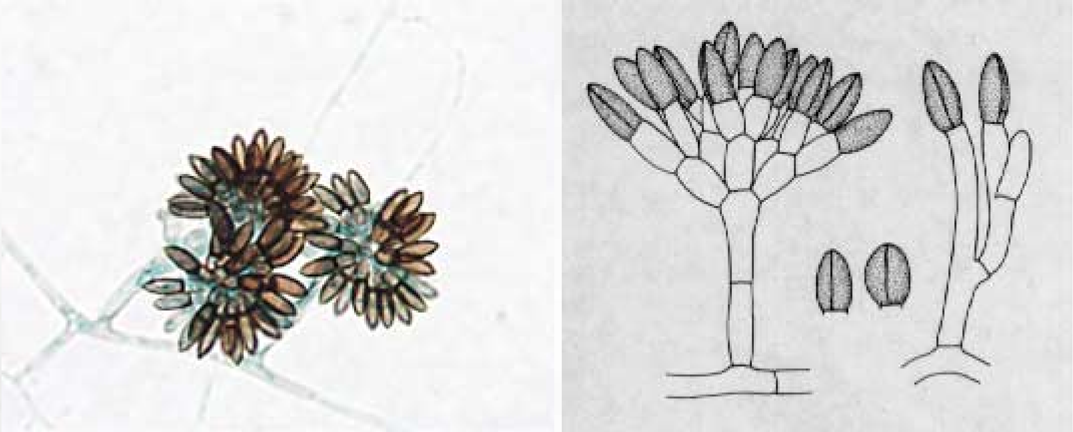


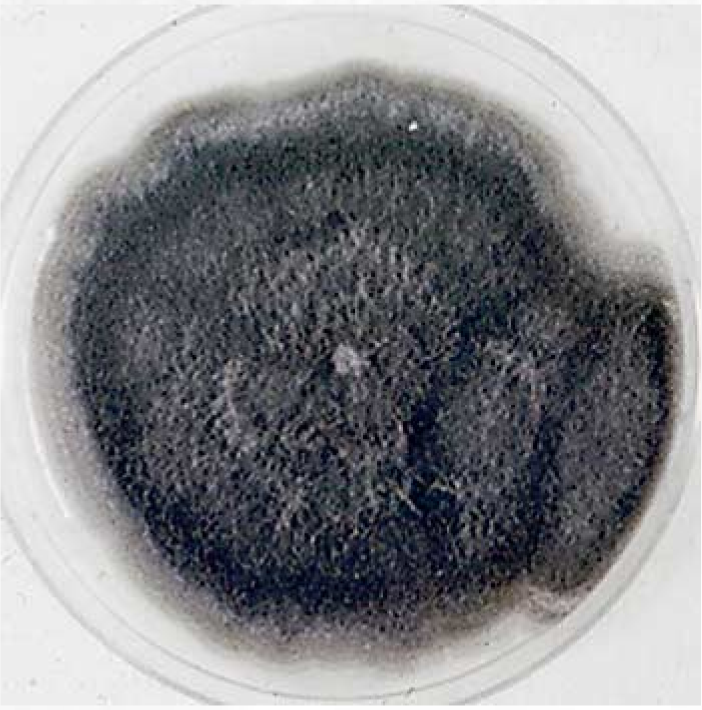
Verticillium theobromae

Characterized by whorls of phialides produced along the length of undifferentiated filaments or on conidiophores. The colourless to brightly coloured 1- or 2-celled spores (conidia) collect in small wet masses. Common in soil and decaying plant matter; also causing plant disease. Some species, such as *V. lecanii* in the above photos, are parasites on other fungi.

Classification: Plectosphaerellaceae (Sordariomycetidae).
Holomorphs: According to Seifert *et al.* (2011) no holomorphs have been identified with *Verticillium* in a more strictly defined sense. However, as more broadly and, as here, more commonly defined *Verticillium*-like anamorphs are known in *Cordyceps*, *Nectria*, *Torrubiella*, and perhaps other genera of the Hypocreomycetidae.
Ref: Gams 1971.

Wardomyces





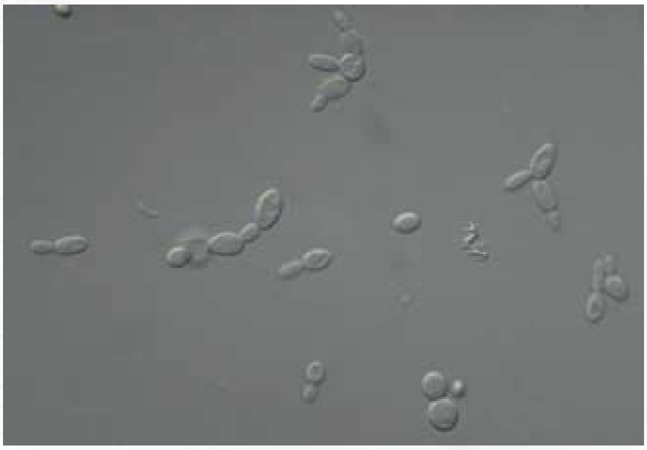
Wardomyces anomala

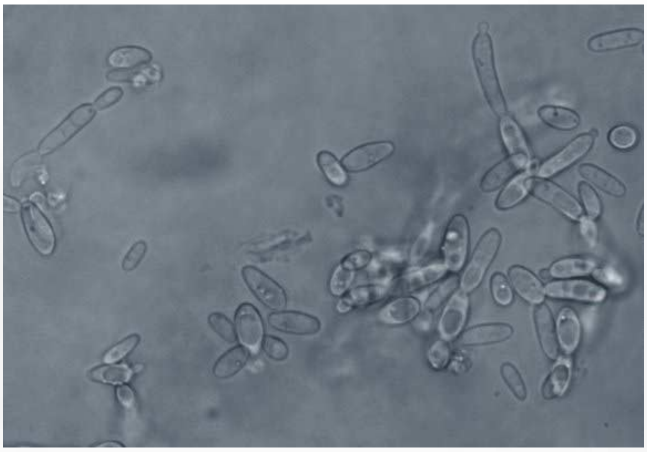
The conidia are the most distinctive feature, being 1- or 2-celled, dark brown, bullet-shaped to egg-shaped, flat at the base, and with a colourless line or germ slit on one side. They are borne on upright, branched conidiophores. Occurring on dung, soil, and meat in cold storage.

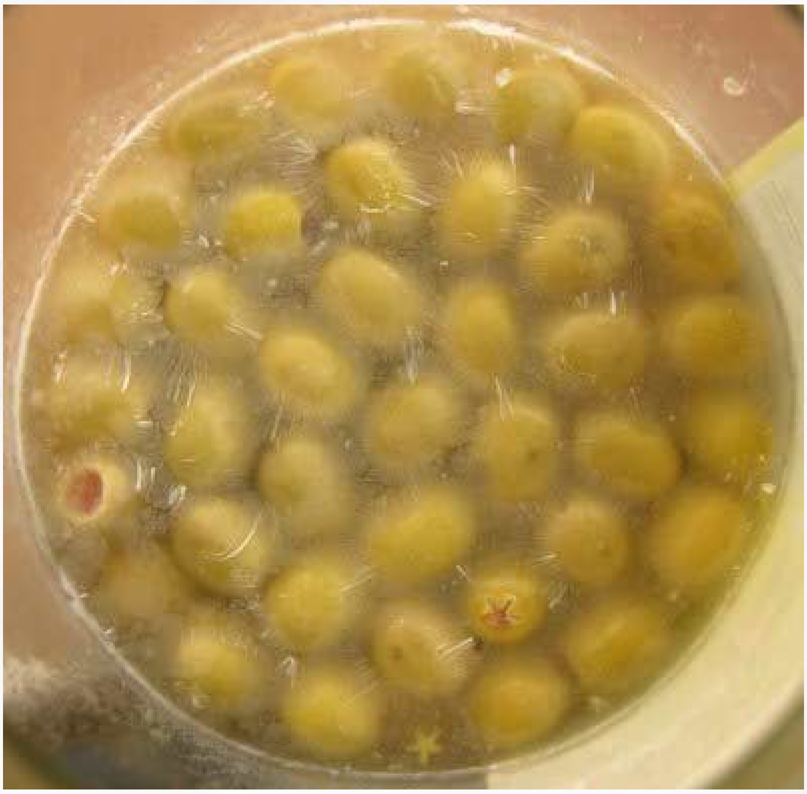
Classification: Microascaceae.
Holomorph: *Microascus*.

Ref: Ellis 1971, 1976.

Yeasts





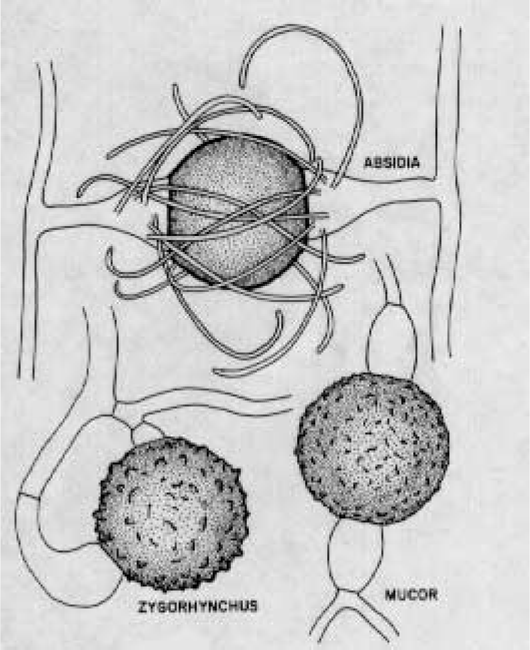


A complex group of fungi resembling one another in existing as single cells that "bud" directly to form new cells. The colonies are pasty in appearance. Some yeasts may form ascospores within their cells. Common in moist habitats and often able to grow at reduced oxygen levels. See the discussion of yeasts under the broader topic of fungal growth.

The pictures above left illustrates *Saccharomyces cerevisiae*, a yeast used for the rising of bread and the brewing of beer. The one at right is probably *Pichia membranaefaciens*, a species found in a variety of habitats. It often colonizes stored foods where it may form a thin film over the surface. The picture above shows a jar of olives colonized by *P. membranaefaciens*.

Holomorphs: various and not necessarily related to one another.
Ref: Arx, Rodrigues de Miranda, Smith, and Yarrow 1977; Kurtzman *et al.*, 2011.

Zygospores



These structures represent the sexually reproductive spores of several genera of Mucorales. They are usually dark, roughened, 1-celled, and connected to the filaments by short cells called suspensors. They rarely occur apart from asexual fruiting structures and are not normally used exclusively for identification purposes.

Classification: Mucorales (Zygomycota).
Ref: Schipper, Samson, and Stalpers 1975; Zycha and Siepmann 1970.

BIBLIOGRAPHY

Specialized reference books are often necessary for identifying fungi. The bibliography presented here contains many such references. Unfortunately, many of these cannot be found in smaller community libraries and must be sought in university and government collections. Some of these large libraries can be visited by anyone, but many others are generally inaccessible. The best way to see a specialized publication is to ask your librarian to request an interlibrary loan. Interlibrary loans may take a few weeks but are usually available.

The Truth About Cobweb

by

Kizzle

original text: https://www.shroomery.org/forums/showflat.php/Number/18642418

This has been long overdue, I'll start by explaining what led me to post this. I've been growing mushrooms for a good 4+ years but not until fairly recently, after assisting with the cultivation of *Agaricus bisporus*, did I start to suspect that what I had always considered cobweb mold may actually be something else. Unlike the competitor molds you're used dealing with cobweb mold is a mushroom pathogen. It's occurrence is in no way linked to contaminated spawn and is rarely a problem in bulk substrates. To ignore that and misidentify other molds as cobweb is counterproductive to determining the source of contamination problems and what to do about them. In trying to make sense of contradicting information I've read a huge amount of information from books, published studies, experiments, etc and thought I'd share some of it.

Just to clarify things up front, the term cobweb mold is often used loosely to refer to any kind of thin wispy grey mold and that's not what I'm referring to. Hopefully I can help distinguish the difference between these molds and the specific mold that causes cobweb disease.

To start, cobweb mold could be defined as a group of closely related species capable of causing cobweb disease in mushrooms. Many of these species are so similar they can only be properly identified from each other through genetic testing. They've been reclassified over the years, and as is often the case in taxonomy not necessarily with complete agreement among mycologists, so you may hear different species or names mentioned. In the US *Dactylium* or the species *Dactylium dendroides* is usually referred to as the causative agent. In eastern countries you'll more commonly hear them referred to as various *Cladobotryum* spp. I also note the Shroomery main site mentions *Hypomyces* sp. which is also correct. In fact *Dactylium*, for the most part, is synonymous with *Hypomyces rosellus*.

Cobweb mold grows on casing layers and mushrooms. Although in theory it could occur on any uncolonized substrate so long as a suitable host is present, it's been shown experimentally that neither spores or mycelium fragments added to spawn will result in development of cobweb disease, nor does adding them to the surface of bulk substrate during spawning, even when a casing layer is then added over it.

Cobweb mold spreads quickly. This is absolutely true, but it's rarely mentioned that the primary reason for this is it's ability to fragment and start growing from multiple points on the casing layer and not solely from the growth speed of a single colony. The growth rate is closely tied to the environmental conditions it is growing in. This is important for two reasons. A slower growth rate may be wrongfully assumed to rule out cobweb during identification. It's also important because changing these conditions can assist in dealing with an outbreak assuming the mushroom species being cultivated is able to tolerate the changes. Lowering temperature and/or RH can slow the growth of cobweb mold or even inhibit it completely.

Cobweb is usually seen in later flushes. IMO this is important to consider both in terms of identification and in finding the source of the contamination. Cobweb proliferates mostly by means of spore. Even high amount of spores added directly to a casing layer requires weeks before the first sign of cobweb disease occurs. With that in mind any the appearance of actual cobweb mold in earlier flushes is most likely the result of mycelium fragmentation and that strongly implies a nearby source. This appears to be true despite the fact that the mold spores can germinate much more quickly on an actual fruit body.

Mushroom stumps are a common point of origin. Now before anyone freaks out and reverts to twist-and-pull, this has nothing to do with the stumps rotting. A cobweb infected mushroom, whether apparent or not, may leave behind a cobweb infected stump.

Aborts are an even more common point of origin. This does not mean aborts need to be picked immediately but they should always be removed while harvesting your other mushrooms. That can be a painstaking task if there is a very large amount of aborts.

This is really open to interpretation. There's definitely a correlation between cobweb disease and aborts but it's hard to say if the aborts are cause of the mold or if the mold is the cause of the aborts. Considering the same conditions that can lead to a lot of aborts can lead to mold contamination...

There are many look-alikes. I find it frustrating how quick people are to identify any fuzzy or grey mold as cobweb mold regardless of where or how it's growing. Pin molds, called that because of the black pins which they may produce, are commonly misidentified as cobweb. In contrast to cobweb, which occurs in the casing laying, pin molds are very common contaminants in spawn and some bulk substrates. In ideal conditions some species can grow at rates matching or surpassing those of cobweb. Despite their somewhat similar appearance these molds are far more difficult to treat and misidentification has apparently left some with the impression that actual cobweb mold is hard to treat.

Cobweb is easily treatable. A common misconception is that hydrogen peroxide only affects cobweb mold. Peroxide will react in some way or another with pretty much any fungus, including mushroom mycelium. The most common reaction to fungi is fizzing caused by the rapid conversion of h202 into water and oxygen bubbles. The fact that cobweb grows solely on the casing surface is what makes it easier to treat than other molds.

On a personal note, despite claims I find it increasingly hard to believe peroxide could be an effective treatment of actual *Cladobotryum* considering it's ability to grow inside the mushroom. It certainly doesn't match my own experiences nor have I seen any studies to support it nor any claim accompanied by documentation showing the mold could indeed be positively identified (visible spores, cobweb disease present). Whether this is due to misidentification or just differences in tolerance between strains/species I'm uncertain.

However I confirm in cases where cobweb disease is present it can be controlled by placing a damp paper towel over the growth and pouring salt over it, and by removing mushrooms showing spotting symptoms. Some may be hesitant to try this, just keep in mind you're salting the casing layer, the damage to the mushroom mycelium is relatively small and there plenty of other areas for mushrooms to develop. That's part of the reason BTW *Trichoderma* almost always reoccurs once it's been growing in the spawn, Trich originating on a casing layer is much easier to treat.

Of course no rambling of this nature would be complete without a RR quote.

> "Cobweb mold is the only thing you can totally kill and eliminate with peroxide. Nobody has lost a project to cobweb mold who has made searches here to find the cure. You're supposed to spray it until wet three times at 12 hour intervals. Spray until all the cobweb mycelium has 'melted' and disappeared. Repeat twice at 12 and 24 hours after the first spray whether you see any cobweb or not."
> RR

Overall cobweb disease does not appear to be particularly common with Cubensis, certainly not as common as many believe. Probably because most Cube cultivators do not use casing layers or use pasteurized casing layers. Spores of *Dactylium* are killed when exposed to 115-122°F. for only 1/2 hour making it extremely unlikely to survive pasteurization. It's uncommon but possible for mushrooms to get the disease even without a casing layer. It such a situation the mold mycelium will not grow on the fully colonized substrates surface but may still be seen spreading to nearby pins and mushrooms directly.

Some miscellaneous info:
A particular species may produce different or no symptoms of the disease depending on the mushroom species being grown.

According to one source *Cladobotryum dendroides* produces a noticeable odor while *Cladobotryum mycophilum* does not.

Spores will not become airborne early on in it's development unless the colony is physically disturbed, like while misting.

Spores are relatively massive. In the presence of typical air currents most spores will have settled after 15 minutes.

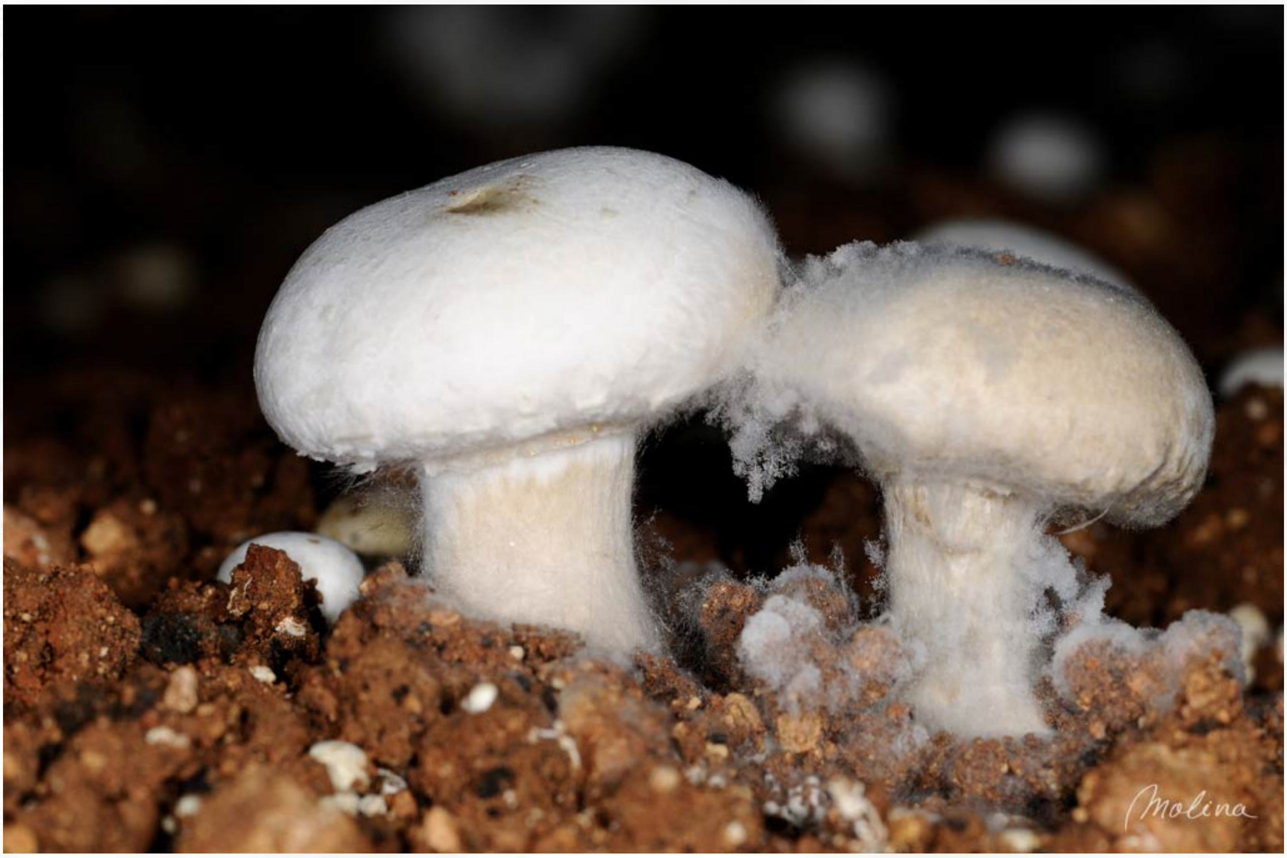
Spores survive a maximum of 7 days in sterile water.

Heavy spore production occurs usually occurs near and on infected mushrooms.

In time, some species produces metabolites which turn the mycelium and/or substrate a pink or yellow color.

When the disease is allowed to progress the mycelium will take on a powdery appearance from the produced spores.

The following are pictures positively identified by reliable sources.



Spore production on 2 cobweb infected mushrooms.

Another good one.

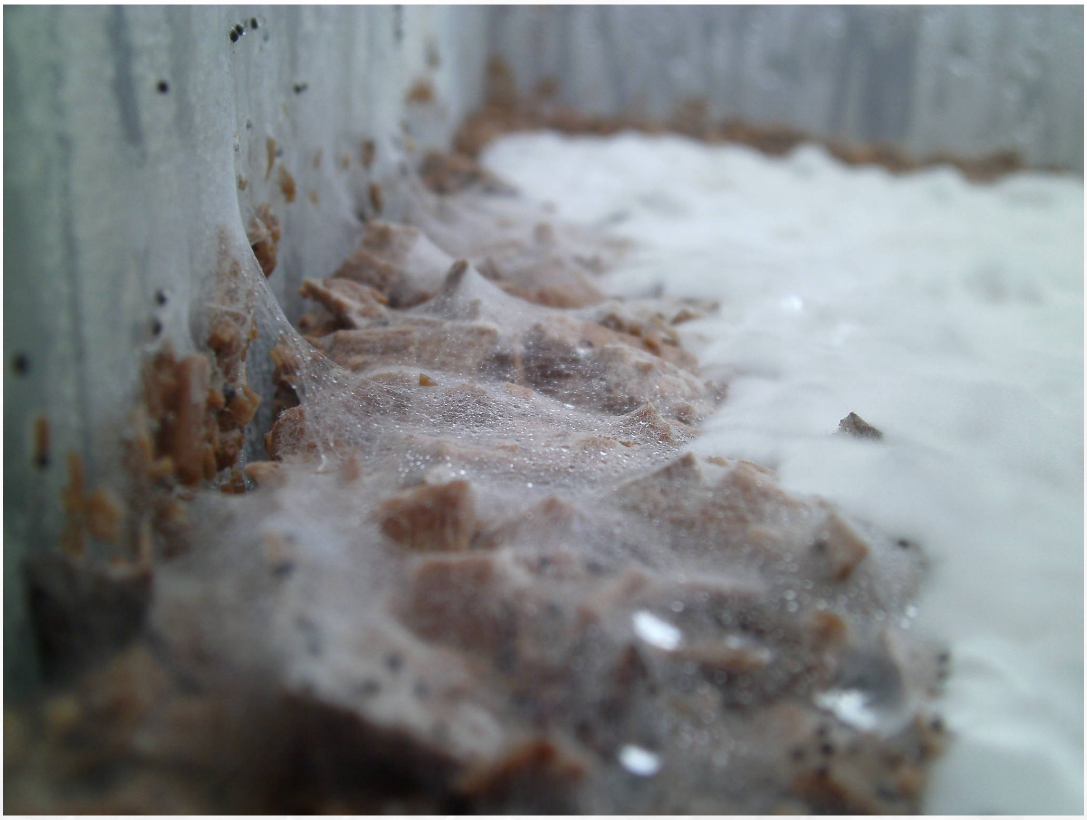
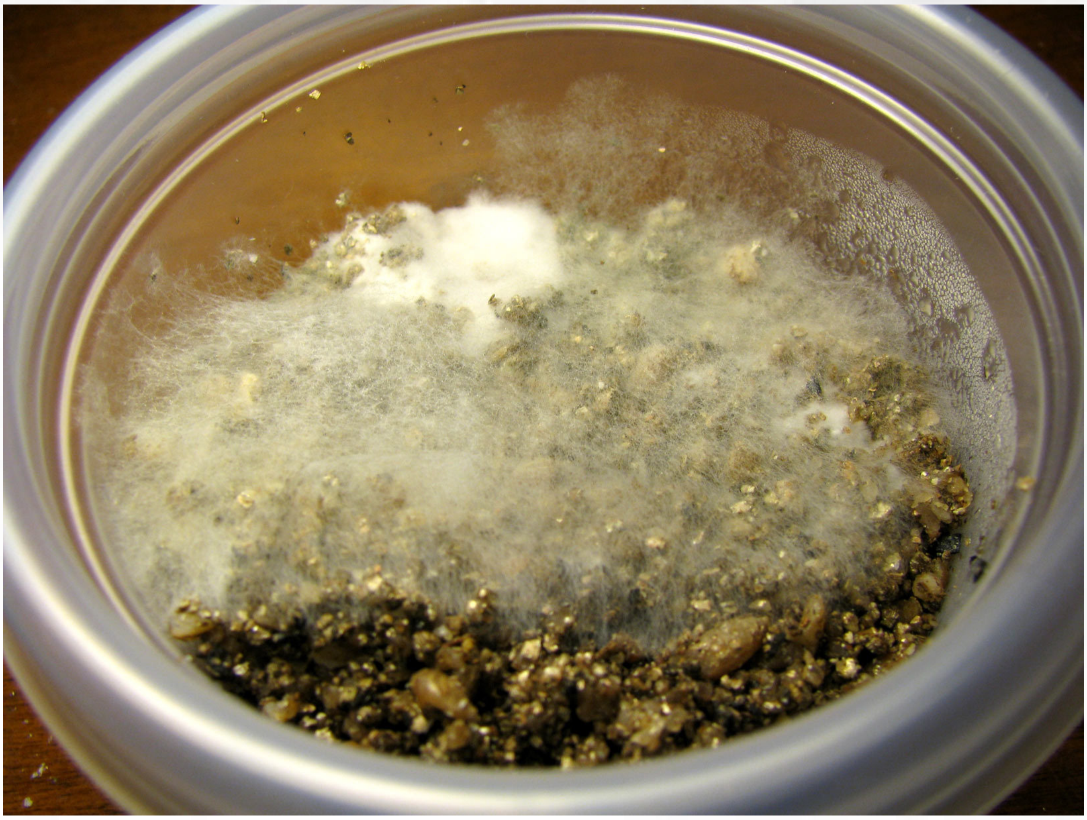
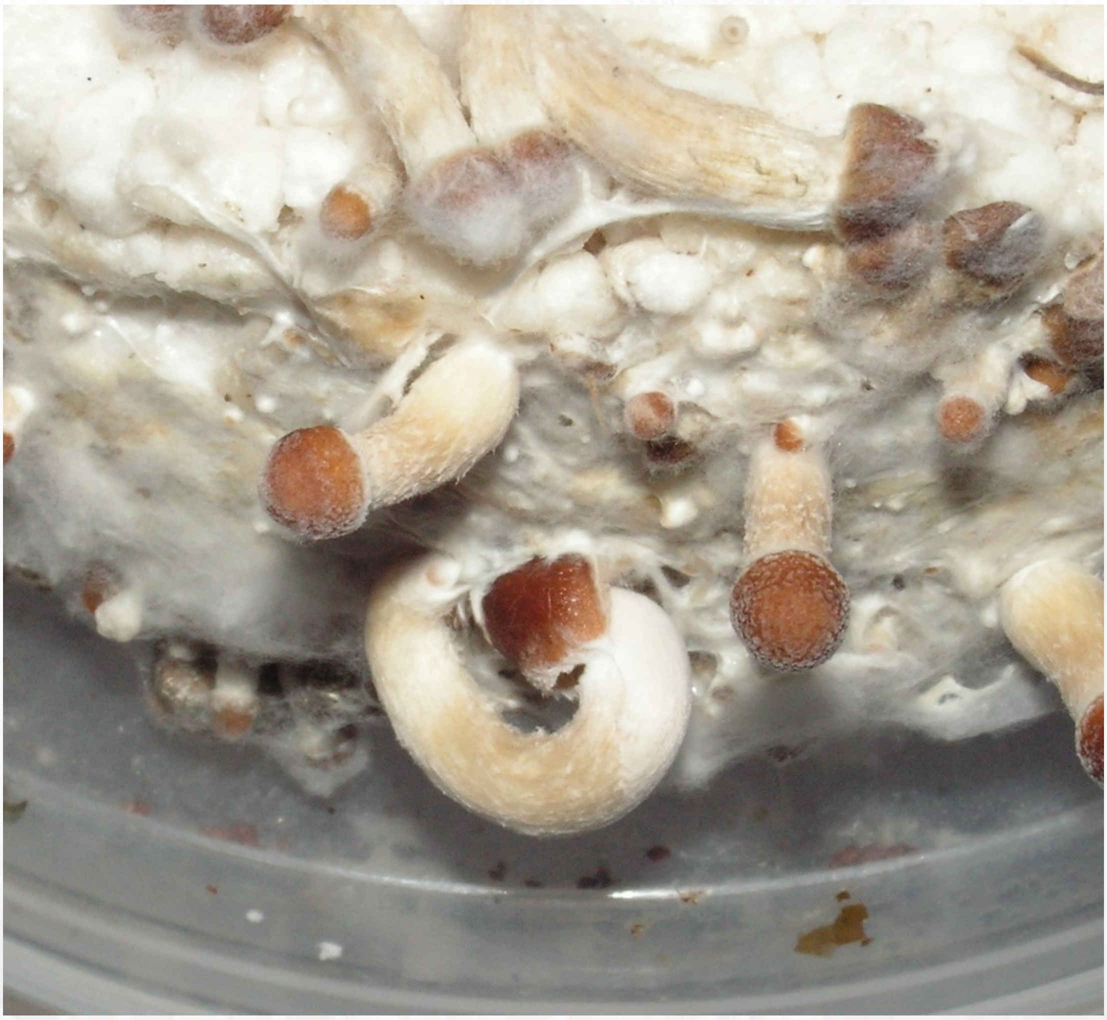
Here are some pictures of cobweb on Cubensis which I should mention to my knowledge have not been identified beyond all doubt.



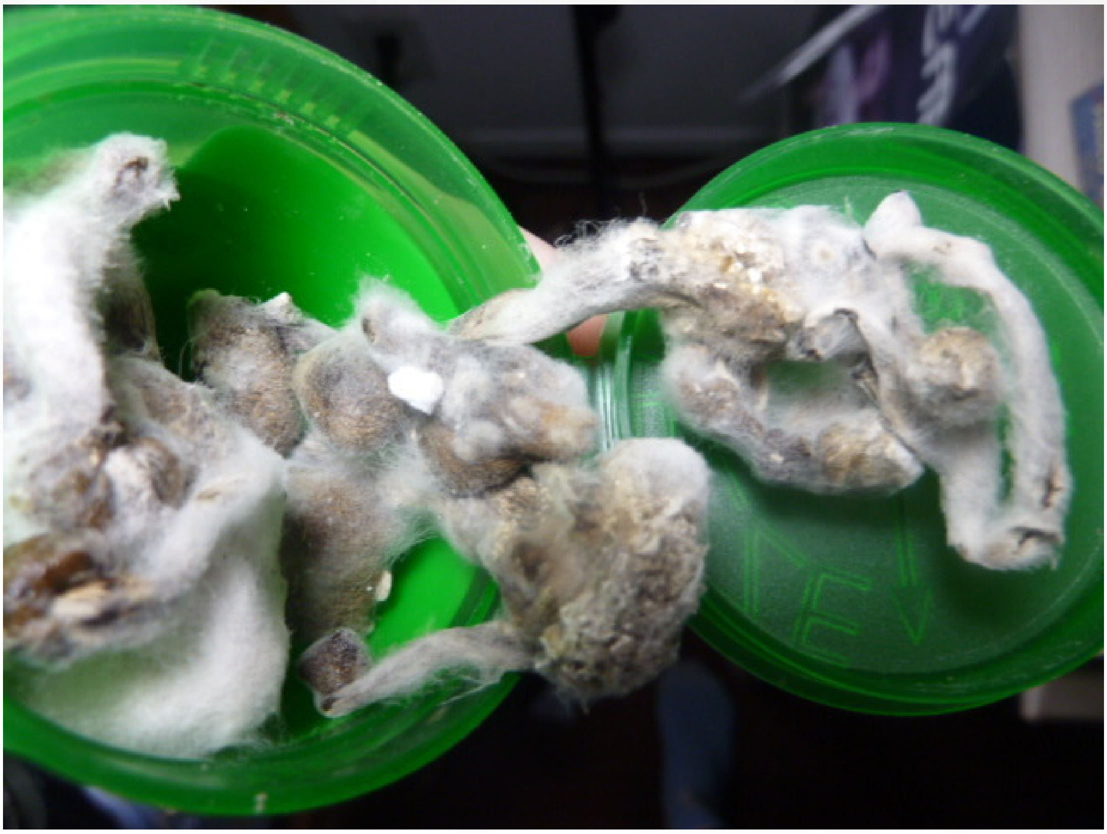
Possible cobweb on partially colonized substrate. It's growing completely over the substrate and not over the mycelium.



Cobweb on the (supposed to be) dry verm layer of a BRF cake. It's no coincidence that it didn't appear until the mushroom mycelium had grown through. That is a necessary for any visible growth on a casing layer, or in this case the equivalent of a casing layer. You can see the powdery of what appears to be spore formation.

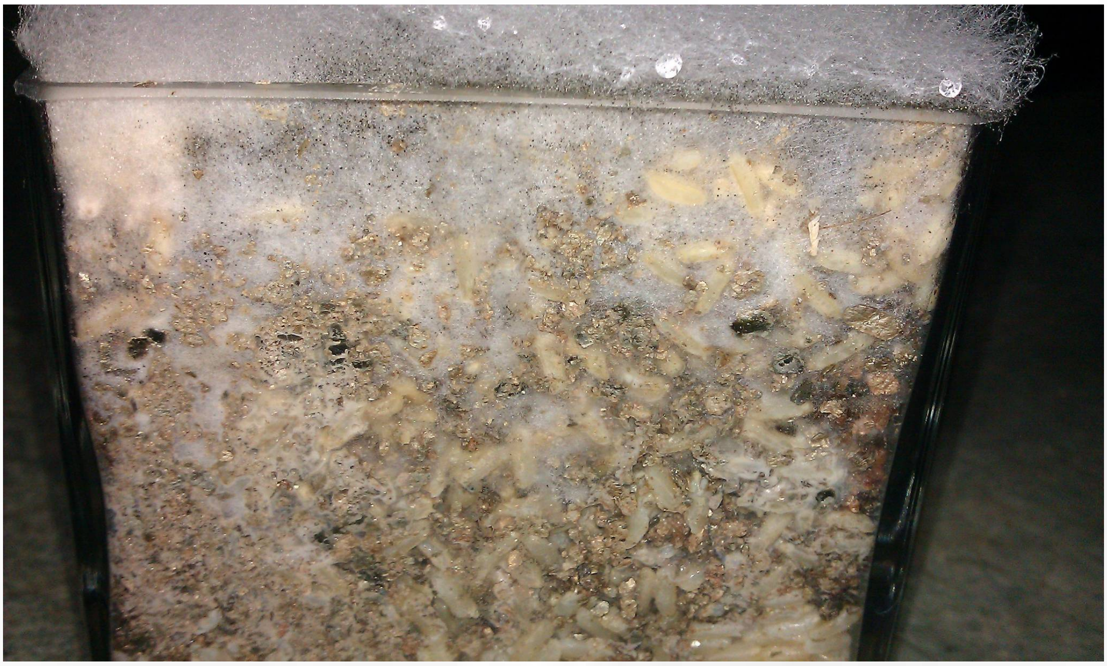


You can't even see them all anymore but there are pins and primordia under all those patches towards the bottom. However no spores for confirmation.

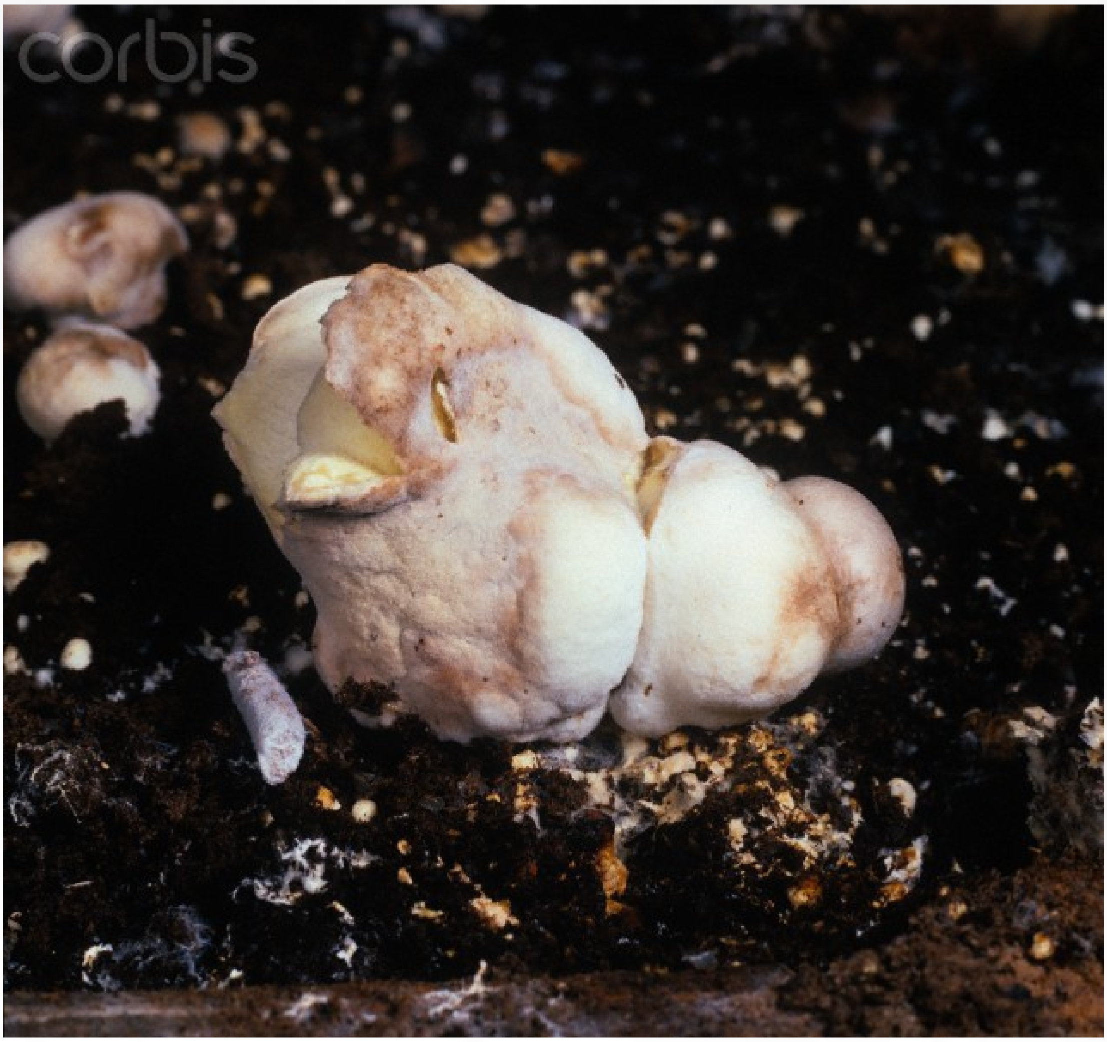


Cobweb on harvested mushrooms.

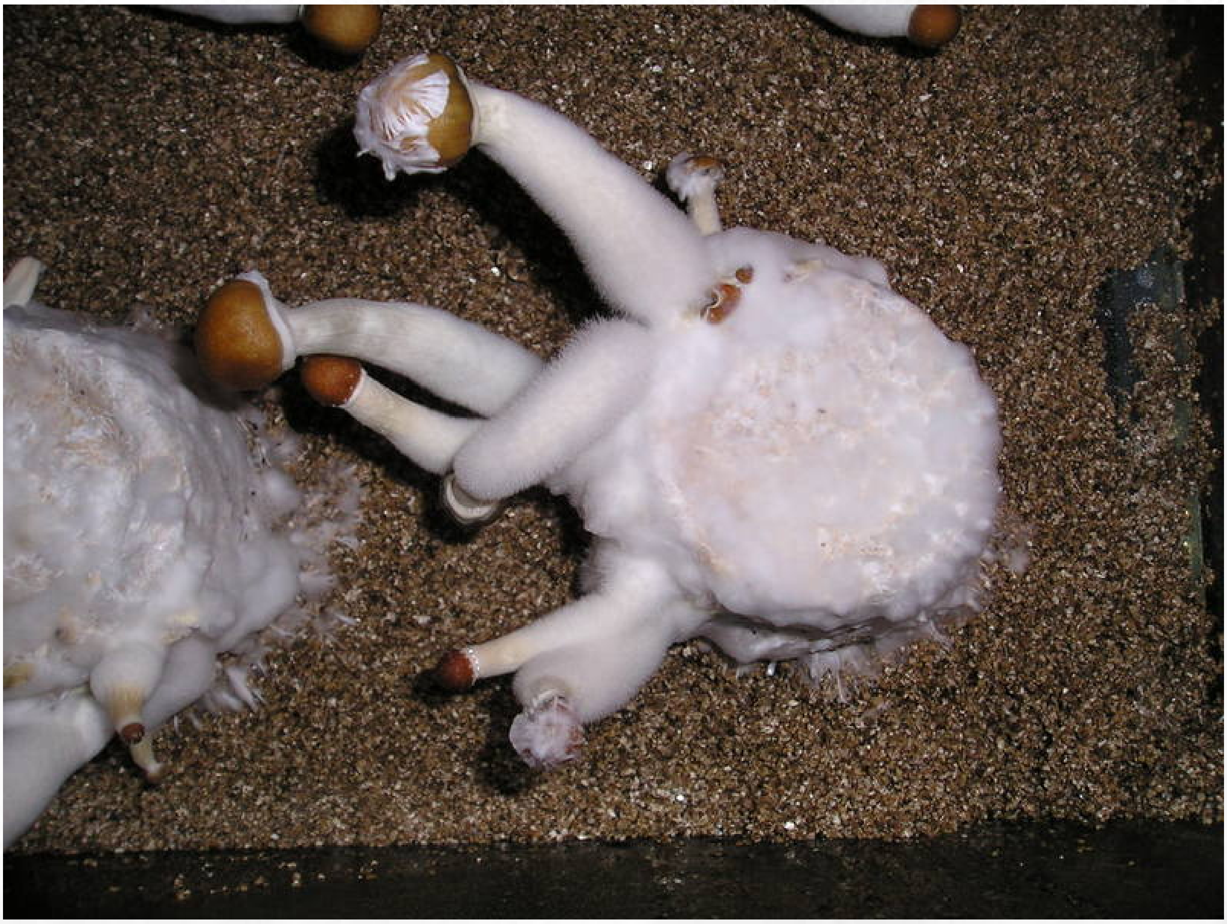
Some things that are NOT cobweb.



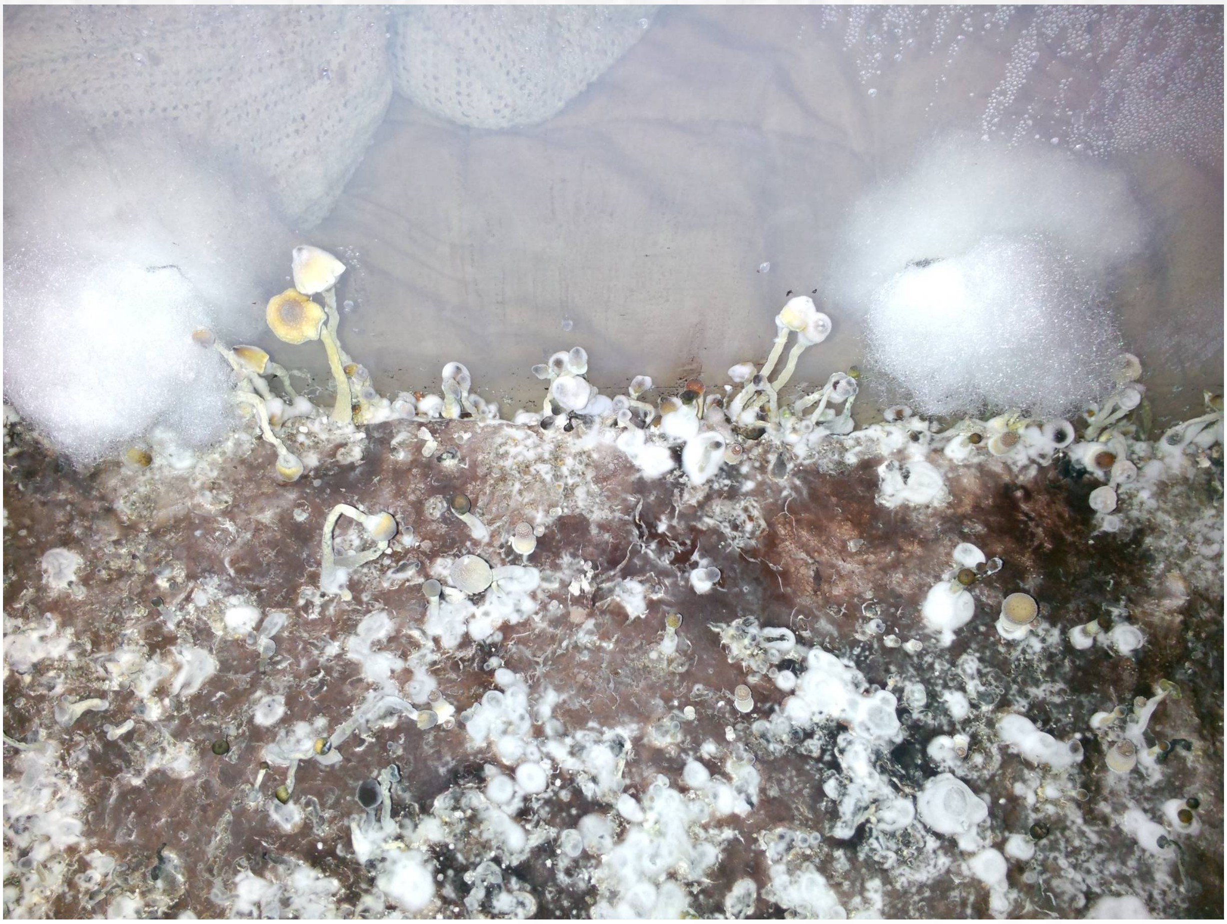
A perfect example of a pin mold which was thought to be cobweb despite the obvious presence of the black pins, and the immature white pins.



Verticillium infected mushroom.



Mushroom mycelium (fuzzy feet).



Old mushrooms and stumps although if there was cobweb there I don't think anyone would notice.

UPDATE: It's been a while since I posted this. I think I can say without a doubt now that actual *Dactylium* is not killed by 3% hydrogen peroxide. I have however discovered there are a couple *Mucorale* (pin molds) species that are when growing in anaerobic conditions. Or in other words they grow when gas exchange is lacking or when the substrate is oversaturated with water. They also do not sporulate under those conditions so if you're seeing the black pins they've establish themselves well enough to compete with the mushroom mycelium even after conditions are fixed and you've most likely already lost the opportunity to fix the problem.

Pilot Study of Psilocybin Treatment for Anxiety in Patients With Advanced-Stage Cancer

PREFACE

Context: Researchers conducted extensive investigations of hallucinogens in the 1950s and 1960s. By the early 1970s, however, political and cultural pressures forced the cessation of all projects. This investigation reexamines a potentially promising clinical application of hallucinogens in the treatment of anxiety reactive to advanced-stage cancer.

Objective: To explore the safety and efficacy of psilocybin in patients with advanced-stage cancer and reactive anxiety.

Design: A double-blind, placebo-controlled study of patients with advanced-stage cancer and anxiety, with subjects acting as their own control, using a moderate dose (0.2 mg/kg) of psilocybin.

Setting: A clinical research unit within a large public sector academic medical center.

Participants: Twelve adults with advanced-stage cancer and anxiety.

Main Outcome Measures: In addition to monitoring safety and subjective experience before and during experimental treatment sessions, follow-up data including results from the Beck Depression Inventory, Profile of Mood States, and State-Trait Anxiety Inventory were collected unblinded for 6 months after treatment.

Results: Safe physiological and psychological responses were documented during treatment sessions. There were no clinically significant adverse events with psilocybin. The State-Trait Anxiety Inventory trait anxiety subscale demonstrated a significant reduction in anxiety at 1 and 3 months after treatment. The Beck Depression Inventory revealed an improvement of mood that reached significance at 6 months; the Profile of Mood States identified mood improvement after treatment with psilocybin that approached but did not reach significance.

Conclusions: This study established the feasibility and safety of administering moderate doses of psilocybin to patients with advanced-stage cancer and anxiety. Some of the data revealed a positive trend toward improved mood and anxiety. These results support the need for more research in this long-neglected field.

Trial Registration: clinicaltrials.gov Identifier: NCT00302744

Arch Gen Psychiatry. Published online September 6, 2010. doi:10.1001/archgenpsychiatry.2010.116

In recent years, there has been a growing awareness that the psychological, spiritual, and existential crises often encountered by patients with cancer and their families need to be addressed more vigorously.[1-4] From the late 1950s to the early 1970s, research was carried out exploring the use of hallucinogens to treat the existential anxiety, despair, and isolation often associated with advanced-stage cancer.[5-15] Those studies described critically ill individuals undergoing psychospiritual epiphanies, often with powerful and sustained improvement in mood and anxiety as well as diminished need for narcotic pain medication. Despite these promising results, there has been no follow-up research.

Today, the medical value of hallucinogens is again being examined in formal psychiatric settings. One substance under investigation is psilocybin, 4-phosphoryloxy-N,N-dimethyltryptamine, which occurs in nature in various species of mushrooms. Psilocybin is rapidly metabolized to psilocin, which is a potent agonist at serotonin $5\text{-HT}_{1A/2A/2C}$ receptors, with 5-HT_{2A} receptor activation directly correlated with human hallucinogenic activity.[16] Psilocybin was studied during the 1960s to establish its psychopharmacological profile; it was found to be active orally at around 10 mg, with stronger effects at higher doses, and to have a 4-to 6-hour duration of experience. Psychological effects were similar to those of lysergic acid diethylamide (LSD), with psilocybin considered to be more strongly visual, less emotionally intense, more euphoric, and with fewer panic reactions and less chance of paranoia than LSD.[17,18]

Recent clinical examinations of psilocybin have indicated that it is not hazardous to physical health.[19] Positron emission tomographic studies demonstrated that psilocybin produces a global increase in cerebral metabolic rate of glucose, most markedly in the frontomedial and frontolateral cortex, anterior cingulate, and temporomedial cortex. These changes were correlated with measures of psychological state and consistent with potential neurobiological substrates of major mental illnesses.[20]

In one recent study, 36 healthy volunteers received a high dose (30 mg/70 kg) of psilocybin with no sustained deleterious physiological or psychological effects. The investigators corroborated previous findings that psilocybin could reliably catalyze mystical experiences leading to significant and lasting improvements in quality of life.[21] In another study, the effects of psilocybin were examined in patients with severe, refractory obsessive-compulsive disorder. Researchers concluded that psilocybin is safe and well tolerated in subjects with obsessive-compulsive disorder and may be associated with "robust acute reductions" in core obsessive-compulsive disorder symptoms, although there was no clear dose-response relationship.[22]

During the first wave of hallucinogen research from the 1950s through the early 1970s, investigators who administered hallucinogens to patients with end-stage cancers reported results that included improved mood and reduced anxiety, even in those with profound psychological demoralization.[23-26] The present study is the first in more than 35 years to explore the potential utility of a psilocybin treatment model for patients with reactive anxiety associated with advanced-stage cancer.[27]

METHODS

Twelve subjects with advanced-stage cancer and a *DSM-IV*[28] diagnosis of acute stress disorder, generalized anxiety disorder, anxiety disorder due to cancer, or adjustment disorder with anxiety were recruited into a within-subject, double-blind, placebo-controlled study to examine the safety and efficacy of psilocybin in the treatment of psychological distress associated with the existential crisis of terminal disease. Participants were recruited through Internet postings, flyer distribution, presentations at local hospitals and wellness centers, oncologist referrals, and study registration on clinicaltrials.gov and by contacting local patient support agencies and health care providers. Medical and psychiatric screening including brain magnetic resonance imaging, communication with treating oncologists, formal psychiatric diagnostic interviews, and informed consent were required for enrollment into the study. Subjects were not paid for their participation. The institutional review board of the Los Angeles Biomedical Research Institute, Harbor-UCLA Medical Center, Torrance, California, approved the protocol and monitored the study.

Of the 12 subjects, 11 were women. Subjects' ages ranged from 36 to 58 years. Primary cancers included breast cancer in 4 subjects, colon cancer in 3, ovarian cancer in 2, peritoneal cancer in 1, salivary gland cancer in 1, and multiple myeloma in 1. All subjects were in advanced stages of their illness. The duration of their primary cancers ranged from 2 months to 18 years. Eight subjects completed the 6-month follow-up assessment, 11 completed at least the first 4 months of assessment, and all 12 completed at least the first 3 months of follow-up. Two subjects died of their cancer during the follow-up period, and 2 others became too ill to continue participating. The study was conducted from June 2004 to May 2008. By the time of submission of this report in 2010, 10 of the 12 subjects had died.

Exclusion criteria included central nervous system involvement of the cancer, severe cardiovascular illness, untreated hypertension, abnormal hepatic or renal function, diabetes, lifetime history of schizophrenia, bipolar disease, other psychotic illness, and anxiety or affective disorders within 1 year prior to the onset of cancer. Medication contraindications included active cancer chemotherapy, antiseizure medications, insulin and oral hypoglycemics, and psychotropic medications in the previous 2 weeks. Subjects also were asked to refrain from taking any medications the day of and the day after the experimental treatment sessions, except for prescription or over-thecounter nonnarcotic pain medications at any time and narcotic pain medications up to 8 hours before and 6 hours after administration of the experimental medicine.

Four subjects had no prior hallucinogen experience. Of the remaining 8, 4 had hallucinogen experience more than 30 years ago. Two had their last experience more than 5 years ago, and the other 2 had taken a hallucinogen within the year prior to their participation in the study. Hallucinogens taken included LSD (7 subjects), hallucinogenic mushrooms (5 subjects), peyote (2 subjects), and ayahuasca (2 subjects).

Subjects met with study staff to review the purpose and intention of participation in the study, the treatment goals, the structure of the experimental treatment sessions, and critical issues to be examined during the course of the treatments. Subjects were informed of the range of emotional reaction that might be experienced while under the influence of psilocybin, including challenging psychological issues that might arise, and were informed that the purpose of the investigation was to determine whether psilocybin could ameliorate the anxiety associated with their advanced-stage cancer. Additional goals of these meetings included establishing a comfortable level of rapport and trust between the patient and research personnel, reviewing significant life issues in the patient's history, and the nature and status of present relationships and concerns.

All experimental sessions took place in a hospital clinical research unit in a room decorated with fabric wall hangings and fresh flowers to provide a pleasing and comfortable environment. Subjects were admitted on the afternoon of the day prior to treatment. A Holter cardiac monitor was attached for 24 hours beginning at admission. Following medical and nursing evaluations, the treatment team met with the subject to review the procedure for the treatment session (described later), confirm the subject's personal intentions, and answer any additional questions. Subjects spent the night in the room on the research unit and were provided dinner and a light breakfast before 06:30 hours. On the morning of treatment, the therapeutic team met with the subject to administer presession instruments, attend to patient comfort, and review treatment procedures for the session one final time.

Each subject acted as his or her own control and was provided 2 experimental treatment sessions spaced several weeks apart. They were informed that they would receive active psilocybin (0.2 mg/kg) on one occasion and the placebo, niacin (250 mg), on the other occasion. Psilocybin and placebo were administered in clear 00 capsules with corn starch and swallowed with 100 mL of water. A niacin placebo was chosen because it often induces a mild physiological reaction (eg, flushing) without altering the psychological state. The order in which subjects received the 2 different treatments was randomized and known only by the research pharmacist. Treatment team personnel remained at the bedside with the subject for the entire 6-hour session.

Psilocybin or placebo was administered at 10:00 hours. The subject was encouraged to lie in bed wearing eye shades during the first few hours as well as to put on headphones to listen to preselected music. Subjects were allowed to remain undisturbed until each hour point, when treatment staff checked to inquire how they were doing. Contact was generally brief; subjects had been advised that there would be ample opportunity after the session and in subsequent days, weeks, and months to discuss the content of the experience. During hourly check-ins, heart rate (HR) and blood pressure (BP) measurements also were taken. Noncaffeinated clear liquids or juices were permitted.

At the conclusion of the 6-hour session, subjects discussed the subjective aesthetic, cognitive, affective, and psychospiritual experiences they had during the session and completed rating instruments. Various self-report inventories and questionnaires were administered from 2 weeks prior to the first treatment session to up to 6 months after the second. Treatment team personnel maintained contact with subjects for the entire 6-month follow-up period, including regularly scheduled monthly telephone calls to update data on adverse events, concomitant medications, and evolving medical and psychological status.

ASSESSMENT MEASURES

Subjects' BP and HR were measured 30 minutes before drug ingestion, immediately before drug administration, and at hourly intervals for the next 6 hours. Temperature was measured just prior to drug administration and 6 hours later at the conclusion of the session.

The following psychological measures were administered the day before each of the experimental sessions: the Beck Depression Inventory (BDI), Profile of Mood States (POMS), and State-Trait Anxiety Inventory (STAI). The POMS, STAI, 5-Dimension Altered States of Consciousness profile (5D-ASC), and Brief Psychiatric Rating Scale were administered at the conclusion of the experimental sessions. The day after the session, the BDI, POMS, and STAI were readministered. Finally, the BDI, POMS, and STAI were administered again 2 weeks after each session and at monthly intervals for 6 months after the final session.

INSTRUMENTS

Beck Depression Inventory

The BDI consists of a series of questions developed to measure the intensity, severity, and depth of depression.[29]

Profile of Mood States

The POMS describes feelings individuals have, with the subject indicating his or her mood during the past week, including the present day. The POMS Brief, used for this study, is a shorter version of the original POMS Standard.[30] Subjects were instructed to fill out the POMS and BDI in reference to their feelings during the past week.

State-Trait Anxiety Inventory

The STAI Form Y is a widely used self-report instrument for assessing anxiety in adults. It includes separate measures of state and trait anxiety.[31] The STAI evaluates the essential qualities of feelings of apprehension, tension, nervousness, and worry. The STAI differentiates between the temporary condition of state anxiety and the more general and long-standing quality of trait anxiety. The STAI state anxiety sub-scale asks for feelings at the moment of filling out the questionnaire, and the STAI trait anxiety subscale asks subjects to indicate how they generally view themselves.

Brief Psychiatric Rating Scale

The Brief Psychiatric Rating Scale provides clinician assessment of the level of symptoms such as hostility, suspiciousness, hallucination, and grandiosity.[32]

5-Dimension Altered States of Consciousness Profile

The 5D-ASC rating scale measures alterations in mood, perception, experience of self in relation to environment, and thought disorder.[33] The ASC items are grouped into 5 sub-scales comprising several items, including the following:
(1) *oceanic boundlessness*, measuring derealization and depersonalization accompanied by changes in affect ranging from elevated mood to euphoria; (2) *anxious ego dissolution*, measuring ego disintegration associated with loss of self-control, thought disorder, arousal, and anxiety; (3) *visionary restructuralization*, including hallucinations, pseudohallucinations, synesthesia, changed meaning of perceptions, and facilitated recollection and imagination; (4) *auditory alterations*, with acoustic alterations and alterations of auditory experiences; and (5) *reduction of vigilance*, associated with drowsiness, reduced alertness, and related impairment of cognition. Subjects filled out the 5D-ASC at the conclusion of the session.

DATA ANALYSIS

Raw BDI, POMS, and STAI data were analyzed using 2-way analysis of variance (ANOVA) with drug as the within-subject factor and day as a repeated measure. When the 2-way ANOVA detected significant main effects of drug or interactions between day and drug, post hoc pairwise comparisons were performed by 1-way ANOVA for each day. The 5D-ASC data were analyzed using 1-way ANOVA with drug as a within-subject factor. Item clusters comprising the oceanic boundlessness, anxious ego dissolution, and visionary restructuralization dimensions also were analyzed using 1-way ANOVA.[34] The Brief Psychiatric Rating Scale data were analyzed using 1-way ANOVA with drug as a within-subject factor. The HR and BP data were analyzed using 2-way ANOVA with drug as a within-subject factor and time as a repeated measure. When the 2-way ANOVA detected significant main effects of drug or interactions between time and drug, pairwise post hoc comparisons were performed by 1-way ANOVA at each time. For the measures listed earlier, significance was demonstrated by surpassing an α level of .05. Paired t tests were used to assess whether niacin placebo and psilocybin produced effects on HR and BP compared with the predrug time, and significance was demonstrated for these multiple comparisons by surpassing an α level of .025. For the BDI, POMS, and STAI, data from each of the 6 follow-up times were compared with the baseline value obtained on the day before the first treatment session, using t tests. For the follow-up data, significance was demonstrated by surpassing an α level of .05.

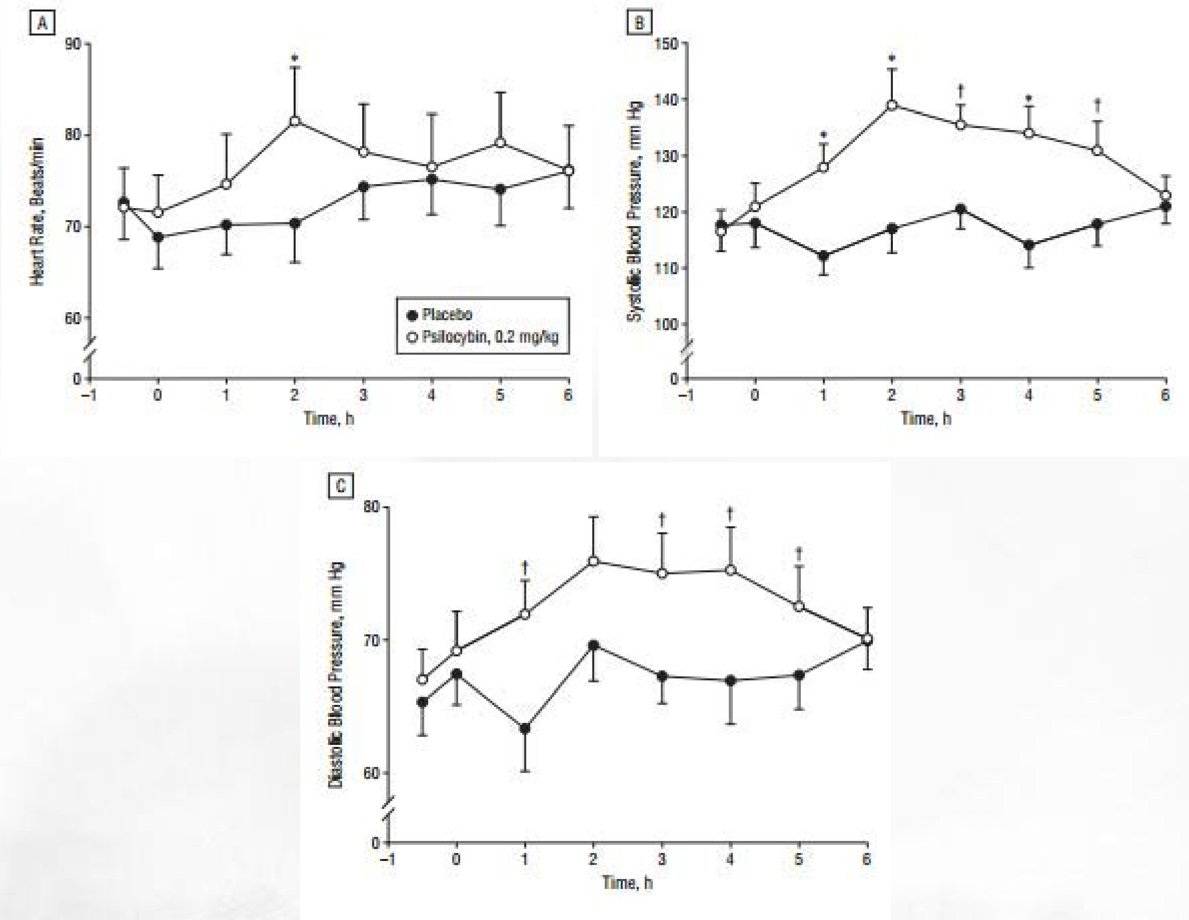

Figure 1. Effect of psilocybin or niacin placebo on mean (SEM) heart rate (A), systolic blood pressure (B),and diastolic blood pressure (C). Psilocybin or niacin placebo was administered at 0 hours. *P<.01, †P<.05 for psilocybin vs niacin placebo control (1-way analyses of variance were used to compare niacin and psilocybin effects at individual times).

RESULTS

CARDIOVASCULAR FUNCTION

The administration of psilocybin at a dose of 0.2 mg/kg induced a mild but statistically significant elevation of HR (psilocybin x time interaction: $F_{7,70}$=2.40, P=.03), systolic BP ($F_{1,11}$= 25.39, P<.001), and diastolic BP ($F_{1,11}$=5.94, P=.03) when compared with niacin placebo. Elevation of HR peaked 2 hours after psilocybin administration, with a mean (SEM) peak effect of 81.5
(5.8) beats/min, which was statistically significant ($F_{1,11}$=11.31, P<.007) compared with 70.4 (4.3) beats/ min during placebo sessions (Figure 1A).

Blood pressure also peaked at the 2-hour point, with mean (SEM) peak systolic BP during psilocybin sessions measuring 138.9 (6.4) mm Hg (compared with 117.0 [4.3] mm Hg during niacin placebo sessions) (Figure 1B) and mean (SEM) peak diastolic BP of 75.9 (3.4) mm Hg during psilocybin sessions (compared with 69.6 [2.7] mm Hg during niacin placebo sessions) (Figure 1C). Holter monitor recordings during the psilocybin sessions showed no sustained tachyarrhythmias or heart block and were consistent with findings during active placebo sessions. Compared with the predrug time, niacin modestly depressed diastolic BP 1 hour after administration (Figure 1C) with a rebound over the next hour but had no effect at other times.

PSYCHOLOGICAL MEASURES

The 5D-ASC demonstrated marked subjective differences between the psilocybin and placebo experiences. Psilocybin particularly affected the oceanic boundlessness ($F_{1,11}=33.12$, $P<.001$) and visionary restructuralization ($F_{1,11}=18.95$, $P=.001$) dimensions (Figure 2A). Psilocybin had smaller but significant effects on anxious ego dissolution ($F_{1,11}=4.91$, $P=.049$) and auditory alterations ($F_{1,11}=5.93$, $P=.03$). The item clusters with marked differences between the subjective states produced by psilocybin and niacin included a significant increase (P<.05) in psilocybin-invoked states of positive derealization, positive depersonalization, altered sense of time, positive mood, manialike experiences, elementary hallucinations, visual pseudohallucinations, synesthesia, changed meaning of percepts, facilitated recollection, and facilitated imagination. Subscales with no appreciable differences between intrasubjective states induced by the 2 treatments included anxious derealization, thought disorder, delusion, fear of loss of thought control, and fear of loss of body control (Figure 2B).

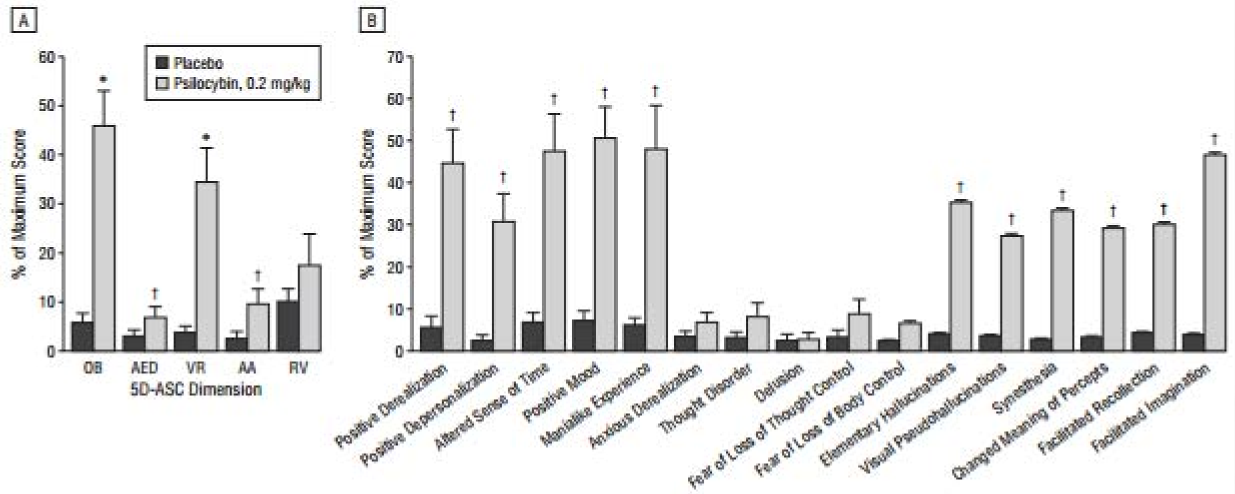

Figure 2. Subjective effects of psilocybin as measured by the 5-Dimension Altered States of Consciousness profile (5D-ASC). A, Five main 5D-ASC dimensions are shown: oceanic boundlessness (OB), anxious ego dissolution (AED), visionary restructuralization (VR), auditory alterations (AA), and reduced vigilance (RV). B, Item clusters comprising the OB, AED, and VR dimensions are shown. Values are the mean (SEM) percentages of the total possible score. *$P<.01$, †$P<.05$ for psilocybin vs niacin placebo control (1-way analyses of variance were used to compare niacin and psilocybin effects on individual 5D-ASC dimensions and 5D-ASC item clusters).

For the BDI, there was an overall interaction of psilocybin and day that approached but did not attain statistical significance ($F1,11=3.75$, $P=.08$). There was no appreciable change from 1 day prior to placebo administration to 2 weeks after experimental treatment, whereas a trend was observed after psilocybin administration, from a mean (SEM) score of 16.1 (3.6) one day before treatment to 10.0 (2.7) two weeks after treatment (Figure 3A). As shown in Figure 3B, BDI scores dropped by almost 30% from the first session to 1 month after the second treatment session ($t_{11}=-2.17$, $P=.05$), a difference that was sustained and became significant at the 6-month follow-up point ($t_7=2.71$, $P=.03$).

The POMS similarly revealed a trend for reduced adverse mood tone from 1 day before treatment with psilocybin to 2 weeks later, a difference that was not seen after placebo (drug x time interaction: $F_{3,33}=2.71$, $P=.06$) (Figure 4A). Paired post hoc tests revealed that mean (SEM) POMS scores were elevated ($F_{1,11}=7.48$, $P=.02$) 1 day before psilocybin treatment (11.3 [3.1]) compared with 1 day before placebo (4.5 [2.0]) and demonstrated that this difference disappeared 6 hours after psilocybin administration. Improvement of mood, indicated by reduced POMS scores, was observed in 11 subjects after administration of psilocybin. The elevation of POMS scores 1 day before psilocybin treatment occurred regardless of whether the subjects were treated with placebo or psilocybin first (ie, there was no interaction between treatment order and drug). As shown in Figure 4B, POMS scores were not altered during the 6 months of follow-up compared with the day before the first treatment session.

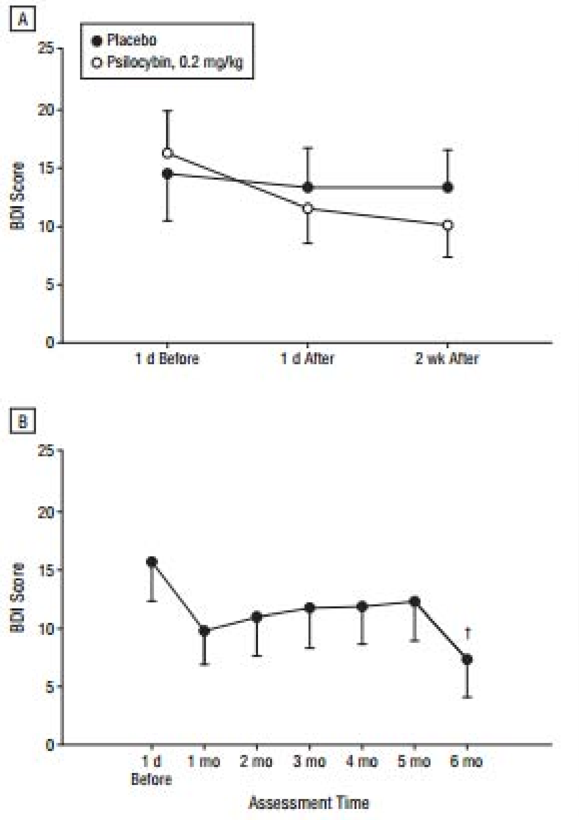

Figure 3. Beck Depression Inventory (BDI) scores. A, Mean (SEM) BDI scores 1 day before, 1 day after, and 2 weeks after administration of psilocybin or niacin placebo are shown. B, Six months of mean (SEM) BDI follow-up data are shown. The BDI was administered at monthly intervals for 6 months after the second treatment session, and the 6 sets of monthly follow-up data were compared with the scores obtained the first time the participants filled out the instruments (ie, 1 day before the first treatment session). †P<.05 for psilocybin vs the value from 1 day before the first treatment session (*t* tests were used to compare individual monthly follow-up values with values on the day before the first session).

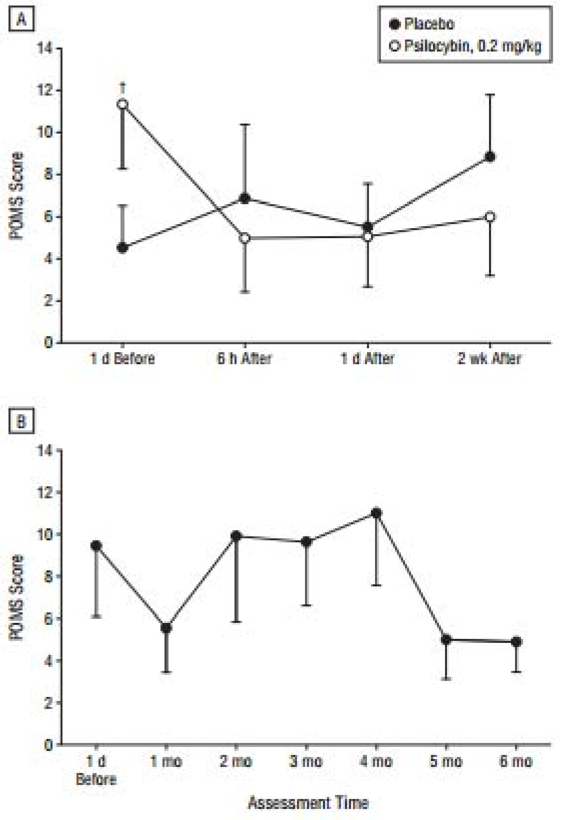

Figure 4. Profile of Mood States (POMS) scores. A, Mean (SEM) POMS scores 1 day before, 6 hours after, 1 day after, and 2 weeks after administration of psilocybin or niacin placebo are shown. B, Six months of mean (SEM) POMS follow-up data are shown. The POMS was administered at monthly intervals for 6 months after the second treatment session, and the 6 sets of monthly follow-up data were compared with the scores obtained the first time the participants filled out the instruments (ie, 1 day before the first treatment session). †P<.05 for psilocybin vs niacin placebo control (1-way analyses of variance were used to compare niacin and placebo effects at individual times).

The STAI revealed no significant changes from 1 day before to 2 weeks after treatment, although a substantial but nonsignificant decrease was evident for the state anxiety subscale 6 hours after psilocybin administration, which was not observed after placebo (Figure 5A and C). Although minimal change was observed in the STAI state anxiety score for follow-up data, a sustained decrease in STAI trait anxiety was observed for the entire 6-month follow-up, reaching significance at the 1-month (t_{11}=4.36, P =.001) and 3-month (t_{10}=2.55, P = .03) points after the second treatment session (Figure 5B and D).

The Brief Psychiatric Rating Scale at the end of the experimental session revealed no appreciable difference between psilocybin and placebo administration.

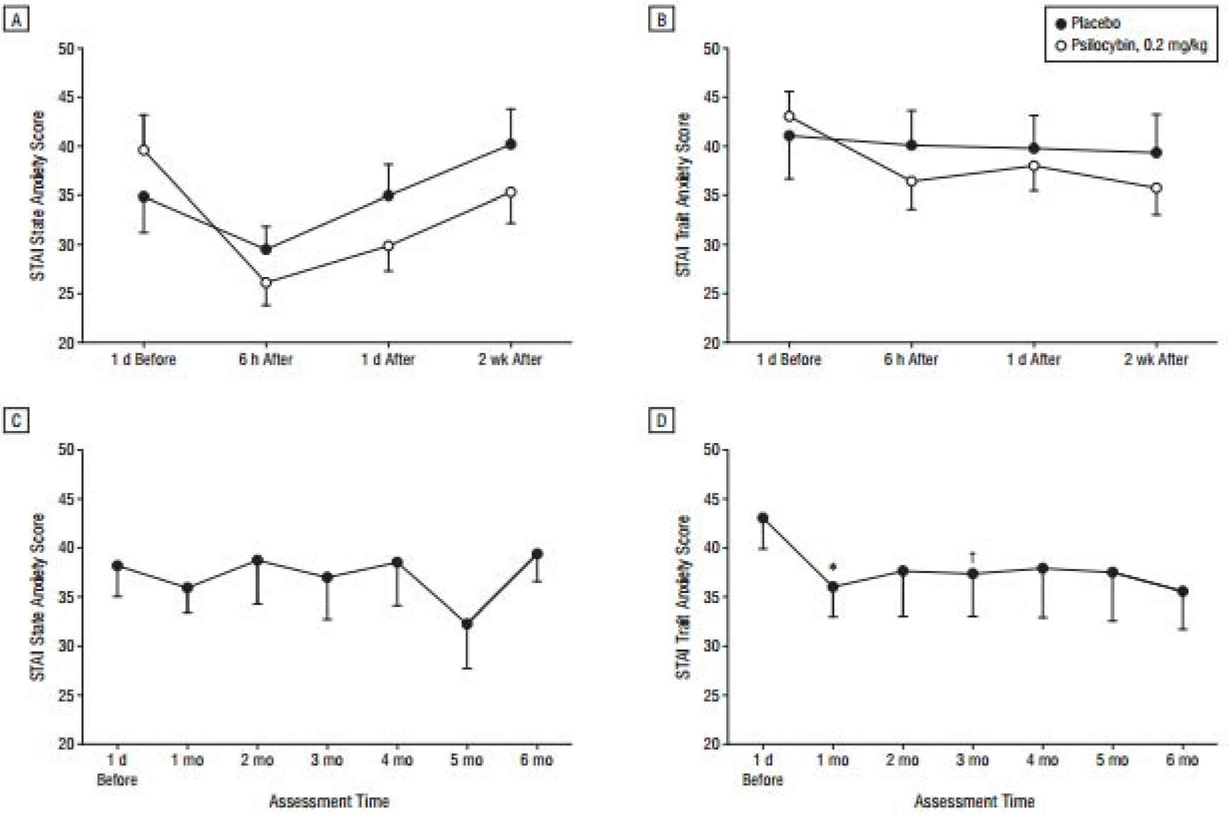

Figure 5. Mean (SEM) State-Trait Anxiety Index (STAI) state anxiety scores (A) and trait anxiety scores (B) 1 day before, 6 hours after, 1 day after, and 2 weeks after administration of psilocybin or niacin placebo are shown. Six months of mean (SEM) STAI state anxiety follow-up data (C) and trait anxiety follow-up data (D) are shown. The STAI was administered at monthly intervals for 6 months after the second treatment session, and the 6 sets of monthly follow-up data were compared with the scores obtained the first time the participants filled out the instruments (ie, 1 day before the first treatment session). *$P<.01$, †$P<.05$ for psilocybin vs the value from 1 day before the first treatment session (*t* tests were used to compare individual monthly follow-up values with values on the day before the first session).

COMMENT

The initial goals of this research project were to establish feasibility and safety for a hallucinogen treatment model in patients with advanced-stage cancer and anxiety. Following discussion with federal and state regulatory agencies as well as hospital institutional review board and research committees, a modest 0.2-mg/kg psilocybin dose was chosen. Although not comparable to higher doses of hallucinogens administered in the past to severely ill patients, the dose used here was still believed capable of inducing an alteration of consciousness with potential therapeutic benefit while optimizing patient safety. Determining safe parameters with this novel treatment paradigm is critical to establishing a strong foundation for this field of study that would allow for future investigations.

Consistent with previous research, we found no untoward cardiovascular sequelae in our subject population.[19] Minor HR and BP elevations after psilocybin administration were evidence only of a mild sympathomimetic effect. Holter monitoring did not identify increased cardiac arrhythmias in comparison with niacin placebo, even in subjects who presented with some baseline cardiac arrhythmia. Niacin may acutely lower BP through vasodilation[35] but had minimal effects on BP and HR in our subjects, except for a reduction in diastolic BP that was noted 1 hour after administration of niacin. This transient effect may have contributed to our detection of a significant psilocybin effect at that time but cannot explain the significant effects of psilocybin over the subsequent intervals because the initial niacin-induced reduction of diastolic BP did not persist. We also observed no adverse psychological effects from the treatment. All subjects tolerated the treatment sessions well, with no indication of severe anxiety or a "bad trip." The fact that psilocybin produced only modest effects on the anxious ego dissolution scale of the 5D-ASC confirmed this conclusion.

When hallucinogens were administered to patients with terminal cancer in the 1960s and early 1970s, the occurrence of a profound psychospiritual experience was correlated with therapeutic outcome.[10,12] Such transcendent states of consciousness are usually associated with higher doses of hallucinogens, so our expectation of demonstrating efficacy was limited.[21] Common themes reported by subjects included examining how their illness had impacted their lives, relationships with family and close friends, and sense of ontological security. In addition, subjects reported powerful empathic cathexis to close friends and family members and examined how they wished to address their limited life expectancy. In monthly follow-up discussions, subjects reflected on insights and new perspectives gained during their psilocybin treatment. However, the frequency of these reports was not quantified.

Although past researchers reported more pronounced therapeutic effects with a higher-dose model, even the lower dose of psilocybin used in the current study gave some indication of therapeutic benefit in quantitative psychological evaluations. In particular, we found that the STAI trait anxiety subscale demonstrated a sustained reduction in anxiety that reached significance at the 1-and 3-month points after treatment. This reduction might reflect a reduced level of stress and anxiety over time. Although the state anxiety on the STAI showed a modest elevation at 6 months, the change was not statistically significant and might have resulted from the deteriorating medical status of most subjects over time.

Mood also improved for 2 weeks after treatment with psilocybin, with sustained improvement on the BDI reaching significance at the 6-month follow-up point. The POMS scores also reflected improved mood 2 weeks after receiving psilocybin. Although not statistically significant, there was a trend toward positive outcome. With a larger cohort of subjects and use of a higher dose of psilocybin, it seems possible that significant results would be obtained on these measures.

Compared with placebo sessions, POMS scores were elevated in subjects immediately prior to psilocybin administration. The reasons for this difference in POMS scores 1 day before administration are not entirely clear. Subject expectations were unlikely to have played a role in the elevation of the POMS scores on the day before treatment because the elevation occurred regardless of treatment order. The most likely explanation for the elevation of POMS scores prior to treatment with psilocybin may be that subject randomization was not complete with regard to this instrument. Nonetheless, POMS scores declined after administration of psilocybin in 11 of 12 subjects, suggesting that psilocybin produces mood-elevating effects that persist after the acute effects of the drug.

Another focus of the study was the effect of a 0.2mg/kg psilocybin dose on somatic symptoms, particularly pain perception. In contrast to previous investigations, we did not find robust reductions in pain perception or lessened need for narcotic pain medication. In the 2 weeks following experimental treatment sessions, several subjects reported lessened pain, whereas others did not. There was no apparent difference between subjects treated with psilocybin and those treated with placebo (data not shown). Although this modest dose of psilocybin was not observed to impact pain, given the impressive reports of earlier researchers,[6] this measure would certainly be indicated for study with higher doses.

Although we used a within-subject, double-blind, placebo-controlled design, the drug order was almost always apparent to subjects and investigators whether the treatment was psilocybin or placebo. In fact, one consistent subject critique of the study was that the placebo sessions were perceived as far less worthwhile than those with psilocybin. Many of the subjects suggested that future protocols provide the opportunity for a second psilocybin session several weeks after the first. The general consensus among subjects was that a follow-up experience with psilocybin would reinforce and extend the perceived therapeutic effects of the initial session.

Future studies also will need to address the issue of controlling for a placebo effect that might otherwise be attributed to the active treatment. Given the subjects' grave prognosis and limited life expectancy, we decided to provide all subjects with an opportunity to experience the experimental medicine and to serve as their own control. Although we believed that to be the ethical course to take, given the life circumstances subjects were encountering, the protocol design contains some inherent limitations. A better experimental design might incorporate an independent control group, receiving only either placebo treatment or a conventional psychopharmacological intervention. Although there is no question that the extensive attention paid to the subjects influenced outcomes, the unique qualities of the psilocybin experience in facilitating strong therapeutic bonds and ameliorating underlying psychological demoralization are important factors worthy of further exploration.

Another limitation of this study was variability in the extent of contact with subjects after treatment. A minimum contact of 1 hour monthly was established, but variability in additional ad hoc communication depended on the needs and wishes of the subjects, some of whom were near death compared with others who were more functional.

Despite the limitations, this study demonstrates that the careful and controlled use of psilocybin may provide an alternative model for the treatment of conditions that are often minimally responsive to conventional therapies, including the profound existential anxiety and despair that often accompany advanced-stage cancers. A recent review from the psilocybin research group at Johns Hopkins University describes the critical components necessary for ensuring subject safety in hallucinogen research.[36] Taking into account these essential provisions for optimizing safety as well as adhering to strict ethical standards of conduct for treatment facilitators, the results provided herein indicate the safety and promise of continued investigations into the range of medical effects of hallucinogenic compounds such as psilocybin.

> *Now that the FDA has permitted research with LSD and psilocybin to resume, we feel it is important to share examples of a remarkable experiment, the results of which were not sufficiently taken into account because this line of research was prematurely halted in the mid-sixties due to political considerations. Childhood schizophrenia is still a difficult problem to treat and causes much suffering. It is a terrible shame that research done 35 years ago is still the last word on the use of psychedelics to treat these conditions. - Ed.*

Hypothesis

The working hypothesis of this study is that psychosis is a massive defensive system of repression-avoidance-denial in the service of protecting the individual from experiencing early childhood trauma. The repression is so massive that the individual ceases to experience himself with any validity. The individual exists isolated in a world without feelings and this world becomes meaningless. One of our little patients told me that he lived in a world of "no nothingness." It was hypothesized that the psychedelic drugs could break through this massive repression wherein the child would re-experience these traumatic events and release the pain bound to those experiences. He or she would acknowledge his own history. Furthermore, through experiencing the loving attention of the staff in a milieu of total acceptance, the child could begin to experience himself as a positive and valid person. The team consisted of a psychiatrist (who chose not to have an LSD experience but was medically responsible for the research), four psychology graduate students and three psychiatric nursing technicians. The author acted as lead therapist of this group. For any one session there were usually three to four staff, relieving each other throughout the day as the sessions were extremely intense and required very active participation by the staff. All staff had had their own experience with LSD and psilocybin, as it is accepted practice that in order to understand what was going on with the children one had to have had personal experiences with the drugs. As we progressed with the work it emerged that one staff person would become the primary therapist for each patient. Each session was continuously recorded for the verbalizations and behavior of the patient. Besides spending time with the patient during the treatment session itself, a total program had to be developed for each patient and that program communicated to all ward personnel to attempt consistency in the therapeutic approach. We were careful to include ward personnel who were not part of the treatment team in the ongoing progress of each patient and to enlist their cooperation in the development of a consistent attitude. As the ward personnel began to see the remarkable changes occurring in the children, they became involved and supportive in the ongoing care of each child.

Ward Conditions

The ward in which these children lived was in a state of constant pandemonium. The ward housed some sixty children ranging in age from four to twelve who were the most severely disturbed children of a larger hospital population. There was constant screeching, fighting and destructive behavior. Many children were destructive towards the environment, to each other, to the staff and to themselves. The primary duty of the ward personnel was damage control. The noise level was always high, as many of the children were extremely hyperactive and vocal. Other children were very withdrawn, involved in repetitious physical motions and when interfered with would lash out at the intruder. There was little interactive or parallel play and any toys or material brought into the ward were soon destroyed. Feces smearing and random urinating were a constant problem. To say the least the environment was not conducive to good mental health.

New Behavior

After nine months of the program and fifty-eight treatment sessions it was decided to continue the program with five patients of the initial twelve. The children discontinued from the program were characterized by a lack of speech and infantile autism and were the least responsive to treatment. They were extremely withdrawn and had no ability to relate to other children or adults. In spite of their severe limitations, all of them did have some marked response to the treatments. During the sessions they showed little responsiveness although some of them became hyperactive and were obviously having some sensory experiences and more interaction with the staff. One girl had a prolonged fear response. Marked changes occurred in the days following the sessions. They showed much more interest in relating to the treatment staff, became animated and playful and remarkably less withdrawn. One girl evidenced extreme frustration at not being able to verbally communicate as she had no language development. The youngest (four years old) and least developed child kept trying to lead a treatment staff person down to the room where we did sessions. They all had interest in making physical contact with the treatment staff and one very autistic child became quite demanding to be held. This was all new behavior for these children. Consequently they all had behavior changes but their potential in relation to other patients was much more limited and we had limited time available to treat them.

Among the children with whom we discontinued treatment, one twelve year old girl had progressed so remarkably that she was able to attend public school during the day and return to the hospital in the evenings. It was felt that she had sufficiently improved, was functioning satisfactorily in the school system and that further treatment was not crucial. Patty was the only patient who was not psychotic. She responded to the treatments more rapidly than the more disturbed patients. A short summary of her treatment will help illustrate the work.

Patty's First Session

Patty had three sessions over a period of three months. Dosage for the sessions were 100 micrograms of LSD, 100 micrograms of LSD with 10 milligrams of psilocybin, and 200 micrograms of LSD. She was hospitalized because of her inability to function at home, in the school or in the community. Her behavior fluctuated from being withdrawn and uncommunicative to very aggressive and sadistic towards smaller children. She stole food and other items from other smaller children and when thwarted in her behavior had violent temper tantrums and had to be physically restrained and isolated. Although her IQ was tested at 72, her low functioning seemed to be caused by severe personality problems and it was estimated that her potential was near the normal range. During the first session she spent the entire seven hours regressing to an infantile oral state. She incessantly repeated, "I'm hungry" and when asked what she was hungry for, she did not reply but only restated her hunger. During the entire session she chewed and sucked on her clothes or others, her fingers, arms and anything or anyone she could reach. She was given an empty baby bottle with cotton stuffed in the nipple and she chewed and sucked on this for hours. It was clear that she was trying to draw nourishment from anything in her environment. During the session one staff member would sit with her, holding her hand or arm and gently hugging her or stroking her. We gave her constant tactile care. For about two hours she aggressively bit the nipple, stretching it and gnawing on it. She finally appeared to become exhausted and uncommunicative for almost an hour. In the latter stages she held hands with staff and smiled quietly without verbalizing. She appeared to be making genuine interpersonal contact.

The Second Session

In the month following her treatment Patty was much more subdued and did not want to talk a great deal about the first session. During the second session she spent a great deal of time sucking on the baby bottle but this time she said she wanted milk in it and we complied. She then went into a panic-like state and talked a great deal of her fear of being rejected by her parents. She insisted that we call them immediately and have them come and take her home. She was extremely anxious that she would be abandoned by them and at one time sadly said of her mother, "She doesn't love me." After some three hours of constant turmoil concerning her familial relationships and her severe agitation over the rejection by her parents, she slipped into a quiet state for a period of time. She then suckled on the milk bottle and when she took it out of her mouth she would repeat, "I am loved." After some four hours she said "I love my mother, my father, my brothers and my sisters, I never felt this way before. I love them." She said that she had never felt that she was loved and the feeling of being loved and loving that she was now experiencing was new to her. She then went into a state for about two hours which is best described as a deep trance state. She was completely still with no movement whatsoever, and was unresponsive to all verbal or tactile stimuli. She finally came out of it and started smiling but still remained unresponsive to any of our inquiries. After about another hour she got up and wanted to go for a walk outside. She was happy and smiling and occasionally would laugh out loud.

Following this session Patty again was much more subdued, her behavior changed remarkably in that her temper tantrums ceased and she was relaxed and content. She interacted with new maturity toward the staff and had a very positive relationship (it looked like adolescent adoration) with one of the male psychology students. They spent a good deal of time with each other.

The Third Session

The third session, two months later, was initially characterized by more oral regressive behavior. She asked for the baby bottle with milk and spent over two hours, biting on it, suckling it trying to swallow the whole bottle, but this behavior did not have a desperate quality to it. She seemed to be more playing with it, enjoying it, and her demeanor was quiet and content. She suckled for long periods and would drift off into a peaceful, tranquil state, completely relaxed, smiling at the sitters when making eye contact. She wanted to be quiet and we were quiet with her - touching her, hugging her, holding her hand when she reached out. She responded to visual stimulation such as a rose with delight and amazement. She thoroughly enjoyed the attention and affection of the staff. Again following the session she was much more mature, interested in relating to adults and wanted to go to school with kids her own age. Her temper tantrums and rage reactions and her stealing behavior had completely ceased. It was felt she was ready to try school off hospital grounds. She was excited about this new situation and did not have any relapses. Patty did not seem to experience fear of the new situation but was excited about the opportunity to be in new surroundings and she did very well. She continued to stay at the hospital after school hours and continued her supportive relationship with the staff. She became a very affectionate and loving child and her personality was fairly subdued and quiet.

Timmy

One ten year old severely autistic boy was continued on the program more as a challenge, as he was very resistant to abandoning his psychotic defenses. He was given a series of ten sessions over a period of ten months, with dosages up to 400 micrograms of LSD. Before treatment he was highly encapsulated, repeating a few phrases and displaying repetitive and catatonic posturing. His only contact with people was looking up their sleeves, he seemed to be checking if and how arms were attached. He would not allow himself to be touched and had no interaction whatsoever, other than attacking other children if they approached or touched him. His treatment sessions were characterized by agitation, fear, panic and anxiety. Occasionally he could relax and allow staff to hold him, rub him and gently feed him. He had long periods where he was totally out of contact with his surroundings. During a later session after some two hours of being out of contact, he sat up rather suddenly, his eyes widened with astonishment and he whispered, "I saw God." During later sessions he evidenced a much larger vocabulary and abandoned his echolalia and repetitive speech.

Timmy's first four sessions were almost exclusively devoted to biting, chewing and aggressive oral behavior. We observed this with all patients, evidencing extreme oral rage. In later sessions patients would attempt to eat us and everything in sight to fill the emptiness they felt. In spite of us not witnessing a lot of what we could identify as conflict resolution during the sessions, his behavior underwent a marked change. His physical attacking behavior subsided and he became interested in relating to other boys his age as well as the treatment staff. He wanted physical contact, became playful and enjoyed himself. His parents began taking him home for weekends due to these behavioral changes and they repeatedly told us that they were amazed at his improvement.

Jenny

This nine year old girl had eight sessions over a period of six months. Her IQ at age five was eighty-two. She had good verbal ability. Her behavior was impulsive, erratic and unpredictable. She was often very aggressive to other children, especially smaller ones, and attacked them viciously without provocation. When she attacked it was often with very flat affect, not associated with anger or retaliation. She was very oral, eating anything she could obtain and attempted to eat inedible objects. She would make sexual advances to adult males. She was socially isolated, did not participate with others, and showed a pronounced inability to make any meaningful relationship with anyone, children or adults.

Jenny's sessions were characterized by her reliving sexual abuse and her fear and alarm and ambivalence over the attention given her. She regressed back to her early infancy and gave repeated evidence of her neediness from her mother and her anger at not being properly cared for (both parents were alcoholics). She was extremely orally aggressive and had to be restrained a good deal as she acted out her anger by biting, scratching, pinching, kicking and attacking staff. Much of the time that she was acting out her affect was quite flat, other times she would be screaming and there was a great deal of conflict over toilet training and power struggles related to this event.

In later sessions Jenny became much more stabilized and she started verbally expressing her hatred of both males and females and wanted to kill babies and children. Behavior changes on the ward were significant. The affect became much more appropriate and she developed a buddy relationship with another one of the female patients, a twelve year old girl. Her erratic, aggressive behavior towards younger children completely subsided; she became much more interested in doing activities with her friend and interacting with adult ward personnel. She began to see herself as more grown up and took pleasure in her new identity. She went to school and was able to function satisfactorily in that setting. Her changes were remarkable and she became quite functional and was no longer a management problem.

Stevie

This nine year old, very small boy had a total of thirteen sessions over a ten month period. Prior to treatment Stevie was extremely withdrawn and isolated and responded to no one. He vacillated between extreme catatonia and excited catatonic rage reactions. He would become assaultive and destructive and especially physically aggressive towards younger and more helpless children. During these times he had to be placed in camisole (full straight-jacket) and seclusion. He never spoke to anyone, made no eye contact and lived exclusively in his own world. What was unique about this boy's psychedelic experiences was his ability to enjoy sensory experiences that are commonly experienced by the normal person. During the first two hours he would delight in the visual and auditory experiences and constantly comment about what he was experiencing.

We soon discovered Stevie had an extensive vocabulary which he never used in his usual state. He would say such things as "the music is following the designs," he would laugh and say, "I love you, designs. Heart designs, ahhh, what a beautiful lady, a whole house full of changes." He rhythmically moved his body very gracefully to the music. He became extremely animated, smiling, sometimes giggling and appearing very much enchanted by his experiences. The long duration of this type of reaction was most unusual with these children. He would also become extremely quiet and peaceful, radiating a serene countenance that is witnessed when individuals are experiencing transcendental states. After the first few sessions he became very excited when told that he was going to have another session. He would run down to the treatment room and participate in preparing it by setting out the things that we would typically bring - fruit, cookies, flowers, pictures, record albums and so forth. When the room was set up he would take a wash cloth, dampen it with cool water, fold it and lay down on the couch and cover his eyes with it, a ritual we would frequently use in attempting to get patients to travel inwardly. He would then want the music started. He was acting like a typical normal person in preparing themselves for a session.

In the second phase he would exhibit intense turmoil, conflict, fear and agitation. He indulged in the entire gamut of behaviors and emotions, biting, spitting, profuse and prolonged swearing and extreme hyperactivity, destructiveness and total catatonic withdrawal. He would carry on extended dialogues between two or possibly more people, evidencing conflict between his mother, father and himself. There was a great deal of anal and genital content to his conversation, with endless repetitions about "shit, piss, penis, nasty, black BM, death, black hearts, throw up, black breasts, black diarrhea, chew it, afraid, burn it hurts." He would interrupt these dialogues by going to the bathroom, standing in front of the toilet, turning in a few circles and then urinating and when he ran out of urine he would continue this behavior twenty to twenty-five times. After an exhausting three to four hours he would appear very beaten up and would allow staff to sit with him, touch him and hold him, feed him and nurture him.

Touching moments would often occur with these small patients, near the end of one session a male sitter was sitting beside Stevie, holding his hand and Stevie opened his eyes and said, "Will you talk to me, David?," David said, "Yes Stevie" and after a moment said, "I don't know what to say?" to which Stevie replied, "Just talk to me with your eyes." This coming from a child who in his usual state was either catatonic or wildly destructive. Very often we had no idea how to interact with the children when they were obviously back in time wrestling with the demons of their pasts. They would be unaware of our presence and often the most we could do was to sit it out with them. Remarkable changes occurred with this boy. He started to relate to treatment staff and wanted to be touched and held. His manic and destructive behavior disappeared and he started relating to boys of his own age and older ones and struck up a bond with another boy on the program. They became good buddies. He became well enough to attend school and was able to function well in that setting. His parents were amazed at the changes and started to visit him and then began taking him home every weekend. He was very verbal, became very playful with the treatment staff and was behaving like a normal boy.

Floyd

This ten year old boy had a total of sixteen sessions over a period of eleven months. He had a history of extreme deprivation. His mother was an extremely agitated, narcissistic woman who made no effort to relate to him at all. For the first two years of his life, he was confined to a crib without any toys or any kind of stimulation. Prior to treatment he was constantly hyperactive and agitated, not wanting contact with others. He spent his days in the yard being completely involved in finding and looking at small bugs. When not in the yard he looked at two books which were about insects and bugs. When staff attempted to interact with him, he would only ask repetitive questions about bugs but was uninterested in any one responding to his questions. He appeared to be actively hallucinating much of the time. He would not carry on a verbal exchange.

In his first session Floyd had a remarkable response to the drug. Within thirty minutes he was obviously experiencing sensory changes and became relaxed and smiled a genuine human smile. His first words were, "What did you do with me? He's not dead yet." He looked at pictures in his book and said, "I'm not making it real, no I'm not." A staff member said "You're alive, aren't you?" to which he replied, "No, no, no, I can't be alive, this is too good." He looked back at the book and said, "Okay, it can't be, turn it off, turn it off, who's doing it." Looking at one of the staff he said, "Oh Judy, don't be real, don't be real." He touched another staff member, looked in his eyes and said, "Don't be real, don't be real, I've got to get out of here. I don't want to be alive, I am afraid of me, turn that off. Tom, don't be real. I'm not real no more. I'm blind. No, no, no, I can see." He then relaxed, looked at various staff members and said, "How come we are all the same?" He didn't ask this in an inquiring way but more as in a declarative way. He then drifted off, listening to the music and went into interior experiences. This lasted for some five hours. Finally, he started to become aware of his present time, became agitated and tense and started to cry, and sadly said, "I want outside." He kept repeating this phrase which we took to mean that the expanded experience he had was receding and he did not want to go back into his isolated world. This was a very painful time for the staff as well and we didn't know how to help him stay alive. This was a unique experience for us in that Floyd had such an immediate response and was able to leave his psychotic defensive posturing and experience himself as a real living being.

During the next session, a month later, there was a similar reaction to the drug. After he started experiencing sensory changes he asked, "Is it real? Is the music real?" then incredulously stated, "We're real, are the feelings doing it?" He was told that having feelings made life real. He then repeatedly asked, "Is it real?" to which we gave affirmation. He then drifted off and started smacking his lips and making lots of movements with his tongue and lips. He said, "I am with Mommy, Daddy is here too, why don't you love me?" His speech then became incoherent and he remained in this state for two hours. Finally he desperately started crying and said, "I want out. I want outside. I want out of here. Please, please, help me open the door, help me, help me, I'm real, I'm Floyd and I'm real. My own little boy." He then looked at staff and said, "Give me some more, please give me some more." We asked more of what and he replied, "Pills. Just give me some more, I want to get out." Staff told him that essentially he had to make himself real, that the pills let him know that he was real but that the pills wouldn't do it, that he had to do it. Floyd finally settled down out of this agitation and became very pensive and very, very sad looking. He went to a window, looked out and quietly said to himself, "Fountain View State Hospital. What a funny place to come back to." Obviously this was incredibly touching and the staff were tearful. The empathy we felt for him was deep, as we all had had the same feeling after coming out of a profound experience back to our usual normative reality.

The next four sessions were very similar to each other and markedly different from the earlier two. These sessions were characterized by his regression to earlier experiences where he had been physically abused and threatened. He repeatedly called the phrases, "I'll be good from now on. I'm sorry. I promise, don't hurt me, stop, stop, help me, help me." He frequently yelled, "Oh, oh, ouch, it hurts," and was physically trying to get away from being beaten. He would also have periods when he would attempt to strike out at the staff, smash himself against the wall and plead to be left alone. He was also very orally fixated and we gave him a baby bottle which he could suck, chew on and then violently fling away.

The seventh session was markedly different in that he did not appear to regress but rather stayed in contact with staff but became very belligerent, aggressive and sexually provocative. He would want to be cuddled by a female, rest his head on her breast and then make an aggressive biting gesture at her breast or suddenly start pounding her breast. He would also climb on a female, make undulating hip movements on her body and would attempt take his pants off. He would also approach a male, be sensual and want to be held and cuddled and then aggressively grab at the male's genitalia or scratch or bite his face. He would run around the room attempting to slap and punch everyone. He would growl and make guttural sounds, howl and become feral and aggressive.

The following three sessions were similar in many respects in that he acted out alternately oral aggression and his need to orally take in good things in the universe. At one time he took the author's fingers, sucked them, opened his mouth as wide as he could and attempted to swallow my hand. He put his hand on my elbow and pushed it in an attempt to eat my hand and arm. I said, "You are so empty you want to swallow me completely." His eyes became very wide and he vigorously nodded his head affirmatively acknowledging that's exactly what he wanted to do. He would also swing into seductive sexual behavior and alternate between being tender towards staff and then biting and trying to eat us. In subsequent sessions, he became obsessed with wanting to be taken to our homes. He would verbalize this precisely saying, "I am very unhappy here, I want to go to your home. I want you to take me to your house." Various staff would take him home after a session and he invariably was very calm, serene, extremely happy to be there and behaved admirably. He was affectionate, ate well, went to bed when told and evidenced none of his hyperactive, anxiety-ridden behavior. He also totally abandoned all preoccupation with bugs and stopped asking endless, meaningless questions.

After a number of these home visits a lot of Floyd's session time was spent in trying to convince staff to let him live with them permanently. He started to attend school and was also able to function well in that setting. He developed a positive relationship with his teacher and developed intense relationships with three of the treatment staff and wanted to dominate their time. However, when they were with other patients he did not become aggressive to the other patients as he had earlier but patiently waited his turn. It was very painful for staff not to be able to meet all of his needs. He did start to relate to other children his age and had meaningful interaction with another boy his age but always preferred to be with the attending staff. His withdrawn, isolated behavior never reoccurred. He attended school and was well behaved on the ward, always looking out for staff to be with and to talk to.

Nancy

This eleven year old girl was the most difficult and challenging person we treated. When first introduced to me, she was in complete restraints twenty-four hours a day. She was in full camisole and her legs were tied to the bed. This was necessary due to her extreme self destructive behavior. If her hands were free, she would gouge out her eyes, hit herself in the head as hard as possible, bite her fingers, tear out her tongue. She was totally emaciated, covered with swellings and bruises, black eyes in sunken sockets. She was incontinent and refused to eat. She was IV fed, she looked like a beaten up, starved, wild, eighty year old woman. She made no eye contact, did not respond to any physical stimuli, attempted to make guttural noises and spit, but unsuccessfully, as she was so exhausted. The attending physician felt that she would probably die. All known drugs had been tried. It was frightening to treat her with LSD, as my concern was her extremely frail physical condition and that she might die during a session.

Nancy was to be our first patient to treat and the physician's attitude was essentially that she was going to die anyway so we may as well attempt LSD as nothing else was available. I was fearful that this would be our first and last LSD session. She was given 200 micrograms of LSD. The session was very long and tumultuous. After thirty minutes she started intense screaming. She briefly stopped, muttered very softly, "I'm sorry" and went back to screaming. She looked Petrified, made rocking motions, furtively looking around as though she were trying to avoid being attacked. She began to verbalize "Gary, hold on tight, hold on tight, hold me." She would scream, "Mummy, ow, oh, hurt, oh." She would go in and out of contact with her surroundings. She remained extremely agitated and frightened, alternating vehement screaming with animal growling. After about seven hours of this violent behavior and screaming, out of exasperation and exhaustion I said to her, "How long are you going to scream?" She stopped flailing about, became very quiet and still, looked at me very directly in the eyes and said very quietly, "I am going to have to hurt for a very long time, so just leave me alone." She then proceeded to flail around, resuming her screaming.

In the following session she was markedly different. She developed a voracious appetite, was very talkative with the staff and required no restraints. As she went by the dining room she stopped, looked in and said with amazement, "My God look at that, they're eating, that's nice." She then regally flourished her hand and said, "Let them eat." Later in the day she told one of the staff, "We went to see Dr. Fisher, Gary, didn't we? I had a camisole test. It was good." The next session, a week later, she was looking forward to the session, telling me in the early morning, "Let's get the test now." She was much more verbal and a great majority of the time was spent in regressing back to conflict with her grandfather. It was obvious she was reliving a sexual trauma, wailing and screaming, "No Grandpa, no, I can't stay like this. I can't do it, hurt Grandpa, hurt, bye Grandpa bye, I don't have to." She would moan and wail. She then began to attack herself and had to be restrained.

The following few sessions were characterized by extreme conflict over pleasure and pain, much of it sexual in nature. In her regressions she would evidence marked sensual/sexual pleasure, laughing, giggling and saying "Don't do it. Oh Honey, no fair. Oh Honey let go, let go. They will kill us. No more. Love me, love me." She would then alternate to fear and anguish, become agitated, start lashing out at herself. When physically held by staff she would bite, spit, claw and scratch at them. This alternation between indulgence and conflict went on hour after hour.

After five sessions, Nancy's ward behavior was totally different. She wanted lots of interaction with the treatment staff, became very demanding of attention and was jealous of other children getting attention. She became bossy, started ordering other children around and took on an "I'm in charge here" attitude. She wasn't hurtful to them, only making it clear that they were inferior and that she knew what was best for everyone. When another child was going to have a session, she would attempt to maneuver her way to the treatment room and when removed became verbally, but not physically, angry. When told one day that she couldn't have a "test" (her word for the session) whenever she wanted it, she said, "Oh, then let's talk. Let's go down to the visitor's room (where sessions were held) and talk." Once there she would lay down on the couch, close her eyes and tell us to be quiet. I went over, pulled her up and sat her in my usual chair and I lay down on the couch. She got quite indignant and told me, "You don't need help, I do. I want the test." She began evidencing behavior which indicated she considered having a session a privilege. She went on her best behavior when informed she was going to have the next session - helping other children, being polite and neat, smiling and being very charming. Prior to her seventh session one of the ward staff, Van, asked her what she was going to see during her next "test," she replied, "God and Van." He laughed and asked her how she could tell the difference. Very seriously she replied, "I'll show you. You'll be there and I'll show you." Van asked, "Where will that be?" She replied incredulously, "Why, in the visitor's room. That is the only place you can see God."

During the next few sessions, Nancy's behavior became quiet, she was always wanting to be in physical contact with one of the staff and especially with one of the males. She would pet and stroke his arm, softly caress his face, smile and sing softly. She wanted to be cuddled and not interrupted in her pleasure. Coming out of the session was usually stressful, she would cry and occasionally revert to soft biting. When told she couldn't bite, she would lick and kiss.

After five months of treatment the focus became on her self-destructive behavior. It was felt that she was no longer psychotic and was using her hitting herself as a way of manipulating and controlling staff for whatever she happened to want at that moment. This was a sure way of getting attention, it was very clear that she wanted to be the sole focus of staff's love, attention and care. We decided that everytime she hit herself we would pinch her, step on her toes, and if we were outside, grab her and run her until she was exhausted. She was extremely indignant about this and gave up most of her self-destructive behavior. One day in a fit of pique she said, "Well I can't fool the A.M. staff anymore but I can still fool the P.M. staff." I looked at her directly and her mouth dropped open as in, "Oh, oh, I shouldn't have given that one away." That evening I met with the P.M. staff, made Nancy sit in the meeting, told them what she had said and clearly outlined how they all had to behave, just like the A.M. staff. She looked daggers at me but she knew that she had been nailed. She then took to placing small pieces of paper on her hands, telling us that the paper prevented her from hitting herself. When we saw her with a piece of paper we would go over and knock it out of her hand and dare her with our stares, to do anything about it. She would often mutter, "God damn" and either pick the paper up or walk away. She then gave up the paper and started to carry kleenex around with her. When we would see this kleenex she would say, "Oh, I've got a cough" or "My nose is running and I need it," we would just look at her and mutter, "oh yea, I bet" and look at her with a message "How dumb do you think I am?" Soon she gave up the Kleenex routine.

The staff person who was primarily working with Nancy left at the end of the fifth month and she was badly shaken by his departure. Her response was amazingly mature, she became depressed, sad and mournful and cried a great deal. She did not act out against herself or others. Another male student from the treatment staff, whom she knew well, took his place and she was grateful for his attention. She would become frustrated at her lack of sufficient language in trying to describe her feelings to him. Sometimes she just held him and sobbed about her loss.

She began to attend school on half days and was able to adjust to the setting. It was hard for her to share adult attention and other children her age did not have her sophistication. She was very bright and didn't miss a thing. She had become affectionate and warm, loved to be physically touched, and smiled happily a great deal of the time. She had given up her self-destructive behavior and wanted to identify with the treatment staff and to be included in the grown-up world. Unfortunately she was often bored because there was a gross lack of stimulation available for her in the ward setting.

Jeannie

Jeannie was a girl who, when initially seen, lived in a totally encapsulated world. Her behavior consisted of hyperactive twirling, yelling a meaningless "word-salad," screaming, and violent attacks towards anyone who came within her personal space. She would work herself up into such manic frenzy that she would collapse in physical exhaustion. During her treatment course with psychedelic therapy Jeannie experienced a number of transcendental phenomena which established the core recovery from her psychosis.

In spite of being blind, burdened with congenital dislocation of hips and knees and raised by a completely psychotic mother, this girl overcame horrendous madness in a devastatingly sterile and chaotic environment of a state hospital ward, to become one of the most tender, loving, compassionate and courageous persons the author has ever known. If Jeannie had had the opportunity to continue her sessions in a benign, safe and nurturing environment, she would have become a functionally superior human being. Our experience with this one girl was all the proof that was needed to attest to the dramatic usefulness of psychedelic drugs in treating the most seemingly intractable psychotic states.

It is most noteworthy to report that at least four of the children had identifiable transcendental experiences and were capable of communicating such experiences to us. It may be that some of the other children had similar experiences but were unable to communicate to us. However, given the age and degree of psychopathology of these children we were amazed that these spiritual experiences occurred.

The Work Ends

Our work was cut short by the political climate that developed after LSD hit the streets. Our project was closed down very quickly in mid 1963 and the staff associated with the project soon left. The abandonment of these children was an extremely painful experience for all of us. We were very surprised and touched with how supportive and accepting the children were of our departure when we said our good-byes. A follow-up was attempted ten years later but proved to be futile. The administration of the hospital was extremely agitated that the media would learn that LSD therapy was done there in the early sixties, as in the early seventies the political landscape around LSD was still very volatile.

To separate out the contribution of the drugs from our intense, devoted and caring commitment to these children was not an issue with which we struggled, although it was an issue often raised by other professionals. The author had worked for over four years with psychotic children in these same settings without drugs with very minimal success. The psychiatric technicians on staff had worked with these same children for many years, again without any significant results. It is only through personal experience with these compounds does one appreciate the potential they offer. However, a strong cautionary word is offered. These materials are so potent that a person interested in using them must have very clear his intention and needs to have guides attend him who are experienced travelers in the realms of consciousness that are unfolded and revealed. We used to say that the most important ingredient in LSD was the person taking it. The second most important ingredient is the guide who sits with that person.

One issue that is generally not addressed in the literature is the vulnerability the psychedelic therapist feels which is inherent in this work. Often included in the expanded state of awareness achieved by the drug-taker is intimate knowledge of the therapist and his state of grace - or lack thereof. The therapist cannot hide from being "seen." Experienced therapists know this well (and hence the emergence of counter-transference) and one's vulnerability is total when sitting with a psychedelic voyager. We had not anticipated this phenomenon to occur with these children as they all appeared to be so disturbed and out of contact with "reality." We were amazed when, in sessions, they would tease us by mimicking us, sorely hitting our most vulnerable and protected spots. Happily, this was done with compassion, humor and acceptance, but nevertheless we got the message. Our humanity and humility were often tested and we were stunned by the children's perceptiveness and their ability to embrace us in our shame - we had so much and they had so little.

Acknowledgment

Invaluable work of the dedicated treatment staff is gratefully acknowledged: Con Cowan, Dave Dion, Bob Haynes, Phyllis Mesker, Tom Parsons, Ethel Pett, Suni Strom. The donation of LSD and psilocybin for the study by Sandoz Pharmaceuticals is also gratefully acknowledged.

Introduction

This paper is a description of a psychotic child's experiences with psychedelic drugs and some judgments as to what these experiences were about. We believe that there was considerable value in utilizing these psychedelic drugs in the psychotherapeutic, treatment of this child who was schizophrenic. Our position is not one of simple broad endorsement of LSD and other psychedelics in the treatment of children grouped in this classification. If there is anything to be learned from this treatment attempt it is that little of what may be called health or growth can occur without intimate and honest relationships between people. The drugs were, however, in our judgment, of extreme importance in making the psychotherapeutic experience.

The hypothesis used in the research and treatment program involving Jeannie and eleven other children diagnosed as childhood schizophrenics is that psychosis is a massive defensive system of repression-avoidance-denial in the service of protecting the individual from experiencing his feelings. The experiences which have aroused such painful and frightening feelings are repressed and the feelings denied existence. The tendency to deny and to defend generalizes to more and more stimuli such that a great part of all experience is either denied or misinterpreted to fit delusional explanations of experiences. The individual exists isolated in a world of no feeling and meaninglessness and this renders him unable to meet social expectations and to relate with other people. The individual has committed psychological suicide - he lives but in the solution of massive retreat he has virtually died.

The rationale behind the use of psychedelic agents with psychotic children was that these drugs have the capacity to activate or chemically energize various areas of the brain to an extreme degree resulting in vivid experiencing in the area of perception, emotion, memory and feeling. In addition, these agents seem to inhibit the higher brain centers which are considered responsible for such functions as inhibition, intellectual abstractions and cognition. The psychedelic drugs tend to release experiences of phenomena normally repressed or denied or not considered essential in meeting the demands of one's own and others' egos. Experiences and feelings ordinarily denied awareness receive proportionately more energy causing them to break into a statue of consciousness which is less strongly dominated by the usual defenses and values which one has developed. Without the usual complicated defensive structures and censures, the individual is able to re-experience himself in a far less distorted way and to re-evaluate the worthiness of his essential self.

The Setting

The present case is a report of one of twelve autistic and schizophrenic children who were experimentally treated with lysergic acid diethylamide and psilocybin in a research study which began in early 1962 and terminated in mid-1963. The setting was a large state institution for the mentally retarded and the population included many severely emotionally disturbed children. All the children in the study were on one ward, a ward which housed some sixty acutely psychotic and behavior problem children and young adolescents. All the children were management problems and the atmosphere of the ward could be described as constant pandemonium. There were all the usual problems of a large state institution-inadequate staff, high staff turnover, overcrowding, insufficient clothing and laundry problems, constant and inadequate physical repairs and the constant need of medical attention because of the hyperactive, destructive and assaultive nature of the children. The ward was bleak and barren as it was impossible to maintain any furnishings due to the wanton destructiveness. As well as the hyperactive, screaming, assaultive, feces-smearing children, there were of course the severely withdrawn, totally autistic children who seldom moved and who lay dotted throughout the ward. An atmosphere little conducive to stimulating mental health.

The Treatment Team and Approach

The writer acted as the head of the treatment team and the ward psychiatrist was the responsible physician. Since none of the staff had any previous experience with psycholytic treatment, the first phase of the program was to train the staff. This consisted of having them become familiar with the then-available literature, having extensive group discussions on the nature and philosophy of the psychedelic experience and then having one (and on occasion, two) psychedelic treatment session themselves. This session was followed up by both individual and group meetings. Consequently there developed a team of co-therapists who worked together closely, intimately, and with amazingly little friction. The team consisted of one nurse, three nurses' aides, and four graduate students in psychology. A detailed account of the development of the treatment approach cannot be given here. However, at the time of the study we had no prior knowledge of effective techniques to utilize with this patient population and consequently we tried various techniques. In our initial sessions we utilized techniques which had proven successful with alcoholics (e.g., Chevelos and Blewett, 1959) but soon discovered that we had to become much more active in the treatment, utilizing interpretation, role playing, and very directive measures. Because the treatment sessions were often excessively long (some lasting to fifteen hours) and often physically arduous and exhausting, we utilized multiple therapists. About midway in the research program we decided to intensely treat the six most responsive of the patients and one team member was assigned as responsible therapist for that child, being assisted by other staff members in the actual treatment sessions. In some very difficulty sessions, we would "go through" (or wear out) all six or seven of the treatment team members.

The Patient

The patient is a twelve year old girl who was diagnosed as a childhood schizophrenic. She was born prematurely after a seven month pregnancy. Birth weight was two pounds, thirteen ounces. Retrolental fibroplasia was diagnosed early as was a congenital dislocation of the hips and knees and a congenital heart murmur. Her early development was slow - she held her head up and sat alone at six months and walked at four years. Single words were spoken at nine months but shortly after this time she discontinued speech until four years. At age three she broke her collar bone and at age five she suffered a head injury from a fall down a flight of stairs. At age five she was hospitalized for a "nervous breakdown," the record showing no details of this episode. From age five on she was,taken to several hospitals, institutions and clinics and was given a variety of diagnoses including CNS pathology, childhood schizophrenia, mental retardation, severe emotional disturbance and severe brain injury from birth. Her behavior from age six, as described by these various diagnostic centers, was characterized as being bizarre, grossly regressive, retarded, hyperactive, assaultive, erratic and destructive. She never attended school because of her severe disturbance although special classes were attempted unsuccessfully at age seven.

She was evaluated for state institutionalization at age ten and was described as indulging in loud screaming, wild jumping about, impersonating a baby through a doll she carried and involving herself in a hectic interplay of scolding with the doll. The intake worker described the patient as reaching a state of physical exhaustion caused by her constant hyperactivity. It was not possible to obtain the patient's cooperation on any examination or testing procedures. She was admitted to the institution seven months later, at age eleven.

Jeannie's mother had her first psychotic episode eight years prior to Jeannie's birth, and presumably following her husband's accidental death. She has had several miscarriages and only two successful deliveries, the patient and a boy who was born when Jeannie was five years old (the age at which she was hospitalized for a nervous breakdown). The brother died at age three years due to strangulation following an acute bronchial disorder. The mother has had several hospitalizations for paranoid schizophrenia since Jeannie's birth and has had extensive somatic treatment (ECT and IST). The father is a career Army officer and reportedly seen as a stable individual.

Hospital treatment for Jeannie had consisted of a number of drugs and a series of ten ECT treatments, none of which had resulted in any improvement.

When Jeannie was seen for evaluation for psycholytic treatment, she was acutely psychotic and had virtually no contact with anyone. She was a rather large girl for her twelve years, quite blind, apparently only able to see very little when she held an object within a couple of inches of one eye. When she moved, she bounded, with a pronounced lurch and limp and it was amazing she had as few fall and crashes as she did. Her hair was rather long, oily and stringy and her skin was covered with severe acne. She always appeared dishevelled and was quite an ugly sight. Her typical day was spent sitting in a corner of the ward with two major activities, one was protecting herself from the assaults of other children and the second was twirling bits of paper in her long fingers, constantly rocking herself, masturbating, and talking word-salad almost incessantly. When other children would come within range she somehow detected them and swung out with her arm to hopefully knock,them flying. If a child would be too persistent in his attack, she would resort to screaming belligerently and make some greater effort to locate him and physically assault him. At times she had a transistor radio which she held right against her ear. However, the radio never functioned too often. She apparently was having hallucinatory experiences, mostly auditory although it was difficult to specify the girl's experiences. She repeatedly talked of riddles and her phrases were often meaningless - when spoken to she would often repeat the last few words of the examiner or else ignore him. On one occasion she said that Tide means "to live," Fels Naptha means "to die" and Blue Cheer means "sick." She often was seen to shout at unseen persons and become distressed by them. She often used a number of pitches in her voice in order to carry on conversations among a number of people although these conversations lacked continuity or meaning. She was able to feed herself, toilet herself and dress herself.

Psychedelic Treatment Regimen			
Treatment No.	*Date*	*Days betweeen Sessions*	*Drugs Utilized*
1	7-24-62		100 mcg. LSD
2	10-2-62	70	100 mcg. LSD
3	10-16-62	14	200 mcg. LSD
4	11-14-62	28	10 mg. Librium; 5 mg. Methedrine; 10 mg. Psilocybin; 200 mcg. LSD
5	12-3-62	18	10 mg. Librium; 5 mg. Methedrine; 300 mcg. LSD
6	1-7-63	35	200 mcg. LSD
7	1-21-63	14	300 mcg. LSD
8	2-4-63	14	10 mg. Psilocybin

15	5-22-63	9	25 mg. Librium; 200 mcg. LSD
16	6-24-63	33	200 mcg. LSD

Excerpts From Session Number One

(*J is patient; F is male therapist; S is female therapist.*)

9.30 a.m.: Drug administered.

9.50 a.m.: Drug appears to have taken effect. J is becoming giddy, silly and hyperactive; talks about the Scribble Head Riddle. J asks with profound seriousness, "How can you make me talk better?" Starts laughing, bounces on couch with great vigor; begins to hold her fingers close to her eyes, move her fingers and laugh and smile at her finger movements. Is becoming very hyperactive and finally yells, "Hold me, hold me," to which F responds by holding her very tightly.

10.20 a.m.: J is pinching and scratching F; F responds by returning the same treatment and J becomes very angry. J says, "My finger nails like you."

10.30 a.m.: J hyperactive and aggressive; F attempts to quietly hold her, reassures her and suggests that she relax and listen to the music. J continues to struggle and F is persistent in his attempting to quiet and soothe J, telling her repeatedly to lie down, relax and listen to the music. J finally gives up her bodily struggles, lies back and softly begins to sob. Her crying becomes more intense. While crying deeply she says, "I'm very sad; I want to go home." Her crying eases somewhat and she holds F and asks with intense feeling, "Why do you make me like this?" She again begins to sob and cry and is full of tremendous anguish and sorrow. She repeats, over and over again, "Leave me alone; leave me alone; leave me alone." This crying anguish with these words interspersed frequently, lasts for about one hour. She is emotionally exhausted.

11.30 a.m.: S enters room and J says, "Mommy," and then says therapist's name. J reaches out to S, holds her and sobs incessantly. She cries, "I'm afraid - I can't see. I'm afraid - I can't see." When J becomes extremely agitated she releases S and goes into a fetal position. This quietens her and she then returns to holding S and crying.

12.15 a.m.: Beginning to moan but appears more relaxed and less desperate. Begins to say, "Scribble Head Riddle." Begins to relax and rest although still crying, but softly.

12.30 p.m.: Beginning to move around again; some gentle pinching; moaning and groaning; says, "I don't feel good."

1.00 p.m.: Becoming much more agitated; begins to yell - no content, just yelling. Now crying in an aggressive manner. This starts a new sequence; she is becoming excited and angry; starts to scratch T's and after she has done so, bites her own hand; lies on her side and begins her first rocking movements; her speech now becoming disorganized and deteriorative; grabs towel and starts to stuff it into her mouth; rocks vigorously with towel stuffed in her mouth. She now gets up and moves about room; finds some food and gobbles it down; starts picking up any item and attempts to eat it; she demands food which we give her; eats voraciously. Gradually relaxes after eating. F sits with her and holds her quietly. F asks, "Why did you cry, J?" to which she replied, "Because my poor little mother made me."

Evaluation of Session No. 1

Attempts to prepare the patient for the experience were probably of no benefit as it was impossible to get her attention in any sustained way or to establish any communication. The first indication that she was having any reaction was an increase in motor and verbal behavior. She bounced around the couch, giggled and laughed, and appeared to be delighted and excited with perceptual changes. Her first words were, "How can you make me talk better?" This is the question to which J has returned so many times and the eventual understanding of its meaning has helped us a great deal in understanding her psychotic process. It appears that for J talking and thinking are one and the same, and she thinks if she could only organize her speech in a satisfactory, coherent or better way, she could then think coherently and thereby control the confusions she experiences. This is one reason why she is constantly talking and trying to master by voice imitation such significant persons or images as the baby, the child, the mother and the father; for it is these figures which cause her painful feelings. It is through organized speech and therefore organized thinking that J hopes she can understand and control her impulsive chaotic feelings. And it is her thinking that is a defense against these feelings which she cannot accept.

J's excitement with her new perceptual experiences progressively increased and she cried out, "Hold me, hold me," expressing her desire for physical contact and probably control over these new sensations. After an hour or so she became anxious, her movements and gestures became exaggerated with a restless driven quality and quickly mounted to hyperactive behavior. Later she scratched the therapists. J's hyperactive, behavior was a result of a preconscious awareness of overwhelming anger. Her hyperactive behavior served as a way of shaking her attention and deterring threatening wishes from becoming manifest and at the same time allowed her to release this tension in a less incriminating way. In later sessions J frequently expressed herself with hyperactive behavior and we were later able to confirm this as being both a defense against, and a released of, her aggressive feelings.

J was encouraged to lie down and listen to the music. She quieted down and began to cry with great anguish. She said, "I'm very sad; I want to go home." Her crying and grief continued periodically for more than four hours and the depth and the honesty of her self pity and anguish surpassed all our expectations for we did not anticipate that J would experience feelings so profoundly. She began referring to her mother and it appeared that she was re-encountering and struggling with this relationship. She asked F sobbingly, "Why do you make me like this?" and later cried out repeatedly, "Leave me alone, leave me alone." These sentences appeared not to refer to F but to her mother and communicated to us J's great burden of her mother - both the guilt she felt over her rage toward her mother and her desire that her mother release her. At these times, J's social conscience arose more powerfully than we would have guessed and engulfed her hostility causing her this experience of intense guilt and self pity. When the emotionality became exhausting, she assumed the fetal position and became quiet.

Later in the afternoon as the power of the drug receded, she again became hyperactive, scratched the therapists and then turned her aggression inwards and bit her own hand. Her speech regressed and deteriorated and she indulged intensively in oral activity. She stuffed a towel into her mouth and at other times tried to eat nearly everything in sight. This oral regressive behavior was interpreted as an attempt to do something about her tremendously unfulfilled oral needs. In the days following the session, some attempts were made to have J communicate about her experiences. The day following the session J told us that in her session she had visited the real Scribble Head Riddle and that the Scribble Head Riddle hated her mother and loved her father. Further, she said that the Scribble Head Riddle's mother was dead and then asked, "Is my mother dead?"

When asked where she had gone, she replied, "Into the dark." When asked if it was all dark, she said, "No, it was light too. The Scribble Head Riddle likes the light." She was able to discuss, with some appropriateness, parts of her session where she had laughed or cried and was able to be minimally reflective about those experiences. One week later she appeared to be better, the rocking movement which was almost constant had ceased. She seemed very anxious to talk but started to talk word-salad and "nonsense." When told that the therapist wanted to talk to her but would only talk about sensible things, she immediately stopped and asked, "What's sensible." When asked what she thought was sensible she began to name concrete items and topics. She then tried to make comments about items or topics. She asked what the word "relation" meant and then attempted to verbally categorize and specify relationships between items. Her speech and affect were noticeably improved and she demonstrated such a serious attempt to be sensible. She gave up her word-salad barrage and her constant reference to the Scribble Head Riddle. She very much wanted the contact with the therapist and was quite anxious to lean how to relate and talk to him.

Excerpts From Session Number Two

9.00 a.m.: Drug administered.

9.30 a.m.: J: "Will I lose my voice? Will my voice go away? I want my voice!" J is rolling around on couch, fairly agitated. She was assured she could keep her voice if she wanted to.

9.40 a.m.: "I feel retarded." J herself and the rest of us laugh as the tone was humorous. J: "I want a peanut butter sandwich." (Such sandwiches are the big treat on the ward.) J takes F's hand, holds it, feels it thoroughly and, the says, "Your hand feels retarded." Again J and staff laugh. She seems to be in a sophisticated humorous mood.

9.50 a.m.: J starts mimicing other patients' symptoms, including stereotypic and repetitive speech, hand movements, gesturing, posturing, etc. She does this in a rather light hearted, laughing and humorous manner, identifying the patients she is mimicing. (We are surprised that she knows all this as we had assumed she was too blind to see such phenomena and too withdrawn to observe or be interested in them.)

10.00 a.m.: J begins to kiss her own hands. This activity increases to kissing her arms. She appears to be becoming agitated. F asks, "What's happening, J?" to which she yells back, "Nothing!" She now begins to cry and as she becomes more sad, she starts kissing herself more frantically and as she kisses herself more, she sobs louder and deeper. She then starts moaning, "I'm a girl, I'm a girl." J begins to rub her face, mouth and head. She then holds her mouth open as wide as it will go and starts jamming her hands into her mouth - throughout all this activity she cries with great anguish and depth. She uses great force in getting her hands inside her mouth and staff is afraid she will injure herself. Female therapist (S) takes J into her arms and J clutches onto S and cries intensely. With great grief J cries, "I didn't do anything." F: "What did Mamma do?" J: "She left me." F: "Was it your fault she left you?" J yells, "Love, love love, love." F: "What was it you put into your mouth?" J: "Nothing, nothing." F: "What did you want?" J: "Food, food." F: "No one fed you." J: "I want to feed myself now." F: "Jeannie, you were never fed. Mamma never fed you. Now you want to gabble up the whole world. You're mad because you never got what you wanted." J yells, "No, no," and wildly lurches out to strike at F. After striking him, she looks shocked and says, "I'm sorry, I'm sorry," and strokes him. She then says, "I know," and F asks, "What?" and J replies, "Oh, ice cream bars, and everything." She then begins to cry again and her crying is full of anger, self pity and anguish.

11.00 a.m.: J seems quite distressed in a diffuse, agitated manner. F: "Why are you so unhappy?" J: "I'm not unhappy. I'm happy." F: "No, you're not happy. What happens when you don't like yourself?" J: "You die!" (with emphasis.) F: "Do you like it that way?" J: "No." F: "What can you do about it?" J: "Stay alive." F: "How can you come alive?" J: "I don't know. I don't know." At this point she returns to stuffing her hands into her mouth, pulling and probing, begins to cry. F: "What would you like to be?" J: "A boy and a girl." F: "Then what?" J: "Be sick." F: "Do people love you more when you're sick?" J: "Yeah, yeah." Again many minutes of wailing wand crying. J: "Boy, boy, boy." F: "Who wanted a boy?" J: Yells, "Nobody!" F: "Did they want a boy?" J: "Boy, boy, I'm a boy, I'm a boy. I want to be a boy." Now she becomes extremely agitated, starts lurching and screaming, "No, no." She continues this extreme agitation and yells, "I'm a girl, Mommy, I'm a girl. No, I'm a boy, I'm a boy. Mommy, mommy. I'm a girl, Mommy. No, no, mommy, I'm a boy." This repetitious material continues for some time. The therapists attempt to intervene and have J accept her mother's rejection of her. This appears to increase her agitation. She begins to becomes disorganized and her psychotic defenses begin to appear. She begins calling out ward numbers, begins to bang her fist on the wall, and stuff her hands into her mouth.

12.30 p.m.: Patient is yelling and screaming,. It is difficult to understand what she is saying. She laughs loudly and falsely. She attempts to cry but can't make it. She calls out, "Scribble Head Riddle, Scribble Head Riddle, I want to feel funny."

1.00 p.m.: Suddenly she stands up, throws her fist into the air and screams with anger, "Oh, I'll kill you, mother." F: "You want to kill mother." J: "No, no, no, I love my mother," and as she says this she smashes the wall fiercely with her fist. She then goes into a flurry of mumbling and ward naming which continues for some time. She is very agitated. After this, she begins to growl like an angry animal. She screams, "I want to stay alive." F: "Did you kill your mommy?" J: "I killed my mommy. The Scribble Head Riddle killed my mommy. Ward 33 killed my mommy. I'm 12 and I'm a ward. I want to kill ward 18. Ward 31 is God. Ward 14 is the Devil. I'm going to kill Ward 18's parents, and Ward 17's parents. Oh, I love Ward 3. I'm going to kill Ward 11's mother." She then became very quiet and very soft and says, "Ward 31 is God. I hate Ward 31. I love Ward 31. It's the Riddle, It's the Riddle." She then goes into a frenzy of activity and this continues for two and one-half hours. Finally she is becoming exhausted, as are the therapists - and 50 mg. of thorazine is administered IM which begins to quieten her. She rambles on incoherently for another hour, is fed, and put to bed and she goes to sleep.

Evaluation of Session No. 2

J was apprehensive at the beginning of the session and expressed serious concern over the possibility that LSD would change her voice or take it away entirely. This statement refers not only to her anxiety over losing her speech-thinking defense mechanisms, but also suggests that she was afraid of losing her only means of relating with others, for loss of speech to J also means total isolation.

We were rather amazed to see J's sense of humor - she was able to feel and relate in a very human way in,the beginning of the hour and it was quite startling to observe this. The bulk of the session was devoted to her conflict over being a girl and being rejected by her mother. She began to experience her rage against her mother but had tremendous difficulty in admitting to that rage. When she would begin to deny her rage she would immediately start indulging in her psychotic behavior. It was also of interest to get a hint of some of the meaning of the "Scribble Head Riddle." Part of that riddle has to do with her both loving and hating something, probably most notably her mother, at the same time. When commenting on this, her tone was one of quiet perplexity.

Excerpts From Session Number Three

9.00 a.m.: Drug administered.

9.30 a.m.: J is tense; she wants to talk to us but we insist she be quiet and listen to the music; she begins to cry and rub her hand on her forehead and mouth. She moans and sighs and is distraught - cries, kisses her hand and says, "I want to like myself" - repeats this numerous times. Occasionally she bounds off,the couch and smashes her fist against the wall.

10.00 a.m.: J: "I'm a girl, I'm a girl." Alternately cries and laughs. Growls and whines. Stuffs a rag into her mouth. Occasionally screams out "No!" When staff try to touch her, she withdraws and says, "No, leave me alone."

10.40 a.m.: J: "My chest feels like I'm the Scribble Head Riddle, I'm not! Hey, S, I want this to go away. I don't like it like this." She then begins to carry on one of her dual conversations about wards, then stops herself and says: "No, you're not supposed to talk like two persons. I'm not going to talk too much."

10.50 a.m.: "I'm well now. I feel different. I feel like a girl. S, please help me." S moves to her and takes her hand. J responds by trying to communicate with S. J: "A girl and a boy. S, is this different or is it the same? How come I have to be a girl? Why do I have to talk this way? Am I supposed to act this way? I'm gonna do just what I want when I feel this way. I have feelings and they're stupid. I guess I could get out of bed for awhile. I'm just not gonna talk two persons any more." J holds S closely and with great affection, kisses her occasionally. Her speech is slow and soft, not driven and harsh as is usual. J appears to go into a reverie-like state which is characterized by calmness. J: "I want to be the mother. Why do I feel this way, S? I'm gonna be a mother. I have a good mouth. I grow back into a girl now, S. Let me try and do something different.. Now, love, that's me and S loving each other. I feel so good. I can't make things start over again." She now becomes very soft and gentle, speaks as though she is speaking gently to herself - "I could feel this way if I like. I love to get along with people. I'm a girl and a good one. I'm making the things I'm not supposed to feel, feel this way. Oh, I feel like I'm supposed to feel! I'm not going to do what I did last time! I feel like I'm a new baby. Turn on the gas - no, no - I didn't mean that (a little agitated). I feel different. I feel good and I can help other people too. Oh, I wish I was sick." F asks: "What's bad?" J: "I feel good." F: "Is there such a thing as bad?" J. "No!" (with great emphasis.) She then laughs and asked: "Would it feel good if I died?" to which S replied, "Yes." J: "I want to die." J then laid down with a deep sigh, closed her eyes, relaxed and stopped talking. She becomes extremely peaceful looking and maintains this state for about twenty minutes. She then mutters softly, "Yeah, this is it, this is it." She strokes S's hand softly and smiles, and says, "I'm a girl." Her expression is positively beatific. She takes S's head in her hands and whispers, "I love you." There is a remarkable grace to her hand and body movements. F: "Did you get to die?" J: "Yes, and I came back alive, see?" Ten minutes later she said, "That's the way it's supposed to be. I can be anything I want." She then becomes quiet and repeats the word "See?" in a questioning manner, to mean "You see, now do you understand."

1.00 p.m.: J begins to talk about good and bad wards - a flurry of rambling speech - in the middle of this she suddenly stops and says, "I want to die again." She then appears to become a little anxious and says, "I can do anything I want to do. See, I'm a good girl." F: "Let's be bad for awhile." J: "Why? I'm a good girl." Appears to be a little agitated with this suggestion. J: "Shall I die? It's fun." D: "What do you want?" J: "To be a good girl." D: "What does that mean?" J: "To get along with everyone." D: "What would happen if you didn't get along with someone." J: "I'd die." Later J says, "Scribble Head's mother is dead," and proceeds to go into an autistic discussion of all the wards in the hospital. She then becomes agitated, talks intermittently about being good or bad and about whether she is a boy or a girl. She proceeds on this track and our attempts at intervention are to no avail.

Evaluation of Session No. 3

In this session, J reached a state of deep acceptance and experienced profound feelings of love and personal integration. At the beginning of the session she was visibly tense and less talkative than usual. There was an almost grave aspect to her feeling tone in contrast to her usual loose, uninhibited and inappropriate behavior. Soon after taking the drug she tried to engage us in conversation but we thwarted these attempts viewing them as a method of hanging on to the world she knows and her defensive psychotic posturing. For two hours, J quietly cried and smiled, engaged in familiar oral activity, expressed anger and kissed herself. Then her feeling tone changed. She became happy, relaxed and full of warmth - she appeared to be overwhelmed with feelings of compassion and love for herself and for us. J was expressing wonder and delight and her voice was relaxed and her words spoken softly and slowly as contrasted witch her usual rapid tense mode of speech. Her warmth of feeling increased dramatically, and she reacted to these feelings and physically and verbally expressed love for herself and for S. She has never behaved this way before. We interpret much of what she said to mean that she was experiencing feelings of love and acceptance for the first time and she was quite amazed at this. Her fear had always been that would annihilate herself and others if she expressed her feelings because the primary feelings that she knew at some level were her tremendously angry ones. We felt that she had been able to achieve a significant state of self-acceptance and love during this session. Her whole manner, speech, feeling tone, bodily movements and appearance was one of profound self-acceptance and peace. This was a very dramatic experience to observe and was very similar to experiences observed, during psychedelic states, with mature and stable adults.

Later in the day she became very much involved with good and bad; and then we asked her to try being bad for a while. She seemed to become anxious at this suggestion and repeated that she had to get along with everyone and than she wasn't so bad. Her anxiety increased and she began a discussion of what one should or should not do; she became increasingly anxious and attempted to define and control her experiences and feelings in the context of good or bad.

After the session, pronounced and quite sudden changes occurred in her behavior and perceptions of her world. Her entire delusional system solidified into an absolute clear-cut dichotomy of good and bad and their respective proponents, God and the Devil. God was good and stood for every socially acceptable value J had ever heard of. He told her to help the staff, to love everyone, not to talk crazy and to do what she was supposed to do, which, as far as we could determine, meant doing what everyone told her to do, staff as well as every patient. She saw the Devil pretty much as an evil temptor who, if she did not resist him, was somehow able to make her do bad things, such as break windows, say bad words, hit other children, scream and yell, get mad, roll her head on the bench and so on. J was never at a loss to tell us how she hated the Devil, which in truth was the strongest part of her. It appeared that in one dramatic act J had chopped her self in half trying to affirm the good, the socially acceptable and the "should" while denying her tremendous anger and antisocial impulses, projecting them to an external force, the Devil. Actually the good was also externalized, for a J told us herself, she was not good unless every one thought she was good. She had reduced herself to a mechanism capable of certain responses which hopefully would elicit reward and approval from others. There was very little Jeannie Drake involved at all. She vehemently emphasized that if someone, any one in the world, did not love her, she would kill herself, choke herself, turn on the gas and die, tear off her spout (vagina), rip open her stomach, etc. Needless to say, her behavior was painstakingly and horribly good. In the battle between her hostility and her cruel, immature conscience (based on her fantasies of mother and her inability to accept the fact of an unloving mother) her conscience was victorious because she so needed mother's love to verify that she herself was worthy. She was incessantly besieged with feelings of worthlessness and evil and directed her death wishes onto herself while at the same time trying to find a way to get out from under the superego's relentless attack. Thinking that she was evil, she attempted to eradicate all traces of herself as a person and externalize her battle between good and evil to God and the Devil. She took a totally passive attitude and was at the mercy of the world. Everyone in the world stood in judgment of her and she undertook the most tremendous task of all, a control of the world. She had to control everyone's attitude towards her. The slightest kind of disapproval from anyone excited feelings of such failure and worthlessness that she wanted to die. At the same time, the expression of hostility on the part of other patients launched her into a frenzy for this caused her to experience dreadful impulses to aggress which threatened the betrayal of her delusional system, thus setting up her ultimate destruction.

We viewed this "personality adjustment" favorably and as a change which included more of reality than she could previously recognize. In part she was attempting to isolate her rage and to become socialized. She did realize that her day to day behavior had something to do with her being where she was psychologically and environmentally, and she started to take initiative in helping around the ward. A couple of weeks later she established a consistent and friendly relationship witch a female patient a few years younger than herself. This attempt to "adjust" on her part was a courageous effort to again face reality, and attempt to understand something in life and to establish a new spot for herself. If she did express any hostility, she blamed it on the Devil. (Later we realized that in her fantasy life she gained "a lot of satisfaction by having the Devil and the Scribble Head Riddle "kill people's parents." She would then "bring them back alive" and would thus maintain an immaculate image of herself.)

Session No. 4

During the initial phases of this session J experienced genuine grief and sorrow and cried. In response to these feelings she frequently extended her arms upwards and said she wanted " to go up" and "Ito go up there, to heaven" which meant that she did not want to experience her sorrow but wanted only feelings of comfort and happiness. She further verbalized this desire by saying, "I am trying to kill hell," and "I am trying to love myself." She then began to devote her time to bring about pleasant and good feelings through the use of her voice and intellect. She repeated hundreds of times, "I am trying to find out why" and "I am trying to make me love myself." She was caught up in such perseverative patterns off and on for the rest of the day. At the end of the day she became very violent and tried to choke herself and others and had to be restrained.

Session No. 5

In this session J was completely unable to tolerate any affect induced by arousal of unconscious material and drove herself into an acute psychotic state involving perseverative manic-like verbal defense and frenzied motor activity. It was impossible to make ourselves known to her and she was completely out of control and encapsulated and isolated by her defense. An additional dosage of 100 mcg. LSD around noon served only to intensify the ongoing reaction.

Session No. 6

During she initial phases of this session J talked much as she had before, saying tat she was going to try to love herself and learn things. She appeared to be looking forward to this experience and was extremely anxious to cooperate. It was important for her to follow our instructions and she seemed to feel that we could help her. All this behavior had been J's way of relating to everyone ever since her third session. What was significant for us was that during the session when she began to get anxious and talked in a defensive manner she would stop herself and say, "No, I'm supposed to lie down and listen;to the music," and would do just that. One might argue that we were only reinforcing and encouraging her "be good" game but we feel that her ability to resist her usual defensive methods even for someone else was excellent progress for her. After the first hour she remained quiet and still for almost three hours. It appeared that she was allowing herself new experiences. She laughed loudly and with genuine gusto, which we had never seen her do before, and for long periods of time she simply appeared very relaxed, calm, quiet and happy. During the latter phases of she session her compulsive controls reemerged and she was anxious and agitated. We felt,that this appeared to be provoked by her difficulty in reentering her more usual state of consciousness. We felt that it was quite significant that she was able to cooperate with the therapists, follow our directions to become quiet, to listen to the music and to learn, and that she was able to surrender these defenses and allow herself new experiences.

The quality of the quietness of the session was also significant in that this type of behavior usually indicates that the individual is exploring internal phenomena, and the quality of the session was in marked contrast to the two previous ones wherein she was extremely defensive and psychotic.

Session No. 7

Throughout most of the morning J was relaxed and content to remain quiet and still. The few times she did speak she launched into a typical discussion of good and bad, God and the Devil. Some two hours later she began referring to apparently traumatic sexual oral events to which she had alluded from tie to time. Although this material was not made precise, it appeared that she had been subjected to forced oral copulation. She appeared to be choking and then spitting vehemently. In addition she moved so as to try to remove her mouth from some presenting object. We directly interpreted the symbolism she presented in this connection but we received little response from her. Soon after this, however, she became anxious and told us "I am trying to think."

In the afternoon her perseverative behavior dwindled and she began to whine and plead apologetically which grew to great and genuine grief over "killing" people. It seemed that she had been confronted with her hostility and death wishes and that these wishes had come true for her. Thus, she was forced to abandon her denial of hostile wishes and was now suffering the consequences. This to us was an important step forward for her. We attempted to communicate to her that she need not be ashamed of her wishes and that in truth she had killed no one. She did not respond to this "support" and continued to grieve and crucify herself for these murderous deeds.

Significantly, she identified these wishes with the past and was unable to accept that these wishes still existed. She begged for forgiveness and pleaded, "Hurry, mother, come back alive," and would deny the existence of any hostility at the present time. However, we felt that this session was a significant one for her.

Sessions 8, 9 and 10

J's 8th, 9th and 10th sessions were quite different from those previous ones and were so similar that they can be described together. In general she remained quiet and still, spoke only when spoken to and experienced little anxiety at any time. We were somewhat dismayed over this change and wondered if perhaps she had found a way to shut off the drug effects and prevent herself from getting herself involved in any significant material. Yet the absence of any defensive behavior suggested that she was having little difficulty tolerating her experiences, whatever they were, and thins was encouraging. The specific content that did emerge was related to her relationship with her mother. She discussed, rather quietly, that it was not good to get mad at her mother and how sorry she would be if her mother got hurt. In describing mother, J said, "Mother is crying, mother is mad, mother thinks I'm lying, mother is crazy." She said that if she hated her mother, she herself would die. She was able to talk about her mother's threat to leave her and the ambivalence she felt about it. She also said that she wanted to leave her mother, but that would be a terrible thing to do. She continued to deny her mother's rejection of her saying tat if she died, then her mother would die, because her mother loved her so much. At one time J said, "I hate my mother when she cries and gets mad at me." D: "Tell her that." J: "Mother, I want to tell you something.... No, I don't, mother, I love you." In retrospect, it appeared that she had indeed done some productive working through for in her 11th session there was a significant breakthrough in her defensive maneuvers and she experienced freedom.

During the month in which thee three sessions occurred she was more quiet, demonstrated little hyperactive behavior, head rolling or bizarre behavior. She sat quietly by herself and very infrequently indulged in her perseverative speech patterns.

Session No. 11

J lay quietly for some three hours and appeared to be experiencing more pleasure and delight than she had since her third session some five months previously. At about noon she appeared very much in contact with her surroundings and still very accepting of her experiences. We began to communicate to her our interpretation of her delusions. She made no remarkable response to these interpretations so we stopped. Soon, however, she began spontaneously to verbalize and we suddenly witnessed her description of the destruction of her psychotic world. J: (in a loud booming voice) "I love the Devil! I am the real Devil and I am the real Scribble Head Riddle! The Devil and the Scribble Head Riddle are my imagination and I am really the Devil and the Scribble Head Riddle!" She stood up and walked around the room, laughing in amazement and continued to say, "I've been bad and I don't care. I.think it is just great." She repeated, ''I think it is just great," at least fifty times. She reenacted many past scenes with her mother, taking both parts. Taking the part of mother, she would whine and say, "Jeannie, are you being a good girl?"and in a booming response, J would yell, "Hell, no, hell, no hell no!" She told us she could say all the bad words she wanted to and proceeded to do so with great passion. She began to toy with her fear of death as reprisal for the expression of her feelings. She said, "I hate mother and God and everybody," and then dramatically fell to the floor as if struck dead and,then leapt back,to her feet, announcing, "I have just died and I don't care and this is just great!" Many times she compulsively repeated the sequency of expression of hostility, death, and the rebirth. Finally, she said, "Let's not have any more of this goody, goody stuff." On several occasions she berated the staff and imitated us in humorous and unflattering ways.

This type of material went on for four hours. Near the end of the day she began mentioning concern over her "good things" and pretended to carry,them about in her hand asking for a safe place to keep them. When questioned as to what these good things were, she stated tat they were the nice things that happened to her, the good feelings she had, and the future. From what we surmised, her good things were her insights which she wanted to salvage from the wreckage of her good and bad world. Perhaps the destruction of that which she had previously tried to maintain caused her to feel there was little with which she could start over. We assured her that her good things would not leave her, only her useless, crazy things but she remained in doubt over thins matter. We took her back to)the ward early win the evening-she was a tired, dazed and happy girl clutching her "good things,." It is an understatement to say we felt a lot had been accomplished.

The next day she was extremely anxious to talk, and we talked to her about her session. She knew that we knew all about her and she was happy. Still she made some feeble references to the Devil, but laughed when we reminded her of events in her session. She laughed with great warmth and genuineness, saying, 'The Devil and the Scribble Head Riddle-yeah, they're me alright!" It appeared that on a very superficial level she wanted to continue with her old ways, but at a deeper level, however, she was ready to drop her psychosis and learn something new.

Sessions No. 12

This session was almost entirely spent in J's reenacting out traumatic events with her mother. This included many scenes which were painful for J and she compulsively and repetitiously went through them, perhaps trying to abreact all the affect out of these events. Her affect would change as she repeated these events and often she would go through one in a light-hearted and humorous manner. When she had finished with one scene, she would start another different one. She also spent considerable time being mischievous and bad and she enjoyed this tremendously. She also indulged in alternately beating and loving a large air-filled rubber mannikin which she identified as mother. She also attempted to nurse on,the mannikin. Several sessions earlier when the therapist had verbalized his hate for his mother, J had become terribly concerned, rushed over to him, placed her hand over his mouth so he couldn't speak and said, "Oh, you must never say that." When he also hit the mannikin and screamed, "I hate you, mother," this also sent J into a panic and she physically controlled the therapist from hitting the mannikin. Now, in this session, she was acting out this ambivalence toward mother, through the mannikin, both verbally and physically. She also continued to hold she "good things" in her hands and seemed,to suck and nurse on these things. She said there was nothing really in her hands but yet these were things that she liked to have that made her feel good. She had difficulty verbalizing the nature of these good thing, but when pressed, named a number of things she liked, including candy, peanut butter sandwiches, staff members, a boy patient she had recently taken to associating with, and money.

Session No. 13

In she first two hours of this session, J lay quietly and made no movements or verbalizations. She then sat up and in a perplexed manner said, "Why do you sometimes get hit by a truck when you go out on the highway of life?" After this she lay quietly for a short time and then started to become agitated. She tried to allay this agitation by trying to express positive feelings for the therapists but soon the shallowness of this attempt was obvious as she started to become aggressive, angry and assaultive. She ended up by screaming desperately, "I want to go out on the highway and get killed." She then would become frightened and yell, "No, no, I don't want to be killed." Perhaps in some existential manner, she was dealing with the question: should I give up my living death (psychosis) and take my chances with the world of reality,? It seems that the resolution of the "Riddle" the pressure of positive and negative feelings (of good and evil, the Devil and God) in oneself and the acceptance of that seeming paradox was the key to her entering "the highway of life." In this dilemma, J is not alone and facing such existential questions is often the core work of the psychedelic experience. When transcendance of the ego-state is achieved, the paradox is resolved and the seeming contradiction of conditions is experienced as a unified state. We feel that J had had glimpses of this unified state, but as with everyone except the saints, the human perception of opposition conditions maintained itself and conflict resulted.

Sessions 14, 15 and 16

J's mother had been released from the hospital. and came to see her. This apparently was exceedingly stressful for J and she became very disturbed. During the 14th session she became totally involved with fear of punishment and reverted back to trying to be good. This undoubtedly was related to the conflict over her rage being activated by having to see her mother. She became manic in her massive denial during this session and it was felt to be very unproductive. During the 15th and 16th sessions, she was excessively quiet, somewhat morose but did have long periods where she appeared to be in a very tranquil and peaceful state. During this time, she spoke softly and gently, only to herself, saying-"Yes, yes, this is it. It's alright." During this period of time we were preparing J for discontinuation of drug sessions as the project was being terminated. She also knew that two of the staff that she had been closest to were leaving and this was distressing to her.

Discussion

The experimental project came to an end at the time when drug laws were enacted which necessitated a long and difficult procedure to obtain these drugs. Consequently, we were forced to tell J that she would no longer be able to have any sessions with these drugs. The conversation that ensued was as follows: F: "J, because of certain problems we're not going to be able to get any more of the drugs we have been giving you and so we are going to have to do without them." J: "Isn't there any more of those drugs?" F: "Well, yes, there's still more of,the drugs but we're not able to get them." J: "Why not?" F: "Well, it's a very long and difficult story but we just aren't going to be able to get any more." J: "Do you know who has any?" F: "Yes." J: "Who has it?" F: "Well, the man who distributes it is called H.A. and he is a representative of the drug company and he lives in San Francisco." J: "Well, just go there and tell him that you need some more drugs." F: "That just won't work." J: "Why not?" F: "He just wouldn't give it to us." J: "Well, just hit him over the head and take them." F: "Then the police would come and get us." J: (In a serious and determined, yet pleading voice) "Well, just go to the man and tell him that Jeannie Drake *says* that she *really* needs it and can't she *please* have some."

One question that is most often asked concerning the results we obtained with these psychotic children is-"But wouldn't you get the same results without the drugs by just giving the time and devotion you gave to these children?" As can be seen, J evaluated the drugs as being an important aspect of her psychotherapy and the writer concurs with J's judgment. The writer had spent over two years experimenting with psychotherapeutic techniques with this type of child and the results were negligible. If one is very familiar with the severity of she problems encountered in these very psychotic children, one can more realistically judge the results of this present work. One extremely important factor which came to be of paramount importance was the constant chaotic and physically stressful environment to which these children were constantly subjected. They had to survive on a sterile ward with sixty other acutely disturbed and acting-out psychotic children. How anyone could maintain a trace of sanity under these conditions is a mystery. The writer often thought that a psychotic withdrawal would be a healthy reaction to having to live in such an environment.

It was obvious that J became much better. She ceased her isolated, autistic behavior to a very large degree-she no longer sat in a corner,.twisting papers, masturbating and talking word-salad. She had chores which she did on the ward. She talked to people rationally and helped with the smaller children. Her comments about other patients, and sometimes staff, were painfully accurate. She tried to learn but found it almost impossible because of her blindness. She did go to the hospital's rehabilitation department and the music instructor discovered, within one hour, that J could learn to play piano "by ear." He was overwhelmed and enthusiastic and highly recommended she be given this chance to learn to play. Nothing came of it. She was able to carry on very sensible conversations with staff, gave intense and undivided attention to her co-therapist when they met between sessions and was able to describe her concerns, reactions and finally, her own dynamics. She developed a very meaningful and intense relationship with the co-therapist. They had a totally gratifying experience with each other, the co-therapist describing J as "one of the most human, one of the best people I know." When the therapist and co-therapist left, they had much more difficulty in the separation than she and it was quite amazing the depth of acceptance she had concerning the necessity of terminating the project and her relationship with both the therapist and the co-theparist. In fact, she was very reassuring and supportive to them and seemed to exquisitely sense their deep feelings of guilt and shame at the abandonment of her and she rest of the children. In short, she carried on in a rather remarkable fashion and with a maturity that literally awed us.

Five-year Follow-up

The patient was discharged in June, 1968 to her parents who had moved to another state. She has not been seen by the writer since May of 1963 and the distance mitigated a personal follow-up. The patient's chart at the state institution was made available and was searched for progress notes for that five-year period. Unfortunately, the record was scanty but it was possible to glean some indication of her psychological condition.

The first notation in the chart was at the termination of the treatment in June, 1963. The psychiatrist's progress report read, "Patient is in good contact with reality; she has fairly good insight; requires no regular medication; cares for all of her own needs and is no management problem; definite improvement."

The writer left the institution in May of 1963 and the co-therapist left a few weeks later. Within three months the majority of the treatment staff had left. Consequently, the patient had virtually no one with whom to continue her therapeutic work.

In February, 1964 a notation was made that she asked one of the ward workers, "When will my craziness wear out?" She also offered the information that she must be happy with her craziness as she didn't want it to leave. In August, 1964 a student worker had Jeannie in a group therapy situation with a number of adolescent girls. There is no data as to the length of time these sessions had occurred but a progress evaluation by the student therapist reveals the following information: "Jeannie loves attention and acceptance and is very pleased when praised; she is a big help to me when I take the group off the ward. It seems as if she is living another life in her mind. She told me, "I'm out to see the world-but how many are there?" She also told me, "Everything is a thousand years old and everything is getting better and better." She converses with herself a lot and in these conversations she is usually mad at herself and talks of her mother.She shows concern about being sick and dying. As we were walking the other day, she very intently told me to listen to her talk and then to answer the questions. One day when she was talking to herself, I went over to her and asked her what she was concerned about. She laughed and answered, "Oh, don't bother, I'm just talking!"

In May of 1966 a progress report indicates that she was not a behavior problem but that her behavior oscillated between hyperactivity and withdrawal. A notation was made that she verbalized concern over fear of drying, of evil, and commented that cleanliness was good.

In October of 1967 she was presented to a consultant psychiatrist who interviewed her before a staff. He noted that she was in good psychological contact "despite her rocking motion." He felt that there had been improvement following her LSD treatment and suggested a manic-depressive psychosis diagnosis based on her alternating between hyperactive and withdrawal moods.

At the time of her discharge in June, 1968 she was described as making rocking movements, that she might be having hallucinatory experiences and that often when eating she would stuff her mouth. She was also noted to participate well in the ward activities, that she did her ward chores, that she spoke coherently and well and that she was a co-operative patient. A final note was that "Jeannie is an enjoyable person."

Unfortunately, the follow-up information is scant and meager. It would appear from these notes that Jeannie generally maintained the progress she had made in her treatment but that she had not resolved her essential conflicts. Apparently she was able to live somewhat in two worlds-,the world of her psychotic preoccupation which was dominated by her impulse of rage toward her mother and the world of external reality. This conclusion is based on her ability to interact appropriately with demands made upon her by ward personnel, her ability to communicate reasonably, her participation in activities and work and the fact that she was seen as not only human, but as an "enjoyable" human. While wrestling with her own stated craziness, she was also able to relate and participate in the real world. This degree of integration is certainly a far superior one to that which she possessed prior to her treatments.

The writer feels that it was Jeannie's great determination to know and to become more powerful than her "craziness" and that was the key facet in her maintaining some degree of sanity. She would actively seek out people and make attempts to understand her chaotic world and had a belief that she was going to get some answers one way or another. Her attitude towards her unintegrated and confused psychic state was one of tolerance with an unrestrained determination to overcome. The writer often feet, very deeply, that this was one very courageous human being.

Other Research Utilizing Psychedelic Drugs With Autistic Schizophrenic Children

Mogar and Aldrich (in press) have recently reviewed the literature on the use of psychedelic drugs with schizophrenic children. They review the work of Bender, Goldschmidt and Sankar (1962); Bender, Faretra and Cobrinik (1963); Freedman, Ebin and Wilson (1962); Peck and Murphy (in Abramson, 1960); Rolo, Krinsky, Abramson and Goldfarm (1962) and Simmons, Leiken, Lovaas, Schaffer and Perloff (1966), as well as some preliminary unpublished data from our own work. Of the total of 91 children treated with psychedelics, 55 were treated by Bender, who gave daily dosages over a relatively long term period (45 to 60 days) but without attempting to conduct psychotherapeutic sessions. The primary purpose of the studies by Rolo *et al*. and Simmons *et al*. was explicitly methodological whereas Freedman *et al*. were attempting to study the schizophrenic process and did not have any therapeutic intent. Our own work was the only one which attempted to create an atmosphere which would optimize the therapeutic process. Mogar and Aldrich state: "Inconsistent findings become much more understandable if the psychedelic experience is viewed as a dynamic configuration of intimate patient-therapist-milieu transactions. In short, the administration of LSD is inextricably embedded in a large psychosocial process which should be optimized in accordance with particular treatment goals."

Despite the diversity along major dimensions known to influence drug response and treatment effectiveness, Mogar and Aldrich make the following conclusions based on their evaluation of the results of the seven studies reviewed. (1) all children were refractory to all other forms of treatment; (2) only slight differential responsiveness as a function of age, diagnosis, duration or severity of illness; (3) most effective results were obtained with at least 100 mcg. doses given daily or weekly over relatively extended periods of time; (4) greater therapeutic benefit was related to (a) the degree of active therapist involvement, (b) an opportunity to experience meaningful objects and interpersonal activities, (c) congenial settings that were free of artificiality, experimental or medical restrictions and mechanically administered procedures; (5) the most consistent effects of psychedelic therapy included: (a) improved speech behavior in otherwise mute children, (b) increased emotional responsiveness to other children and adults, (c) an elevation in positive mood including frequent laughter, (d) decreases in compulsive ritualistic behavior; (6) although differences in patient attributes, treatment techniques, research design and other non-drug factors seemed to effect the *frequency* and *stability* of favorable outcome the types of improvement found were essentially the same in each study.

The reviewers conclude that the collective findings argue strongly for more extensive applications of psychedelic drugs in the treatment of this type of child.

Acknowledgment

The writer wishes to acknowledge, with great admiration, the contribution of this patient's co-therapist, David Dion, M.S.

Evidence from seven independent studies indicates LSD may help free the most severely imprisoned minds.

In recent years, a number of exploratory investigations have been reported involving the administration of psychedelic agents to young children suffering from severe forms of psychological disturbance (Abramson, 1960; Bender, *et al*., 1962; Bender, *et al*., 1963; Fisher & Castile, 1963; Freedman, *et al*., 1962; Rolo, *et al*., 1965; Simmons, *et al*., 1966). As either therapeutic or experimental undertakings, these studies are extremely fragmentary and suffer gross shortcomings. As a case in point, wide diversity along major dimensions known to influence drug response and treatment effectiveness characterize this work. These include the agent employed, dosage level, number and frequency of administrations, therapist expectations and previous experience with psychedelic drugs, and finally the setting and circumstances surrounding the drug-induced state. With regard to patient characteristics, the children treated were demographically varied and covered a broad age range. More importantly, the samples were markedly heterogeneous with respect to the nature, severity, and duration of modal symptoms. The major experimental shortcomings included small samples, subjective and vague criteria of drug effects and improvement, and grossly inadequate follow-up.

Despite their diversity and severe limitations, these seminal explorations in an extremely complex area of research seem worthy of wider reportage and more serious attention than they have hitherto received. Almost without exception, these reports have appeared in obscure publications or remain unpublished. A more significant reason for their relative neglect has been the polarized controversy surrounding psychedelic agents which has all but completely curtailed publicly-sanctioned research.

In this critique of the use of psychedelic agents with severely disturbed children, the various studies conducted thus far will be comprehensively reviewed and integrated. Particular attention will be given to their similarities and differences along known relevant dimensions in order to detect communalities and possible reasons for inconsistent findings. While some attempt will be made to resolve seemingly contradictory results, the heuristic value of this work will be emphasized rather than its conclusiveness . Hopefully, the tentative conclusions derived from these initial efforts will point the way for more definitive studies into the therapeutic efficacy of psychedelic agents with childhood disorders.

Patient characteristics

A fairly exhaustive search of clinical and research reports revealed a total of 91 severely disturbed children who have been administered one or more psychedelic agents for experimental and/or therapeutic purposes. As detailed in Table 1 this collective group of patients ranged from five to fifteen years of age, with the large majority between six and ten years of age. Careful examination of the seven independent studies disclosed little basis for assuming a significant relationship between age and drug response. However, tentative relationships were suggested by both Bender (1963) and Fisher and Castile (1963). Bender noted that in contrast to pre- adolescents, younger children manifest consistently different reactions to a variety of medical and pharmacological treatments. For this reason, she hypothesized that her older patient group (12-15, N = 8) would not show the dramatic positive changes obtained with the younger children. Contrary to expectations, comparable favorable effects were found irrespective of age differences. Fisher and Castile, on the other hand, concluded that older children were better candidates for psychedelic therapy because verbal communication was possible and also because they tended to be less withdrawn, more schizophrenic than autistic, and displayed more blatant symptomology. While these patient features were obvious advantages for the particular therapy technique employed by Fisher and Castile, it is unlikely that this symptom picture consistently distinguishes older from younger psychotic children. Thus, on the basis of the available evidence concerning the immediate and subsequent effects of psychedelic drugs on children, age per se appears to be an inconsequential variable.

All of the patients treated in these studies were described as severely and chronically disturbed with a primary diagnosis of autism or childhood schizophrenia. With regard to duration of illness, most had been hospitalized for periods ranging from two to four years. Many were afflicted since birth. An apparent exception was the single patient studied by Rolo and his co- workers (1965). This twelve year old boy had been hospitalized for four months. No estimate of the duration of his illness was reported. At the opposite extreme, the twelve children treated by Fisher and Castile were probably the most severely disturbed with an average illness duration of 7.6 years.

The modal symptoms characterizing the majority of children given psychedelic treatment were well summarized by Simmons and his coworkers (1966): (1) preoccupation with and stereotyped manipulation of objects (toys, etc.); (2) isolation of the self from contact with animate objects (including minimal eye contact); (3) failure to acquire general social behaviors (including speech); and (4) bizarre rhythmic repetitive motor patterns. This syndrome conforms closely to the classical picture of infantile autism (see e.g., Rimland, 1964). As suggested earlier, the symptoms picture of the older children treated by Bender and by Fisher and Castile resembled adult schizophrenia more than infantile autism. This was also true of Rolo's single patient. Although autism was invariably present, the "schizophrenic" children were less withdrawn and manifested a greater variety of symptoms including overt aggression, hallucinations, paranoid delusions, and psychosomatic disturbances. Almost without exception, long-standing mutism was characteristic of all 91 patients prior to psychedelic treatment.

Despite these significant communalities among the seven groups of children studied, individual differences in patient characteristics extended over a fairly broad range. Without discounting the possible importance of individual differences, there is little indication in the work reviewed here of differential response or benefit as a function of age, diagnosis, duration or severity of illness. As will become apparent in subsequent sections of this paper, the failure to detect such relationships seems partly due to fragmentary patient data and the crude estimates available of drug response and subsequent changes in behavior. Consistent with this hypothesis, the differential findings reported by Fisher and Castile appear to reflect their more detailed assessment of personal history information and individual differences in both pre- and post- treatment symptomology. They also applied more stringent criteria of improvement than the other investigators.

Rationale and hypotheses

Explicit hypotheses or theoretical bases for administering psychedelic drugs to disturbed children are almost completely absent in these exploratory studies. The lack of a definite rationale is hardly surprising when one considers the enigma surrounding both schizophrenic behavior in children and response to psychedelic drugs. Despite great diversity in expectations and technique, there was one point of departure shared by all investigators, namely, that all known forms of treatment had been attempted without success. Thus, the use of a potent experimental drug with the particular chronic patients selected seemed justified.

With regard to the purpose of these studies, all were to some extent exploring the therapeutic potential of psychedelic drugs rather than their psychotomimetic properties. This was least true of Freedman and his coworkers (1962) who viewed LSD primarily as a means of studying the schizophrenic process by "intensifying pre-existing symptomology." This orientation contrasted sharply with Bender's view. Noting that withdrawn children became more emotionally responsive while aggressive children became less so, she hypothesized that psychedelic drugs "tend to 'normalize' behavior rather than subdue or stimulate it." This basic difference in expectations seems at least partially responsible for Bender's extremely favorable outcomes and Freedman's rather poor results. Regarding all forms of psychotherapy, it has become a truism that " where there is no therapeutic intent, there is no therapeutic result" (Charles Savage in Abramson, 1960, p. 193).

Consistent with their explicit therapeutic intent, Bender, Fisher, and Simmons each offer essentially the same hypothesis based on a psychological interpretation of childhood schizophrenia: "The working hypothesis of this study is that the psychosis is a massive defensive structure in the service of protecting and defending the patient against his feelings and affectual states" (Fisher & Castile, 1963). Psychedelic drugs were viewed as a powerful means of undermining an intractable defense system and thereby making the patient more receptive to contact and communication with others. In attempting to explain the predominantly positive results in this area of research (see Table 1), it is worth emphasizing that the collective work of Bender, Fisher, and Simmons accounts for over 75 per cent of the 91 children treated with psychedelic drugs. Although their techniques differed considerably, these investigators shared a psychological conception of autistic symptoms and a psycho-therapeutic orientation to drug treatment.

Although Freedman was prompted to use LSD primarily as an experimental device to study psychosis, he did mention that he was influenced to some extent by the dramatic improvement in autistic children reported by Peck and Murphy (in Abramson, 1960) and by the apparent success of Cholden, Kurland, and Savage (1955) in their work with adult mute catatonic patients. As will become apparent in the discussion of results, a partial and often transient alleviation of mutism by LSD treatment has been one of the most consistent effects reported in the children studies.

A final secondary objective worth mentioning is that the more recent studies (Rolo, *et al*., 1965; Simmons, *et al*., 1966) were influenced by Bender' s earlier reports of successful LSD treatment. These studies were attempts to replicate Bender's findings using various control measures and other methodological refinements.

Drug regime

As indicated in Table 1, LSD-25 has been by far the most frequently employed psychedelic agent in work with psychotic children. An exception was Benders s second study (1963) in which she gave one-half of her patients LSD-25 and the other half UM L491. The experimental drug UML-491 was described as a more potent serotonin inhibitor without the psychedelic properties associated with LSD-25. Based on a variety of biochemical indices and observations of differential behavior changes, Bender reported no apparent differences between the action or effectiveness of the two drugs.

Fisher and Castile employed LSD-25 and psilocybin at times singly and at times simultaneously. These investigators were unique in using a variety of dosage level drug combinations both with the same patient on different occasions and with different patients on the same occasion. The specific drug regime adopted for a given session was determined by clinical criteria of the patient' s particular defense structure and his expected resistance to psychedelic drugs. Stated differently, Fisher and Castile were the only investigators who attempted to optimize the psychedelic experience for a given patient rather than mechanically administering a constant dosage of the same agent to all patients. This feature of their method was consistent with the greater attention paid to individual patient differences and their general orientation to psychedelic therapy as a psychopharmacological process.

Concerning dosage level, most investigators settled on 100 micrograms as optimal. Although this was the average dosage used by Bender, she differed from the others by starting treatment at a relatively low level (50 mcgs.) and gradually increasing the amount to as high as 150 mcgs. As suggested earlier, Fisher and Castile usually administered multiple agents and employed a wide range of dosage levels (with LSD, 50 to 400 mcgs.). As their work progressed, they developed a definite preference for the prolonged high dose psychedelic experience, especially with older schizophrenic children. Their most effective results were obtained with pre-treatment medication of 10 mg. Librium, 10 to 15 mg. of Psilocybin given approximately one-half hour later, followed by 250 to 300 mcg. of LSD administered twenty minutes later. In addition, Fisher and Castile often gave "boosters" during the session itself ranging from 25 to 100 mcg. of LSD. Boosting was considered beneficial " (a) when the patient seemed to be caught up in a problem area which he could not break through; (b) when the patient kept defending himself from new experiences; (c) when the patient increased his defensive, stereotyped behavior and the psychotic controls became intensified."

With regard to frequency and total number of treatments, the seven studies varied widely - from Freedman's single session per patient to Bender's daily sessions over periods as long as one year. Although more frequent and prolonged treatment was often impossible for non-clinical reasons, Fisher' s group averaged five sessions per patient given preferably at two week intervals. With both Rolo' s single patient and Simmons' pair of identical twins, experimental requirements precluded an optimal therapeutic regime. Both investigators attempted double-blind procedures and more objective observational methods. Rolo administered 100 mcg. LSD on 28 consecutive days while Simmons gave a total of nine 50 mcg. LSD treatments, approximately two per week, interspersed with inert placebo sessions and control (no-drug) trials.

After citing extensive evidence indicating rapid tolerance of LSD-25, Freedman concluded that repeated administrations would be ineffective with psychotic children. Bender, on the other hand, found little indication of either rapid or sustained tolerance to LSD using her method of continued daily administrations over extended periods. With her relatively large group of patients, Bender did observe a leveling off of reactivity after several weeks or months of uninterrupted treatment. She considered it unlikely, however, that this effect was due to physiological drug tolerance. The impressive improvement rates obtained by Bender in contrast to Freedman's results offer support for a high frequency regime of moderately large doses. It is worth noting that Fisher and Castile arrived at a similar conclusion without knowledge of Bender's work. Parenthetically, the significance of a possible drug tolerance effect is further lessened by the findings of more recent experiments indicating that tolerance to LSD diminishes almost as rapidly as it develops (Hoffer, 1965).

Physical and psychological milieu

It should be emphasized that the findings obtained in these studies are the result of an interrelated set of determinants, only one of which is the ingestion of a particular chemical agent. The significance of seemingly contradictory results has often been obscured by the persistent search for static, " drug-specific" reactions to LSD. Inconsistent findings become more understandable if the psychedelic experience is viewed as a dynamic configuration of intimate patient therapist-milieu transactions. In short, the administration of LSD is inextricably embedded in a larger psychosocial process which should be optimized in accordance with particular treatment goals.

Even a cursory examination of the work with autistic children clearly reveals that at least some important aspects of the physical and psychological milieu were considerably less than optimal. In the seven studies reviewed here, only Fisher and Castile attempted to create a specifically non-medical atmosphere that was minimally threatening to the patient. Modeled after the widely-adopted Saskatchewan technique (Blewett & Chwelos, 1959; Hoffer, 1965), the procedure developed by Fisher and Castile included the following key features: (1) a high dose, 7 to 10 hour session; (2) the use of a variety of therapeutically-meaningful or aesthetically-pleasing stimuli (music, flowers, pictures, food, etc.); (3) a positive patient-therapist relationship formed prior to the session itself; (4) the presence of both a male and female therapist who "had thorough acquaintance with the phenomena of the drug through personal experience"; and (5) active therapist involvement with the patient including role-playing (e.g., father, mother). Importantly, these conditions have repeatedly been found to significantly enhance the personal value of psychedelic experiences.

In each study, the circumstances under which the session was conducted were consistent with the purpose and expectations of the investigator. Consistent with his psychotomimetic orientation, Freedman' s patients were supervised by a familiar psychiatrist primarily for the purpose of careful observation and note-taking. No attempts to relate to the children or personal experience with the drug were reported. The same applies to Bender's group although the intent in this case was clearly therapeutic. She apparently administered LSD as a conventional daily medication that did not require any special conditions of preparation, therapist involvement, or setting. However, her reports are replete with descriptions of spontaneous interactions between staff and children. Supervision of Bender' s patients was performed mainly by ward attendants. The adults present in the sessions conducted by both Rolo and Simmons were also ward attendants.

The primary purpose of the studies reported by Rolo and Simmons was explicitly methodological. Both research projects employed the double-blind method and attempted to follow a predetermined, uniform procedure during each experimental and control session. As means of standardizing the sequence of events and increasing objectivity, both investigators systematically presented various playing objects, games, and tasks to the child. Rolo's single patient was encouraged to engage in quite simple, familiar activities such as throwing a baseball or playing cards. Simmons, on the other hand, created a far more elaborate series of game-like situations that were novel and intrinsically interesting, requiring sustained patient-adult interactions, and importantly were specifically designed to simulate or elicit normal social behavior and emotional responsiveness.

A number of probable effects of the physical and psychological milieu are suggested in these studies that bear a significant relationship to the investigator' s orientation, on the one hand, and differences in benefit or outcome, on the other. As indicated earlier, the expectations of a particular research team seem highly related to various aspects of both drug regime and setting. With regard to differential improvement rates, a major determinant seems to be the degree of active therapist-patient interactions permitted during the drug-induced state. Secondly, greater therapeutic benefit seems to occur in congenial settings offering some opportunity to experience meaningful objects and interpersonal activities. Finally, psychedelic therapy with psychotic children seems most effective in natural, flexible settings that are reasonably free of artificiality, experimental restrictions on spontaneous behavior, and mechanically administered procedures. Conversely, barren medical or laboratory environments seem clearly anti- therapeutic.

Results

As emphasized previously, each of these exploratory studies suffered major shortcomings either as therapeutic or experimental undertakings. Almost without exception, the findings reported consist mainly of observational data obtained during the acute phase of drug reactivity. The use of pre-treatment baselines against which to measure change either during or after psychedelic therapy were generally absent. In most cases, follow-up data was not obtained. Although caution in interpreting results is certainly indicated, it should be pointed out that these limitations are shared by the bulk of research on drug- and psycho-therapies. Furthermore, objective evaluation of improvement in severely disturbed children presents unique problems due to the nature of autistic symptoms, especially the ubiquity of mutism. Even the few cases not suffering from a complete absence of speech were untestable by standard psychological assessment methods.

In their initial study, Bender and her coworkers (1962) administered the Vineland Maturity Scale at the beginning of treatment and again three months later. At the followup testing, ratings were qualitatively higher for all children. In the second study (Bender, *et al.*, 1963), the Rorschach, Draw-A-Person, and Bender-Gestalt tests were given to the ten verbally responsive children on at least two occasions; before treatment and again after a three to eight month interval. In these aggressive, overtly psychotic patients, Bender reports that "there were two major changes observed: (1) There was a decrease in personalized ideation and a corresponding gain in accuracy of response; and (2) An inhibition of strongly emotional or 'feeling' reactions to the cards." Other favorable changes reported included decreases in hallucinations, negativism, and regressive defenses with a corresponding increase in reality-contact. Similar types of improvement were found in the older children treated by Fisher and Castile.

With regard to her major group of young autistic children, Bender reported significant improvement in speech and verbal communication:

> "...the vocabularies of several of the children increased after LSD or UML; several seemed to be attempting to form words or watched adults carefully as they spoke; many seemed to comprehend speech for the first time or were able to communicate their needs... Very few of these changes in communication had been noted previously in such a large number of children, and at such a relatively rapid rate" (1963, p. 91).

Since mutism is a cardinal symptom of autistic children and probably the major impediment to successful therapy, it is worth emphasizing that at least temporary speech improvement has been one of the most frequently reported effects of LSD in the work conducted thus far. Other communalities include an elevated mood, less compulsive ritualistic behavior, and increased interaction with others. All investigators reported some favorable change in these major areas with the exception of Rolo' s single patient . Rolo's group abandoned the attempt to estimate improvement since their judges could not distinguish between LSD and non-LSD trials. Bender, on the other hand, made the following observations:

> "They appeared flushed, bright eyed, and unusually interested in the environment... They participated with increasing eagerness in motility play with adults and other children... They seek positive contacts with adults, approaching them with face uplifted and bright eyes, and responding to fondling, affection, etc." (1962, pp. 172- 3). "There is less stereotyped whirling and rhythmic behavior... They became gay, happy, laughing frequently... Some showed changes in facial expression in appropriate reactions to situations for the first time" (1963, pp. 90-91).

As indicated earlier, Simmons' patients were subjected to a uniform sequence of game-like situations that evoked a variety of measurable responses. During each LSD session and non-LSD session, a total of 20 specific behavioral measurements were taken by a recorder observing the patient through a one-way, screen. The behaviors recorded included physical contact with the adult present, vocalizations, destructive acts, laughter, stereotyped movements, and eye-to-eye contact. In contrast to non-LSD trials, the most pronounced and consistent changes observed during LSD sessions were: "(1) An increase in social behaviors manifested by increased eye to face contact and increased responsiveness to adults, (2) An increase in smiling and laughing behavior generally considered an indication of a pleasurable affective state, and (3) a decrease in one form of non-adaptive behavior demonstrated by a reduction of self-stimulation."

Considering the wide diversity in these studies, the major findings of Bender, Fisher and Castile, Freedman, and Simmons are remarkably similar. Differences in orientation, patient attributes, drug regime, setting, treatment technique, research design, etc. seem to affect the frequency and stability of favorable outcomes (see Table 1). The types of improvement, when and if they occur, appear to be essentially the same in each study. In short, when LSD is effective with autistic children, it is effective in characteristic ways.

The influence of non-drug factors is well illustrated in the work of Fisher and Castile. Although they optimized the physical and psychological milieu, their patients were the most severely disturbed and displayed the greatest variety of symptoms. Furthermore they made conservative estimates of improvement based on the extent and stability of favorable changes after treatment was terminated. In contrast, most of the findings reported by the other investigators concerned the immediate effects of treatment. These differences account in part for the relatively modest improvement rates reported by Fisher and Castile.

The lack of even short-term follow-up data on the majority of children treated with psychedelic drugs has been a major limitation of the work reviewed here. Follow-up information is particularly crucial because the available evidence strongly suggests that when used alone, LSD produces only transient alleviation of symptoms. In order to bring about enduring improvement, the drug induced state requires active therapist patient interaction and/or subsequent psychotherapy. In this connection, Simmons noted that:

> "Therapeutic intervention in severely retarded or regressed children utilizes to a great extent close physical interaction to which the child must respond. In the usual state it is often difficult to intrude upon the child because of a general lack of responsiveness... The results of our experiments clearly demonstrate changes in exactly these areas with increased attendance to

> physical and face contact with an attending adult and concomitant reduction of competing self-stimulatory behavior... Thus, two possible criteria for the successful intervention into autistic children are met... A third piece of data which must be considered is the increase in smiling and laughing behavior. . ." (1966, p. 1207).

The collective work reviewed here supports the main conclusion reached by Simmons and his co-workers and argues strongly for more extensive and systematic applications of psychedelic drugs in the treatment of autistic schizophrenic children: "LSD-25 appears to offer a useful adjunct to psychotherapy because of its positive effect in the areas described which are closely related to the process of psychotherapy."

Summary and conclusions

1. Seven independent studies are reviewed involving a total of 91 autistic schizophrenic children who had been given psychedelic drugs for therapeutic and/or experimental purposes.
2. The large majority of children treated in these studies were between six and ten years of age and were completely refractory to all other forms of treatment.
3. There was only slight indication of any differential response or benefit as a function of age, diagnosis, duration or severity or illness.
4. A variety of psychedelic agents, dosage levels, frequency of administrations, and treatment schedules were employed. The most effective results were obtained with at least 100 microgram doses of LSD-25 given daily or weekly over relatively extended periods of time.
5. Concerning the physical and psychological milieu, greater therapeutic benefit was related to: (a) the degree of active therapist involvement with the patient; (b) an opportunity to experience meaningful objects and interpersonal activities; and (c) congenial settings that were reasonably free of artificiality, experimental or medical restrictions, and mechanically administered procedures.
6. The most consistent effects of psychedelic therapy reported in these studies included: (a) improved speech behavior in otherwise mute children; (b) increased emotional responsiveness to other children and adults; (c) an elevation in positive mood including frequent laughter; and (d) decreases in compulsive ritualistic behavior.
7. Differences in patient attributes, treatment technique, research design, and other non-drug factors seemed to effect the frequency and stability of favorable outcomes. The types of improvement found were essentially the same in each study.
8. Although each of these studies contained serious therapeutic and experimental flaws, it was concluded that the collective findings argue strongly for more extensive applications of psychedelic drugs in the treatment of autistic children.

Table 1
Summary of Patient Samples, Drug Regime, and Improvement Estimates

Reference	Patients	Age	Agent	Dose (mcg)	Treatments	Schedule	Excel. (a)	Good	Poor
Abramson 1960	6	5-14	LSD	40	3-6	weekly	5	-	1
Freedman 1962	12	6-12	LSD	100	1	-	-	5	7
Bender 1962	14	6-10	LSD	100	45 (b)	daily	7	7	-
Bender 1963	44	6-15	LSD, UML	50-150, 4-12mg	60 (c)	daily	20	21	3
Fisher i Castile 1963	12	6-15	LSD, psiloc.	50-400, 10-20mg	1-11 (d)	biweekly / monthly	4	4	4
Rolo 1965	1	12	LSD	100	28	daily	-	-	1
Simmons 1966	2	5	LSD	50	9	twice weekly	2	-	-

The Effects of Consciousness-Expanding Drugs on Prisoner Rehabilitation

by

Timothy Leary

These articles by Dr. Timothy Leary are part of his book "High Priest",

The first of two articles describing the Harvard-Concord Prison Project, in which the author's own version is flanked by official reports and newspaper accounts of the same story.

During the Fall and the Winter of 1960, much of my time and energy was going into the study of the effects of the psychedelic mushrooms. I was also carrying on an active program of lecturing, teaching, and field work in Clinical Psychology in the Harvard Graduate School. I had been brought to Harvard in 1959 in order to introduce existential-transactional methods for behavior change. After 15 years of doing research on psychotherapy, I had come to the conclusion that there was very little that one person called a doctor could do for another person called a patient by talking to him across a desk, or listening to him as he lay on a couch.

I developed a lot of theories and a lot of methods on how behavior change could be brought about in ways more effective than the standard clinical interview method. There are two main points to the theories I developed; first, (transactional) I was convinced that the doctor had to throw away his role and status as a doctor, had to join the other person actively and collaboratively in figuring out the solution to his problem As much as possible, the doctor had to turn over the responsibility to the who knew most about the problem at hand, namely, the patient. I developed many techniques for getting patients to help each other.

The second point in my theory (existential) was that the doctor has to leave the safety of his consulting room and get out there in the field where the so-called patient is having his unique problems and where he is going to solve his problems. I saw the role of the doctor as that of a coach in a game in which the patient was the star player. The coach can help, can point out mistakes, can share his wisdom, but in the last analysis, the guy who does the job is the guy out there in the field, the so-called patient.

I was enthusiastic about these theories because they worked, and because there is no joy in teaching that can equal that thrill which comes when you watch someone who's been hung up, and blocked, and confused, and making a mess of things suddenly learn how. All this had started happening before I got involved in the drug research, and I had already become a controversial figure around the Boston area, because everything that I was saying made a tremendous amount of sense to patients, but the doctors, the psychiatrists, the social workers, the psychologists, were not so quick to accept these theories. You see, I was asking them to give up the status and the omniscient position which they felt their training entitled them to. I asked them to turn over the authority and the star role in the game to the patient.

I was taking one day off a week to drive down to New Bedford, Massachusetts with two or three graduate students where we were working in an orphanage teaching social workers and nuns to set up groups in which older kids would help younger kids, and in which children at every age level were encouraged to take more responsibility for running the school and planning their lives.

We set up another project in a slum housing district in a Boston suburb. Here were hundreds of people who were bogged down socially and psychologically. They couldn't afford psychiatric help and there was none available for them. With another group of graduate students, I used to go down there one night a week with tape recorders and blackboards. We set up headquarters in one of the slum apartments and started teaching groups of the neighbors how they could help each other and become psychiatrists for each other and develop some facility for solving their own problems.

All this, of course, was very déclassé at Harvard. Universities are supposed to be research institutes and if you get too involved in service functions or helping people, you're considered a bleeding heart. I was able to justify the work in the orphanage, the work with alcoholics, the work in the slum projects, by using the phrase methodology. We weren't really trying to help these people. No sir, not us. We were trying to develop new techniques and scientific methods for changing psychotherapeutic theory. Of course, if people enjoyed it and got help, that was an interesting by-product which supported the method and the theory. It was all experimental, you see. It became a tradition in the center where I worked that any time they got a call from a do-good social service agency requesting Harvard's help in curing any sort of social disease, the request was likely to get bucked to me because they knew that this was my vice and my eccentricity.

One day I got a note in my box saying that two men from the Department of Legal Medicine were interested in enlisting Harvard's help in the psychological rehabilitation of prisoners. Now prison work is considered to be the least interesting, lowest status work you can do in the field of psychology, psychiatry, and sociology. The problems are hopeless. Criminals never change. The atmosphere is dreary and the academic rewards are slim. But when I found this little piece of paper in my box requesting an appointment from two officials from the Department of Legal Medicine, I let out a big grin and chuckled all the way to my office because this was just the chance I was looking for.

By this time, we had given the psychedelic mushrooms to about 100 people in a wide variety of circumstances and we had learned a lot about the process. In spite of the bungling, and the confusion, and our ignorance, we still hadn't caused any damage to anyone and there were a lot of mistakes that we'd never make again. By this time, we had learned a few things about how to run the sessions. About 90 percent of the people who were taking the magic mushrooms were reporting the most ecstatic and educational experience of their lives. The problem was, there was no way to get any measurement as to how much good we were doing. There was no way to keep score.

That of course, is the main problem in the field of psychotherapy. You can develop a completely effective method of treating people's psychological problems and there is no way you can prove it. you can work with 1.000 people and help every one of them change their way of thinking and their way of acting, but there are no statistics like hits, runs, and errors to tabulate your score. The problem is that half the people you help are going to get better jobs, and half of them are going to quit the jobs they have. Half of them may increase the intimacy and closeness and meaning in their marriages, but the other half may leave their wives. Changing a person's psyche is one thing, but measuring results in an observable way is another thing. Because who's to say which behavior reflects growth and change.

Here's where the prison came in. The prison is the ideal place to do a study in psychotherapy behavior change because when you try to rehabilitate prisoners you've got an iron-clad statistic you can work against. It's called the recidivism rate. When you are working with people outside, they may quit their job and join the Peace Corps, or they may quit their job and join the ministry, or they may quit the ministry and take up guitar, and you know about the growth of this person, but who else will believe it? But when you work with prisoners and you think you've helped them change, grow, and become more effective people, there's an easy way to tell. Where are they a year after you've finished with them? Are they back in jail, or are they making it on the outside. Prisoner rehabilitation presents the most effective check for someone who claims he can bring about change in behavior. In the prisons of Massachusetts the recidivism is about 70 percent. Seven out of every ten men who leave prison, return. If you develop a new and sure-fire way of changing man's mind, the prison presents the toughest and cleanest test of your effectiveness. Can you keep him out of jail? That's why I wanted to get into the prison.

Now, the reason why the prison psychologists wanted to get into Harvard is because everyone in any academic or professional activity in the Boston area has one way of measuring his success. Can he get on the Harvard payroll? The word Harvard in the Boston area is a powerful status symbol that operates at every level of society. There are several thousand janitors around the Boston area, but if you are a janitor at Harvard, you're a prince among custodians. The same with a cook, a gardener, and a psychologist.

A week later, I found myself host at a corner table in the Harvard Faculty Club with two officials from the Massachusetts Prison System. What they wanted was simple. They wanted to have Harvard graduate students assigned to the prisons as psychology interns with a possible long-range hope of getting themselves clinical professorships at Harvard. And what I wanted was to get Harvard graduate students into the prisons because that's where I felt that all embryonic psychologists should be - out in the field, dealing with real people and real problems. But there was something else I wanted - and that was the chance to show that we could rehabilitate criminals by using the sacred mushrooms. And so the deal was made. I agreed to get Harvard approval to send graduate students to internships in the prison and they agreed that if I could get the approval of the warden and the prison psychiatrists, I could give psychedelic mushrooms to prisoners.

About a week later I drove out to the prison. I wore my Harvard tweed suit and my button-down shirt. The warden was impressed and pleased. It wasn't often that Harvard professors came out to the prison proposing to do research and training with Harvard graduate students. But the whole thing hinged on the approval of the psychiatrists, because the sacred mushrooms were DRUGS and to work with DRUGS you had to have the medical O.K. So, we walked down the hallway to the metal cage that let us into the prison. We opened up the first steel door and we stood in the anteroom. Then we rang a bell, a slot opened, and a guard looked at us and opened up the second metal door. We walked into the middle of the guard room, across the prison yard to the hospital where we rang the bell and got peered at through the slot, heard the metal hinges creak, and walked into the prison hospital. We walked down the corridor to the psychiatrist's office and knocked on the door.

After a minute, out walked one of the most entertaining and interesting men in American psychiatry. The first thing that struck me about the prison psychiatrist was that he was the best-dressed man I had ever seen. He was short, graceful, like a ballet dancer. The first negro psychiatrist I had ever met. I spent an hour talking with Dr. Madison Presnell. He was no intellectual; he mispronounced some of the polysyllabic words, but he had a light in his eye and a wise, cool way of looking at you which told you he was a man who had seen a lot, and suffered a lot, and was still looking for the funniest and wisest part of everyone he came in contact with.

In sizing up Dr. Presnell, I could say to myself a word which I had heard used quite often in recent months. He was "hip." I was obvious too, that he had had some experience with psychedelic drugs. Which ones he didn't make clear. He could have had LSD in medical school, or mescaline in psychiatric research, or maybe pot in the Village, but he knew what I was talking about.

A few days later Dr. Presnell came over to Harvard to meet some of my bosses, and the following Sunday, he brought his beautiful and intelligent wife and his two lovely children over to my house for cocktails. It was on a Sunday afternoon. We had a straightforward and hones discussion. He sat down on a chair in my study, thought for a minute and said, The plan you propose to get the psychedelic drug to prisoners is the best idea I've ever heard for dealing with an impossible problem. If you're smart enough and dedicated enough to know how to do it, this could be the best plan for the treatment of prisoners I've hear proposed. There's one chance in a hundred you can pull it off, but if you do, you will have accomplished more for American society and for prisoners rehabilitation than has been done in the last four thousand years since the code of Hammurabi. But, it's risky business. You're bound to run into trouble. As a matter of fact, the more successful you are, the more trouble you're going to stir up. Because one thing I've learned as a prison psychiatrist is that society doesn't want the prisoner rehabilitated and as soon as you start changing prisoners so that they've discovered beauty and wisdom, God, you're going to stir up the biggest mess that Boston has seen since the Boston Tea Party. I'll give you medical coverage and I'll be glad to serve as psychiatric consultant and I'll back you up all the way with the wardens, with the guards, with the mental health department, but sooner or later as soon as they see the thing you do working, they're going to come down on you - the newspaper reporters, the bureaucrats, and the officials. Harvard gives drugs to prisoners! And you're going to gave to do the impossible - you're going to have to cure prisoners with you left hand, and that's something that's never been done before and you're going to have to hold off the entire bureaucracy of the state of Massachusetts with you right hand and that's never been done before, not even by Kennedy. So, I'll back you all the way, until you make a mistake, and when you make that mistake, and they all start coming down at you, exactly at that point, I'm going to walk out because I'm not you. I'm not the new Freud and I have no ambitions to play that game. I'm a negro from the South with a degree from a second-class medical school, with a wife and two kids whom I'm trying to support and educate in an insane society, and I'll help you all the way to win, but I'm not going to lose with you.

And so it was settled. Dr. Presnell would line up volunteers in the prisoner population for the sacred mushroom project and I would go back to Harvard and get graduate students who would volunteer their time and energy and their nervous systems to take drugs with maximum security prisoners at the penitentiary.

A few days later, I was in my office when a knock came on the door, and I was visited by a graduate student named Ralph Metzner. Metzner had a reputation for being one of the smartest students in the department. He was a graduate of Oxford, an experimentalist, a precise, objective, and apparently very academic young man. He said he had heard about the prison project and he wanted to work with me on it. My first reactions were that Metzner was too academic, too dainty-British, too bookish, too ivory tower, to walk into a prison and roll up his sleeves, and take drugs that would put him out of his mind, with rough and tumble prisoners. Metzner said he wanted to learn how. Then I said, Before you can give drugs and take drugs with anyone else, you have to have some experiences yourself. Are you ready to take mushrooms? He was ready. As a matter of fact, that's exactly what he wanted to do, to have a session.

And so it happened that on March 12, 1961, at my home in Newton, Massachusetts, I ran a session for Dr. Presnell and his beautiful wife, for Ralph Metzner and his girl friend, another graduate student, and Gunther Weil and his wife, Karen. This was the 52nd time I had taken psilocybin with other people. The notes on the session say, This training session was designed to introduce several new subjects to the sacred mushroom experience under supportive circumstances.

The session took place in my study. Since this was an exploratory training session, I told the participants that they should relax, have a good time, be entertained, and learn what they could. Dr. Presnell was the dominating factor in this session. His joking and warm attitude created a benign atmosphere. Each new subject had his spouse or a trusted friend present. After a long period of happy relaxed giggling, the joking became more and more philosophic. Members of the group would leave the room periodically to be by themselves or to talk in pairs, but my study operated as the center for the session. There were no discordant notes, no anxiety, depression, or friction. We were finally getting to the point where we knew how to set up a pleasant session. Each member of this six-person group reported a deep ecstatic, educational experience.

A few days after this session, Ralph Metzner, Gunther Weil, and I drove out to the concrete prison and met with the six volunteers who had been selected by Dr. Presnell. Sitting around a table in a dreary hospital room, with grey walls, black asphalt floor, bars in the windows, we told six sceptical and suspicious men about an experience that could change their lives.

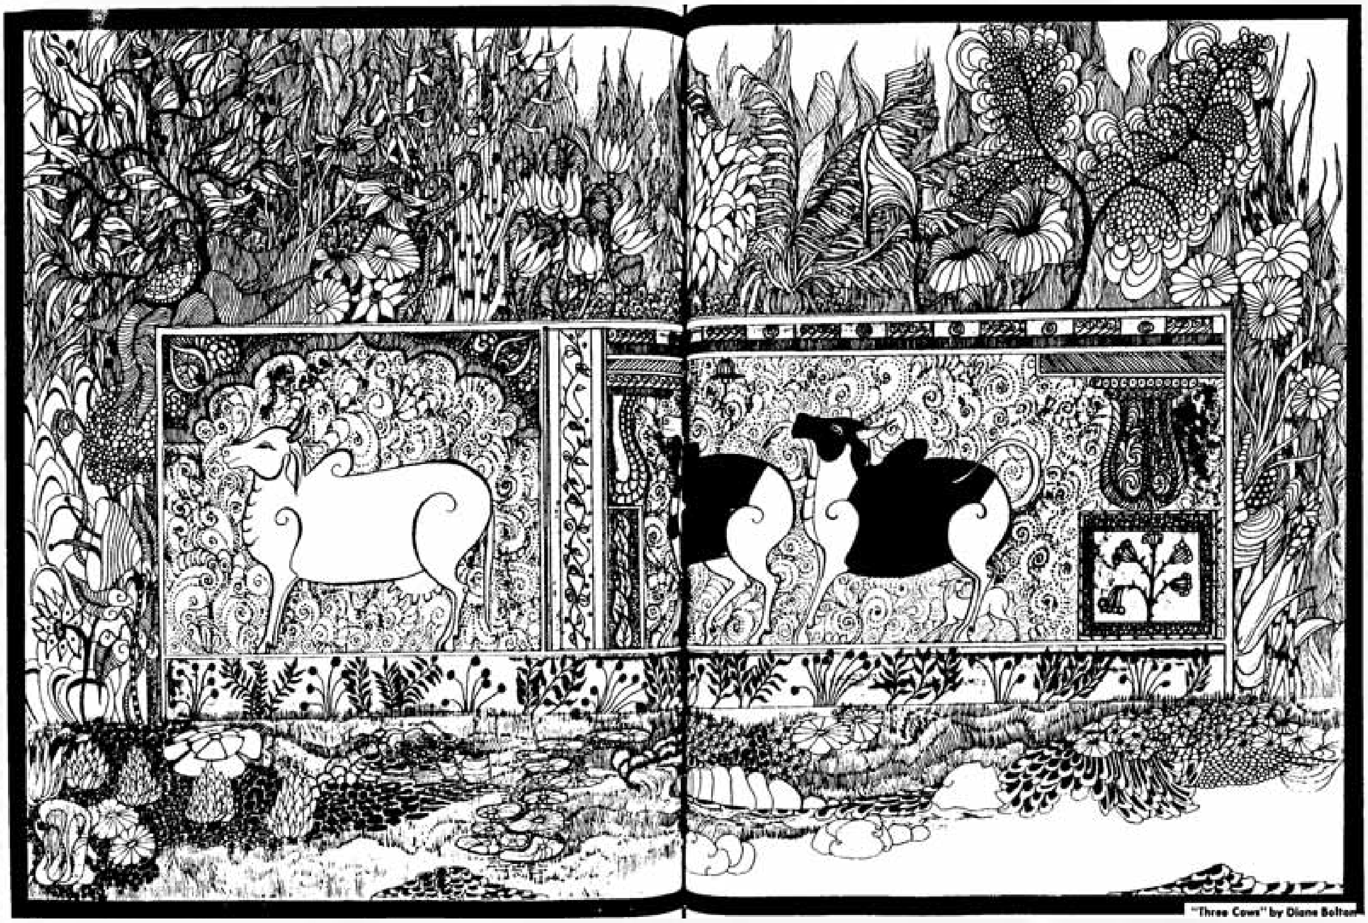
The first psychedelic session in the prison was well-planned. The first thing we did was to tell the prisoners as much as we could about the psychedelic experience. We brought in books for them to read, reports by other subjects, articles that described both the terrors, as well as the ecstasies of the experience. We spent most of the time describing our own experiences and answering groping questions. We made it very clear to the prisoners that this was nothing we were doing to them. There was no doctor-patient game going here. We would take the drugs with them. We were doing nothing to them that we wouldn't willingly, happily have done to us.

We also made a research contract with the prisoners. We said something like this, "We want to find out how and how much you change during this experience. For this reason, we want you to take a battery of psychological tests before you eat the mushrooms. Then, after three or four sessions with the sacred mushrooms, we'll give you the tests again. The aim here is to find out how you change, like you weigh yourself on a scale before and after you go on a diet. But, after you've taken the tests before and after the sessions, we'll give you the results. We'll go over the tests with you and explain how you were before and how you changed. Nothing in this project is going to be a secret. We've told you everything know about the drugs before you take them and we'll tell you everything we know about you after you finish your sessions." That sounded like a good deal to them and the following week, each prisoner was administered a long and complicated battery of psychological tests.

And so it happened that on March 27, 1961, in the large ward room in the prison infirmary in Concord, Massachusetts, five prisoners and three Harvard psychologists met for a trip. In the morning I would turn-on with three convicts and the two other prisoners and the two graduate students would act as observers. Then in the afternoon, Gunther Weil and Ralph Metzner from Harvard and the two observing prisoners were to take the drug and the rest of us were to act as guides.

We brought a record player, tape recorder, and some books of classical art with us. Otherwise the room was bleak in decor with four couches, a large table, and a few chairs. At 9:35 in the morning the bowl of pills was placed in the center of the table. I was the first one to turn-on in the prison project. I reached over, took fourteen milligrams of psilocybin. Then I handed the bowl to the prisoner next to me and he took twenty milligrams and passed it on to the guy next to him who took twenty and the next man. Then we pushed the pills into the middle of the table and sat back to see what would happen.

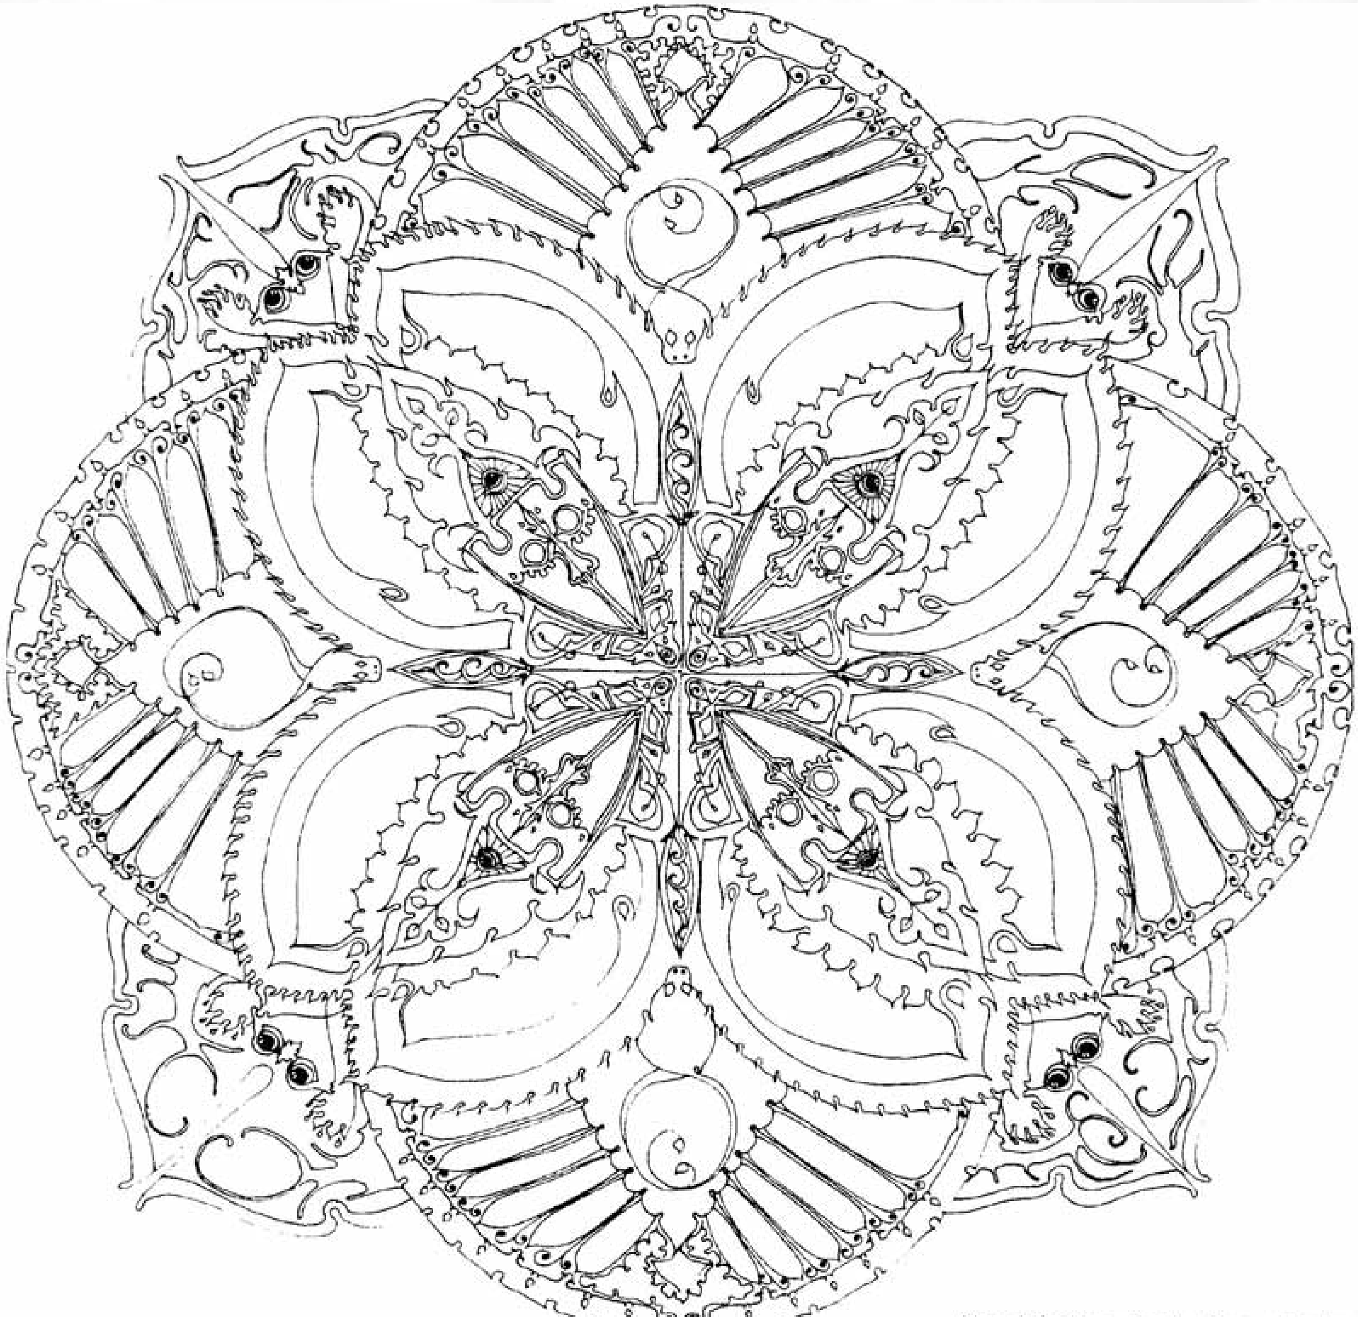
I'll never forget that morning. After about half an hour, I could feel the effect coming up, the loosening of symbolic reality, the feeling of humming pressure and space voyage inside my head, the sharp, brilliant, brutal intensification of all the senses. Every cell and every sense organ was humming with charged electricity. I felt terrible. What a place to be on a gray morning! In a dingy room, in a grim penitentiary, out of my mind. I looked over at the man next to me, a Polish embezzler from Worcester, Massachusetts. I could see him so clearly. I could see every pore in his face, every blemish, the hairs in his nose, the incredible green-yellow enamel of the decay in his teeth, the wet glistening of his frightened eyes. I could see every hair in his head, as though each was as big as an oak tree. What a confrontation! What am I doing here, out of my mind, with this strange mosaic-celled animal, prisoner, criminal?



"Three Cows" by Diane Bolton

I said to him, with a weak grin, How are you doing, John? He said, I feel fine. Then he paused for a minute, and asked, How are you doing, Doc? I was about to say in a reassuring psychological tone that I felt fine, but I couldn't, so I said, I feel lousy. John drew back his purple pink lips, showed his green-yellow teeth in a sickly grin and said, What's the matter, Doc? Why you feel lousy? I looked with my two microscopic retina lenses into his eyes. I could see every line, yellow spider webs, red network of veins gleaming out at me. I said, John, I'm afraid of you. His eyes got bigger, then he began to laugh. I could look inside his mouth, swollen red tissues, gums, tongue, throat. I was prepared to be swallowed. Then I heard him say, Well that's funny Doc, cause I'm afraid of you. We were both smiling at this point, leaning forward. Doc, he said, why are you afraid of me? I said, I'm afraid of you, John, because you're a criminal. He nodded, I said, John, why are you afraid of me? He said, I'm afraid of you Doc because you're a mad scientist. Then our retinas locked and I slid down into the tunnel of his eyes, and I could feel him walking around in my skull and we both began to laugh. And there it was, that dark moment of fear and distrust, which could have changed in a second to become hatred, terror. We'd made the love connection. The flicker in the dark. Suddenly, the sun came out in the room and I felt great and I knew he did too.

We had passed that moment of crisis, but as the minutes slowly ticked on, the grimness of our situation kept coming back in microscopic clarity. There were the four of us turned-on, every sense vibrating, pulsating with messages, two billion years of cellular wisdom, but what could we do trapped within the four walls of a gray hospital room, barred inside a maximum security prison? Then one of the great lessons in my psychedelic training took place. One of the four of us was a Negro from Texas, jazz saxophone player, heroin addict. He looked around with two huge balls of ocular white, shook his head, staggered over to the record player, put on a record. It was a Sonny Rollins record which he'd especially asked us to bring. Then he lay down on the cot and closed his eyes. The rest of us sat by the table while metal air from the yellow saxophone, spinning across copper electric wires bounced off the walls of the room. There was a long silence. Then we heard Willy moaning softly, and moving restlessly on the couch. I turned and looked at him, and said, Willy, are you all right? There was apprehension in my voice. Everyone in the room swung their heads anxiously to look and listen for the answer. Willy lifted his head, gave a big grin, and said, Man, am I all right? I'm in heaven and I can't believe it! Here I am in heaven man, and I'm stoned out of my mind, and I'm swinging like I've never been before and it's all happening in prison, and you ask me man, am I all right. What a laugh! And then he laughed and we all laughed and suddenly we were all high and happy and chuckling at what we had done, bringing music, and love, and beauty, and serenity, and fun, and the seed of life into that grim and dreary prison.



Mandala Drawing by Susan Frahm

Well, the session went on and on. There were high points and low points, ecstasies and terrors. My friend John, the Polish man, got sick and vomited. We all got pretty thoughtful. Why are there prisons? Why do some men put the warm cellular envelopes of their fellowmen in metal cages? What were we doing here? Then after a few hours, Ralph and Gunther and the two remaining convicts turned-on. Gunther was silly and acting like a hipster, and Ralph fell down on the bed and experienced visions of Blakean terror. Two prisoners came and held his hand and guided through. Dr. Presnell would check in every now and then, walk around the room like a dainty, graceful cat, not saying much, but taking it all in. And the guards came in bringing metal trays of food which we all looked at with disbelief, the way you'd look at a plate of worms or a pot of sawdust served up to you on a plate, and someone said, Man, do they call that food? Since we Harvard people weren't allowed to eat prison food at the expense of the state, Dr. Presnell went out and got milkshakes and sandwiches which we all shared, and we had never tasted food so good.

Then at five o'clock, there was a bang on the door, and we opened it and the guards came in and said, Time is up, men. Back to the prison ward. Ralph, Gunther, and I went with the five prisoners back to the lockup part of the hospital and sat there on beds, and smoked, and laughed, and compared notes on what we'd seen, and where we'd been. Then it was time for us to go. We shook hands, said we'd be back tomorrow, and Ralph and Gunther and I walked out of the prison, across the dark yard, rang the bell, and waited until the iron doors opened into the guardroom, and then across the guardroom, through the two metal doors, and down the metal stairs, past clanking, steaming, old-fashioned radiators, and then we were outside. Ralph and Gunther got into their car and drove back to Cambridge, and I got in my car and drove to Newton.

As I rode along the highway, the tension and the drama of the day suddenly snapped off and I could look back and see what we had done. Nothing, you see, is secret in a prison, and the eight of us who had assembled to take drugs together in a prison were under the gaze of every convict in the prison and every guard, and within hours the word would have fanned through the invisible network to every other prison in the state. Grim Walpole penitentiary. Gray, sullen-walled Norfolk.

Did you hear? Some Harvard professors gave a new drug to some guys at Concord. They had a ball. It was great. It's a grand thing. It's something new. Hope. Maybe. Hope. Perhaps. Something new. We sure need something new. Hope.

> In the evaluation of the dominant moods of any historical period it is important to hold fast to the fact that there are always islands of self-sufficient order - on farms and in castles, in homes, studies and cloisters - where sensible people manage to live relatively lusty and decent lives: as moral as they must be, as free as they may be and as masterly as they can be. If we only knew it, this elusive arrangement is happiness. But men, especially in periods of change, are swayed by alternating world moods which seem to be artificially created by the monopolists and manipulators of an era's opinions, and yet could not exist without the highly exploitable mood cycles inherent in man's psychological structure. The two most basic alternating moods are those of carnival and atonement: the first gives license and leeway to sensual enjoyment, to relief and release at all cost; the second surrenders to the negative conscience which constricts, depresses, and enjoins man for what he has left unsolved, uncared for, unatoned. Especially in a seemingly rational and informed period like our own, it is obvious how blithely such moods overshadow universally available sets of information, finding support for luxurious thoughtlessness at one time, for panicky self-criticism at another. Thus we may say that beside and beyond a period's verifiable facts and official doctrines, the world image "breathes". It tends to expand and contract in its perspectives, and to gain or lose solidity and coherence.

Second Annual Report: Psilocybin Rehabilitation Project.

All the professional work on this project was volunteer. The expenses for clerical assistance and salaries for ex-inmate workers were covered by generous donations from the Uris Brothers Foundation, New York, Eileen Garrett, President.

Applications to three offices of the U.S. Public Health Service requesting support for continuing his project were refused.

Exactly two years ago the Harvard psilocybin project initiated a research program at Massachusetts Correctional Institution, Concord, designed to test the effects of consciousness expanding drugs on prisoner rehabilitation.

The project was designed as a pilot study - necessarily exploratory - since little was known about the long range application of the substances.

The key issue was the use of a consciousness-expanding drug; but equally important was the philosophy underlying the research, which emphasized:

Democratic Collaboration:

Inmates were given responsibility for planning and evaluating the work. This was seen as preparation for assuming roles as responsible citizens in a democratic society.

Sharing of Information:

The inmates were given all information relevant to their treatment. This was seen as a necessary step in increasing trust and self-respect.

Spiritual Insight:

The transcendental experience provided by the drugs propels the subject beyond space, time, ego, culture, etc. The implications of this visionary experience were utilized in the program.

Interpersonal Trust and Closeness:

Evidence shows that when subjects share in ego-shattering experience together they develop strong positive emotional bonds.

Self-help and Mutual Help:

The most successful rehabilitation methods (A.A., Synanon, Group Dynamic "T" Groups, etc.) seem to those which turn over responsibility to the subjects themselves and which stimulate them to help each other. The drug experience facilitates this tendency.

Emotional and Practical Support:

The model used was not doctor-patient or expert-client but that of human beings who believe in each other and want to help each other.

The project developed the model of friends who are available to help group members stay out of trouble and maintain a responsible role in society. In our research we helped inmates get jobs, purchase union cards, made small loans and spent hours in friendly advising interaction.

Procedures

Since its initiation, the project has operated under the medical and psychiatric supervision of Dr. W. Madison Presnell.

Inmates received on the average four doses of psilocybin. Dosage ran from 20 mg in early sessions to 70 mg. Now we employ 30 mg as a standard, moderate dose.

Inmates were given personality tests before and six months after the program began. Significant decreases in hostility, cynicism, social delinquency and irresponsibility were registered.

There seems to be general agreement that the effects of the program in-the-institution were quite dramatic. The behavior and attitude of the project members became more mature and social.

The post-release events, however, involved a different set of factors and required several revisions in the program.

Post-Release Program:

The main conclusion of our two year pilot study is that institutional programs, however effective, count for little after the ex-convict reaches the street. The social pressures faced are so overwhelming as to make change very difficult.

We recognized very early in our work the advantages of a post-release program.

Our philosophic and theoretical orientation led us to encourage inmates to plan and execute their own program.

We fondly hoped for a halfway house run by ex-inmates along the lines of the successful Synanon program.

In June 1961 a non-profit organization, Freedom Center, was set up to administer the post-release program.

Our hopes for a convict-run halfway house did not materialize.

We had too few men in the Boston area and they were to caught up in the desperate struggle to survive, to spare time to help others.

In 1961 as a beginning step towards a halfway house, we began "Project Contact." The purpose of this project was to keep in regular contact with all group members.

By these means we were able to reach ninety-one percent of ex-inmates living in Massachusetts.

A newsletter and personal letters also kept up contact and seemed to be effective in helping the rehabilitation spirit stay alive.

But increased contact only strengthened our convictions than an A.A. type organization of ex-convicts is necessary.

The initial step of finding the small nucleus of men who are ready to make the dedication needed has not yet taken.

As a possible solution we hope to be able to send two ex-inmates to spend a month living at Synanon House, Santa Monica.

The director of Synanon, Mr. Chuck Dederich has expressed interest in this project.

The next step of selecting two ex-inmates to make the trip is waiting to be taken.

Upon their return, Freedom Center is prepared to offer its resources to support a local self-help residence program.

Results:

Plans and hopes are one thing but the actual score card of accomplishments provides the crucial evidence. What are the available results?

Psilocybin is safe:

Thirty-five inmates and ten Harvard staff members have had group Psilocybin experiences at Concord.

There were 131 inmate ingestions and 37 staff ingestions, a total of 168 experiences. There were no episodes of violence, lasting disturbances or negative after-effects.

Physically and psychologically there is clear cut evidence that in a supportive environment the drug effect is safe and positive.

Those interested in using psilocybin for research or therapy purposes can proceed with confidence if their program is open, supportive, collaborative.

Psilocybin produces temporary states of spiritual conversion, interpersonal closeness and psychological insight.

Forty-five percent of the entire inmate group clearly underwent a mystical, transcendent, death-rebirth experience.

This figure should be modified, however. The results for running sessions improved so that 100% of our recent groups were undergoing transcendent experiences.

The life changing therapeutic effects of the psilocybin experience do not last for more than 72 hour unless the subject is in a situation which encourages him to maintain his emotional and spiritual insights.

Therefore, psilocybin must be used in on-going programs of therapy or self-help. When employed in such programs psilocybin is a dramatically useful, educational and rehabilitative instrument.

If the subject shares time and space subsequently with those who have had the experience his chances of maintaining ths insights are increased.

The actual score board is difficult to interpret. The aims of this project were: 1) to help keep men on the street and 2) to help them in constructive contact with each other.

Result Percentages:
January 15, 1963
Percentage of men released who are now on street 73
Percentage of men now back for technical parole violation 19
Percentage of men now back for new crimes 8

If ex-convicts who have had a psilocybin experience in a supportive environment meet regularly after release (these statistics suggest one a month) the chances of their remaining on the street will be dramatically improved.

The Harvard staff members - Dr. Ralph Metzner, Gunther Weil, Dr. Ralph Schwitzgebel, Johnathan Clark, David Kolb, Michael Hollingshead, Kathy Harris, Dr. Timothy Leary - who contributed several thousands of hours each to this work cared deeply and suffered keen disappointments as they witnessed the failures.

But the results summarized in this report offer some consolation that the time shared in psilocybin experiences, and the meetings in and out of Concord were educational and somewhat effective.

Summary

Thirty-one inmates of MCI Concord participated in a rehabilitation program combining:
-Psilocybin administered in a supportive setting, and
-volunteer contact of inmates after release.

The evidence after two years of operation suggests that the drug is safe, that the experience temporarily provides personal and spiritual insight, and has some effect in keeping inmates out of prison.

A listing of the major mistakes and improvements in method will be found ind two publications, one in press and one in preparation.

Convicts gains cited by study.

Insight drugs called boon.

IFIF is the Internal Federation for Internal Freedom, a non-profit organization involving the use of consciousness-expanding drugs.

The supply of the drug has, temporarily at least, been cut off because the medical supervision required by Federal regulation in the administration of drugs for research has been withdrawn.

Backing withers.

But troubles or no, IFIF and the zealous psychologists dedicated to the proposition that widespread use of drugs such as psilocybin will pretty much cure the intellectual ills of mankind are news.

And the group has been asked to vacate the medical building in Charles River Park for lack of medical affiliation.

In addition, the supportive backing at the academic level, principally at Harvard, has been withering.

The latest concerns a study made on the religious impact the drug ingestion made on some 33 convicts at the Concord Reformatory in which eight Harvard psychologists worked on the pilot program.

Dr. Timothy Leary, one of the co-founders of IFIF, wrote the report on the pilot program which began in mid-March of 1961 and continued for almost two years.

Beginning with six convicts a senior investigator and two graduate students, the study came to include 33 convicts and eight psychologists. All participated in the drug ingestion.

In Dr. Leary's opinion, the experiment was an unqualified success. Ingestion of the drugs produced "sudden insight that one has been living in a narrow space-time-self context."

"It's all a game, Doc, cops and robbers - we're such tough guys," he quotes one convict as saying. "We take it all so seriously as though that's all there is to life."

He reports also of frequent mystical insight among the convicts, particularly the death-rebirth experience.

"I felt helpless and wanted to murder you guys who did it to me; then I realized it was my own mind doing it; it's always been my own mind imagining troubles and enemies," he quotes one convict.

Return rate drops.

Over half the hardbitten convicts displayed a sudden swing towards increased religious understanding and need, according to the study report.

More important, perhaps, in the long run is the fact that the recidivism rate among the convicts who have been discharged dropped sharply.

"Seventy-five percent are holding their own against stiff winds and treacherous currents," Dr. Leary says.
The expected return rate of ex-convicts to the Concord Reformatory would be between 50 and 70 percent.
But even in his claimed success among the convicts, Dr. Leary runs up against a Doubting Thomas in the Reformatory Superintendent Edward Grennan.

Control questioned.
Grennan feels that study was done without a control and was therefore unscientific.
"These men received an extremely high degree of personal attention," he said. "The psychologists even set up a kind of criminal AA for the paroled prisoners in Cambridge. They made themselves available to them around the clock."
"I feel that the same rate of recidivism might have been achieved if the same concentration and attention were given to any parolee by highly-placed members in any community."
Commenting on the religious aspects of the survey, Prof. Walter Houston Clark of the Andover-Newton Theological Seminary had this to say:
"The student of religious behavior who studies phenomena such as those described in the study cannot but be struck by the similarities to intense religious groups of an evangelistic nature."
"As with them, the experience tends to be dramatic; individuals are changed as to their life goals and the experience tends to be individualized, for while some are greatly helped, there are others on whom the experience seems to have very little permanent effect."

Similarities noted.
"However, it may not be without significance that 62 percent of one group, as indicated in the study, reported their lives were changed for the better; for studies have indicated that roughly the same percentage find help in MRA and AA."
On the basis of the study report, Prof. Clark hinds the psilocybin experience to be mystical in nature. As such, and administered with proper setting and preparation, he feels it may release latent religious sensitivities to make possible an experience closely akin to a truly religious experience with a profound change in attitudes and values resulting.
He sees the drugs as useful also in the form and rehabilitation of convicts (and all others) to more wholesome life aims, a factor which religion could not ignore. But he ends on a note of caution.
"We have been speculating quite freely, basing our speculations largely on the experiences of a few convicts. But enough has been done to suggest creative possibilities in the drugs, the most constructive seemingly to lie in the field of religion and moral regeneration. The use of the substance, however, is very much in the experimental stage, and must have medical and scientific psychological supervision. But its results cannot be ignored by scholars, theologians or leaders of organization.
Such, then, is the latest triumph of the IFIF oriented group. Or are the naysayers correct in holding to their deep doubts?

Dr. Leary's Concord Prison Experiment - A 34 Year Follow-Up Study

Abstract

This study is a long-term follow-up to the Concord Prison Experiment, one of the best known studies in the psychedelic psychotherapy literature. The Concord Prison Experiment was conducted from 1961-1963 by a team of researchers at Harvard University under the direction of Timothy Leary. The original study involved the administration of psilocybin-assisted group psychotherapy to 32 prisoners in an effort to reduce recidivism rates. This follow-up study involved a search through the state and federal criminal justice system records of 21 of the original 32 subjects, as well as personal interviews with two of the subjects and three of the researchers, Timothy Leary, Ralph Metzner and Gunther Weil. The results of the follow-up study indicate that published claims of a treatment effect were erroneous. This follow-up study supports the emphasis in the original reports on the necessity of embedding psilocybin-assisted psychotherapy with inmates within a comprehensive treatment plan that includes post-release non-drug group support programs. Despite substantial efforts by the experimental team to provide post-release support, these services were not made sufficiently available to the subjects in this study. Whether a new program of psilocybin-assisted group psychotherapy and post-release programs would significantly reduce recidivism rates is an empirical question that deserves to be addressed within the context of a new experiment.

Keywords: psilocybin, psychedelic, psychotherapy, recidivism, Leary, Concord Prison Experiment

Background

This paper reports on the results of a long-term (34 year) follow-up study to the Concord Prison Experiment, one of the best known studies in the psychedelic psychotherapy research literature.[1] The Concord Prison Experiment was originally conducted during 1961-1963 by a team of Harvard researchers under the direction of Timothy Leary (Leary 1963; Leary *et al*. 1965; Leary & Metzner 1968; Leary 1969; Riedlinger & Leary 1994).

The Concord Prison Experiment arose out of preliminary research into the subjective effects of psilocybin (Leary, Litwin & Metzner, 1963). Leary and associates found that 88% of their subjects in the preliminary study reported that they learned something of value about themselves and the world, while 62% claimed that the experience of psilocybin changed their lives for the better. In some subjects, the administration of psilocybin produced a "mystical" or "transcendent" experience similar to experiences of religious conversion. Based upon the preliminary evidence, Leary speculated that psilocybin experiences might be powerful catalysts of behavior change in subjects with criminal records.

Research evaluating the use of psychedelic psychotherapy in subjects with criminal records was also being conducted around the same time by Tenenbaum, who administered LSD to criminal sex offenders while they were incarcerated in Atascadero State Hospital, California (Tenenbaum 1961), and, in the Netherlands, by Arendsen Hein, who administered a series of doses of LSD to twenty-one chronic criminal offenders (Arendsen Hein 1963). These studies generated promising results but focused on measuring symptom, behavior and personality changes rather than recidivism, the return to prison post-release for parole violations or new crimes.

Design of the original experiment

The Concord Prison Experiment was designed to evaluate the use of a form of psilocybin-assisted group psychotherapy in the reduction of rates of recidivism. As described by the researchers, the form of treatment was "a collaborative group program; we avoid the traditional doctor-patient, researcher-subject, professional-client roles (Leary *et al*. 1965)."

The subjects in the study, all volunteers, were incarcerated in Massachusetts Correctional Institute Concord, located outside of Boston not far from Cambridge, where Harvard University is located. Subjects were limited almost entirely to prisoners nearing their possible parole dates, with just a few subjects released more than a year after the experiment concluded. Leary thought that recidivism would be an objective measure of behavior change that would more persuasively demonstrate the effects of psychedelic-assisted psychotherapy than subjective self-report questionnaires and tests. Differences between pre- and post- values of standardized tests of psychological functioning were also evaluated. Among the tests administered were the Minnesota MultiPhasic Personality Inventory (MMPI), the Thematic Apperception Test (TAT), and the California Personality Inventory (CPI).

The experimental treatment was administered in the context of group therapy, with each group composed of about four subjects and two members of the experimental team. The treatment generally took place over six weeks of bi-weekly meetings which included two administrations of psilocybin. The treatment involved a combination of an initial battery of tests, twice a week non-drug preparation sessions over the course of two weeks at which the test results were discussed and preparations were made for the first psilocybin experience, a day-long group experience of psilocybin with doses ranging from 20-70 mg., several post-psilocybin sessions devoted to discussion and integration of the initial psilocybin experience and preparation for the second and usually final administration of psilocybin, followed by several more non-drug sessions. After the final session, the identical battery of personality tests was readministered with the results again fed back to the subjects. This cycle was repeated over the course of two years for a total of 32 subjects.

In most treatment groups, one subject who had completed the cycle of treatment was included so as to give the new subjects exposure to a peer who had already been through the psilocybin experience. As a further method of providing emotional support to the subjects for their frequently challenging psilocybin experiences, one of the group leaders usually self-administered psilocybin as a demonstration of solidarity and trust in the healing potential of psilocybin.[2]

Once subjects who had completed the treatment process had been approved for parole, additional group meetings were held to address the details of trying to create a new life outside of prison. Though no post-release group meetings were originally planned, they were soon considered necessary to support the efforts of the subjects to live within the law and remain out of prison. Substantial effort was expended by the experimental team to remain in contact with subjects post-parole so as to provide continuing emotional support and leads on jobs and housing. A non-profit organization, Freedom Inc., was created to coordinate post-release efforts. However, Leary noted, "This phase (post-parole) of our program was never fully developed. We now realize that it is necessary to set up a halfway house where members can meet regularly and discuss mutual problems along Alcoholics Anonymous lines. For practical and material reasons, we were limited to irregular individual contacts with group members (Leary *et al*. 1965)."

Reported outcome of the original experiment

The Concord Prison Experiment is generally accepted to have had somewhat beneficial results (Grinspoon & Bakalar 1979) or to have been an astonishing success (Stafford 1979; Lee & Shlain 1985, Stevens 1987) in reducing recidivism rate. In addition, some of the psychological measures showed changes that would be expected to support the development of more positive behaviors.[3]

Recidivism rates of the experimental group were initially measured on January 15, 1963, when 28 of the 32 subjects had already been released from one to eighteen months, with an average ten months post-release. At this first follow-up, Leary reported in two papers that the recidivism rate was 32%, slightly more than half of what Leary claimed was the expected 56% recidivism base rate for inmates at Concord Prison (Leary & Metzner 1968, Riedlinger & Leary 1994). In a slight discrepancy, Leary reported in another paper that the recidivism rate as of January 15, 1963 was just 27% (Leary 1969). In his autobiography, Leary reported that, "We had kept twice as many convicts out on the street as the expected number." (Leary 1968). The recidivism base rates were generated through a review of the records of all 311 prisoners who had been discharged or paroled from Concord in 1959. This recidivism base rate study was conducted by Metzner and Weil, both of whom were graduate students affiliated with the Harvard Social Relations Department and co-investigators with Leary on the prison project (Metzner & Weil 1963).

The longest period of follow-up reported was from data gathered as of July, 1964, when 27 subjects were reported to have been evaluated at from 18-26 months post-release (Leary *et al*. 1965). As of July, 1964, the total recidivism rate of the experimental group was reported by Leary to be no different than the expected base rates, with 41% of the experimental group who had been released reportedly still out of prison and 59% having been reincarcerated.[4]

Despite the lack of a reduction in overall recidivism rates, Leary still claimed that the experimental treatment had a significantly positive influence. Leary reported that in the control data gathered in the base rate study, the recidivism rate was due equally to new crimes and parole violations. However, in the experimental group, 52% were reported to have been returned on parole violations while only 7% were incarcerated for new crimes. With a total recidivism rate of 59%, Leary stated that the expected percentage of subjects reincarcerated for new crimes would have been 29.5% and the expected percentage of subjects reincarcerated for parole violations would also have been 29.5%. The discrepancy between the expected and actual numbers of subjects reincarcerated for parole violations compared to new crimes was reported to be significant at the .01 level.

The difference between recidivism for ostensibly less serious parole violations as compared to new crimes was considered a sign of the continued, though limited, success of the experimental treatment. Leary hypothesized that the higher rate of recidivism in the experimental group attributable to parole violations rather than new crimes might have been the result of the experimental group being more closely supervised than other parolees, resulting in an increased number of technical parole violations of a minor nature. As Leary wrote, "The main conclusion can be stated as follows: One and one half years after termination of the program, the rate of new crimes has been reduced" (Leary, 1965).

Genesis of the follow-up study

Recognizing the historical importance of the Concord Prison Experiment, the Massachusetts Department of Corrections had preserved many of the original records of the experiment. Michael Forcier, a researcher with extensive experience conducting research for the Department of Corrections, was aware of the continued existence of a collection of papers from the Concord Prison experiment. These papers included an uncoded list of the names of the subjects in the experiment, a series of progress reports by Leary, correspondence between Leary and the Department, and some personal accounts written by the subjects about their subjective experiences under the influence of psilocybin.

In 1991, Forcier read an op-ed article about the author of this paper's previously published twenty-five year follow-up study to the Good Friday Experiment, the other major psilocybin experiment that Leary sponsored during his time at Harvard (Doblin 1991). Conducted in 1962 by Walter Pahnke, M.D., then a Ph.D. student working under the direction of Leary, the Good Friday Experiment was designed to evaluate the potential of psilocybin to catalyze religious experiences when taken by religiously inclined people in a religious setting. After reading about the follow-up to the Good Friday experiment, Forcier contacted this author and offered to assist with a long-term follow-up study to the Concord Prison Experiment. After quite a lengthy process, approval was obtained for the Concord follow-up study from the office of then-Governor William Weld.

Research objectives

This follow-up study was conducted in order to measure the impact of the experimental treatment on recidivism rates from both parole violations and new crimes at 2.5 years post-release, the longest point in time for which base rate statistics for a control group had been gathered, and also to review the records of the criminal behavior patterns of the subjects over a 34 year period. A secondary aim was to seek to interview some of the original subjects in order to determine what they felt were the long-term consequences of their participation in the experiment and to gather information on any reported linkages between the subjects' experiences under the influence of psilocybin and the nature of subsequent behavior change.

Due to the importance of the Concord Prison Experiment in the psychedelic literature, the long-term follow-up also offered the opportunity to raise awareness in a new generation of students and researchers about what this author believed at the beginning of this follow-up was a successfully proven approach to behavior change. It was also hoped that this follow-up might help to catalyze additional research extending and expanding on Leary's pioneering study and its reportedly promising results.

Methodology

The follow-up experiment was designed primarily as a search of the criminal histories of the subjects, using both Massachusetts and Federal data bases. A supplemental part of the experiment was planned to include interviews with any subjects who were located and willing to be interviewed. The readministration of the same set of psychological measures used by Leary was considered but rejected since there was no way to link any newly obtained results to the initial scores, which were reported only as group averages.

Limitations of the data set

The criminal histories of the subjects in the Concord Prison Experiment for the time period of the experiment and several years thereafter are contained only in file folders in storage at the Department of Corrections. The Concord Prison Experiment took place well before the records of the Department were computerized, thereby necessitating the follow-up study to be conducted primarily through physical examination of the records on site at the downtown Boston offices of the Department of Corrections. Federal records were accessed via computer.

Although a list of the names of 32 subjects who participated in the experiment was among the papers retained by the Department of Corrections, file folders could be located for only 21 of the original subjects. As a result, there is no way to determine the exact recidivism rate of the entire experimental group for periods of time longer than previously reported by Leary. Nevertheless, the total recidivism rate as of July, 1964 for the sample of 21 subjects whose files were located is quite similar to the rates reported by Leary for the entire experimental group, demonstrating that the lost folders are likely to form a random subset of the entire cohort. As a result, the recidivism rate for the subsample of 21 subjects at 2.5 years post-release is likely to be similar to that of the entire sample. Furthermore, by comparing the cumulative records from the smaller sample of 21 subjects as of July,1964 to that of the larger sample as reported by Leary, also as of July, 1964, it is possible to calculate both lower and upper bounds for the recidivism rate of the entire group of 32 subjects at the timepoint of 2.5 years post-release.

Reanalysis of the reported short-term recidivism success

Leary claimed a remarkable reduction of recidivism rates in the short-run, at the date of the first follow-up as of January, 1963. A careful review of all the source documents, including the base rate study, prove that claims of an initial treatment effect were false. Leary's report of a dramatic treatment effect was the result of a misleading use of the base rate data.

To show an initial treatment effect as of January, 1963, Leary compared the recidivism rates of his experimental group after they had been out of jail an average of ten months (32%) with the recidivism rates of men who had been out of Concord Prison an average of 30 months (56%). The difference between the two rates was called the treatment effect. However, the appropriate comparison should have been between recidivism rates of the experimental and control groups at similar periods of time post-release. Recidivism is, among other factors, a function of how long someone has been out of prison, with rates rising over time since more time presents more opportunities for criminal behavior and police apprehension. Leary's flawed comparison has not been criticized to date, in part because in all the papers in which Leary reported data from the January, 1963 follow-up, he failed to mention that the base rate study figure used for comparison was for recidivism rates at 30 months. Perhaps another factor is that the base rate study was published in a journal that is not widely available.

Also unreported by Leary, the base rate study contained a graph indicating the recidivism rate as a function of time. It was thus easily possible for Leary to have compared recidivism rates at identical periods of time post-release. When the appropriate comparison between the experimental and control group is made for the identical period of 10 months post-release, the recidivism rate for the control group turns out to be 34.3%, compared to 32% for the experimental group. This results in a 2.3% reduction over the base rates, not the 23% reduction reported by Leary. The 2.3% reduction is not significant and is the same as a finding of no treatment effect.

Parole violations or new crimes?

As of the July, 1964 follow-up, Leary reported that only two subjects were returned to jail for new crimes, while 14 were returned as parole violators.[5] The disproportionate rate of recidivism due to supposedly technical parole violations instead of new crimes is the basis of Leary's claim that the Concord Prison experiment was still a success as of July, 1964 despite there being no reductions in overall recidivism rates as compared to the base rate control group. Leary claimed that many of his subjects were returned to prison for minor technical parole violations. He hypothesized that these technical parole violations were due to the extra supervision the subjects received as a result of having been in the psilocybin experiment. Unfortunately, the results of this follow-up do not confirm Leary's claim that virtually all of the subjects in his study who were returned to prison were returned merely for technical parole violations.

Through comparing the findings of the follow-up with Leary's reported results, it was possible, with some difficulty, to discern Leary's method of categorization between new crimes and parole violations. Leary's method involved counted only the reason for the first reincarceration post-release, ignoring everything occurring after that first reincarceration. As of July, 1964, 12 out of the 18 subjects in the subsample of 21 subjects who had been released prior to this date had been returned to prison. By Leary's counting method, only one of these 12 had been returned for a new crime, while 11 had been returned for parole violations. Of the 15 out of 21 subjects who were returned to prison within 2.5 years post-release, only one was returned for a new crime while 14 were returned for parole violations.

Leary's method, using only the reason for the first reincarceration to determine whether a subject was returned to prison for a new crime or a parole violation, isn't as straightforward as it initially appears. For example, many of the experimental subjects were arrested for a new crime while on parole, immediately or shortly thereafter returned to prison as a parole violator because of the new arrest, then subsequently convicted and sentenced for the new crime, all within the follow-up period. By Leary' s counting rules, these subjects were considered parole violators because they were first returned to prison for a parole violation. They were not counted as having committed a new crime despite the fact that they had, in fact, committed a new crime that directly resulted in a rapid return to prison (but initially for violation of parole), followed by a subsequent conviction for the new crime. As another example, several subjects were first returned to prison for a parole violation that was not linked to an arrest with subsequent conviction for a new crime and were subsequently released within the follow-up period. They were then later arrested for a new crime, convicted and returned to prison again for that new crime, all within the follow-up period. These subjects were also counted as having been reincarcerated for parole violations and not new crimes since their first reincarceration was for a parole violation.

It may be true that Leary's subjects were more closely monitored than other parolees. If that were the case, the result of this intensive monitoring would have resulted in a rapid violation of parole for new crimes that had been committed but for which the criminal justice system needed more time to arrive at a conviction. Parolees who were less intensively monitored may not have been returned to prison until they were actually convicted for new crimes. The rapid link between arrests for new crimes and parole violations prior to new convictions, combined with Leary's counting rules, resulted in the illusory appearance that fewer new crimes and more technical parole violations had been committed by the subjects in this experiment. The results look quite different when recidivism due to a new crime is defined as a return to jail during the period of the follow-up for any incident that later resulted in a conviction for a new crime (regardless if the subject was first returned to prison for a parole violation), and a parole violation is defined as a return to prison for anything short of an incident that led to a new conviction (such as not reporting in to the parole officer, not keeping a job, associating with known criminals, or suspicion of or arrest for a new crime but no new conviction). These definitions represent reasonable criteria; the present author is not certain that these are the exact definitions used in the base-rate study.

Using the above definition of a return to prison for the commission of a new crime, it turns out that of the 18 subjects who had been released prior to July, 1964, seven (39%) had been returned to prison for a new crime, five (28%) had been returned for parole violations, and six (33%) had not returned to prison. Of the seven returned to prison due to new crimes, one subject was first returned to prison for a new crime while six had been returned to prison as a result of parole violations linked to incidents that subsequently resulted in convictions for new crimes. Of the five subjects who had been returned for parole violations, two were returned for parole violations linked to a suspicion of a new crime but without conviction. Only three were returned for technical parole violations, in each case due primarily to problems related to the use of alcohol.[6]

Of all 21 subjects evaluated at 2.5 years post-release, eight (38%) had been returned to prison for a new crime, seven (33%) had been returned to prison for parole violations, and six (29%) had not returned to prison. Of the eight returned for new crimes, one was returned first for new crimes and seven were returned for parole violations that were associated with incidents that later resulted in convictions for new crimes. Of the seven returned for parole violations, four were returned for parole violations linked to a suspicion without conviction of a new crime and only three were returned for a technical parole violation, in each case due primarily to problems related to the use of alcohol.[7]

Neither as of the July, 1964 follow-up nor at 2.5 years post-release were a disproportionate percentage of the subjects returned to prison for parole violations as compared to new crimes, when parole violations are defined as returns to prison not linked to convictions for new crimes and new crimes are defined as returns to prison for incidents linked to new crimes. Only a small minority of subjects who were sent back to prison were returned for technical parole violations, just three of 12 (25%) as of July, 1964 and only three of 15 (20%) as of 2.5 years post-release. Regardless of whether the results of the Concord Prison experiment were somehow an improvement on the ratio of new crimes to parole violations in the base rate study, the distinction between parole violations and new crimes is largely meaningless since the majority of what Leary considered "parole violations" were caused by incidents that later led to convictions for new crimes.

Longer-term recidivism rates

Of the 21 psilocybin subjects for whom records could be searched, the actual recidivism rate at 2.5 years (30 months) post-release was 71%, with 15 out of 21 of the subsample having been returned to prison. The bounded range of possible recidivism rates for 2.5 years post-release for the entire experimental group of 32 subjects is 56%-88%.[8]

The 71% recidivism rate of the sample of 21 is just one percentage point below the mid-point of the range of possible values (72%), again suggesting that the subsample is likely to be a random sample of the entire group. The range of possible recidivism rates is similar to the expected recidivism base rate of 56% at 2.5 years post-release, and to the previously reported recidivism rate as of July, 1964 of 59%. There is thus no treatment effect, in terms of reduced recidivism rates, at the longest point in time for which base rate statistics for a control group are available. The finding of no treatment effect at 2.5 years post-release is not surprising, given the lack of such an effect as of July, 1964, with subjects from 18-26 months post-release.

From 30 months post-release to the time when this long-term follow-up was conducted (an additional 31.5 years), the total recidivism rate was 76%. One of the six subjects who stayed out of jail for the first 2.5 years post-release was returned to jail after that period of time for the commission of a new crime, while the remaining five subjects were not reincarcerated.

Follow-up interviews

Only three subjects were able to be located and contacted by phone. Two agreed to be interviewed and one declined. Of the two subjects who agreed to be interviewed, one had returned to prison after participating in the experiment while the other had not. A special meeting was arranged at which the author of this paper brought the two subjects willing to be interviewed to the home of Leary for an emotional reunion and tape-recorded interview. The meeting took place on January 20, 1996, just several months before Leary died. Gunther Weil, one of Leary's co-investigators on the experiment, also participated in the meeting.

Both experimental subjects expressed their gratitude at being able to participate in the experiment. Both felt that they had benefited personally from their psilocybin experiences and did not suffer any long-term negative problems linked to their psilocybin experience. Both had vivid memories of their psilocybin experiences. Neither had taken a psychedelic drug on their own after the experiment.

The subject who returned to prison spoke about a remarkable experience he had while under the influence of psilocybin. He described it as, "being back in the womb I'm seeing a movie, it's my two older brothers and they're saying, 'Mom, can we go out and play?' 'Sure, Bob, sure, Al, you can go out.' I'm saying, 'Wait for me, I want to go out, too.' She says, 'You can't go out.' And I said, 'Why?' And she says, 'Because you're not even born yet.' It was a funny sensation."

He reflected on the experience and commented, "I firmly believe that I would never have gone back to prison if I had had help [post-release], if someone would have guided me, taken an interest. Who the hell wants to do time?" After his final release from jail, he said he became more responsible, got married and became a father. He reported that his son also had served time in jail, and commented that he wished his son could have a psilocybin experience because it might have helped him see his life options in a new, more responsible manner.

The subject who did not return to jail speculated that he was able to stay out of jail primarily because he had a family to return to post-release. The crime for which he went to jail had been committed six years prior to his arrest, which he said came about because he told someone about his earlier crime who then told the police. This subject credited the psilocybin experiences with helping him to stay out of jail, saying, "I know this thing [the psilocybin experience] was great for me in my life for about two years after I had taken it. You know, my wife and I would discuss it every once and a while, and she'd ask me, 'How do you feel?' And I'd say, ' I feel great you and I are together, so I got something out of it.'" He reflected on the content of his psilocybin experience by saying, "You tear your life down and you put it back together."

Leary's reflections

Leary, though weakened by terminal illness, thoroughly enjoyed the meeting with the ex-prisoners. He reminisced about the elation he frequently felt leaving the prison after a successful experimental session, realizing that he had brought a degree of mental freedom to people behind bars.

Leary also mentioned several elements of the experimental design other than the use of psilocybin that he thought were important but might easily be overlooked. The main point he wanted to make was that, "There were no secrets. We gave you guys all the power" The prisoners were given the results of all the psychological tests that were administered, they could decide on the dose they wanted to take, and they even played a role in deciding which other prisoners could participate in the experiment. At that time, this degree of openness was rare but Leary chose to be democratic about information and procedures in order to empower the subjects to take greater control over their lives.

Leary elaborated on the theme of relinquishing control. "Giving full disclosure, no secrets, but one of us [the experimental team] would always be in control, we would trade off. Once I really lost it. At one point, I was sitting there talking to the group and it was like a hypnotic thing. Everybody was like really into it, I was really into it, and suddenly I had this flash like you were all in my web, like a spider. I got into a whole control thing, and I felt really shameful about that. The next minute I collapsed. I kind of woke up and I was on a cot and you guys were all looking at me like mom. I was completely vulnerable, but everybody was so kind and sensitive. It was tremendous."

When asked what changes in the experimental design he would implement if he were to try to replicate the experiment, the first and only change he noted was, "One thing would be to set up the halfway house system.. A support system is really needed." The lack of post-release support was the most important weak link in the therapeutic intervention. This was recognized early on and the experimental team devoted a substantial amount of time keeping in touch with the subjects post-release, trying to find them living arrangements and jobs, and offering emotional support. The establishment of a half-way house was, however, beyond the means of the experimental team.

A higher standard

When Leary left Harvard, he left science behind and focused on becoming a cultural change agent of the most controversial nature. Until now, it has been generally assumed that all his scientific contributions were reliable. Indeed, this author's Good Friday Experiment follow-up study confirmed the basic findings of that Leary-sponsored experiment, although the author did uncover the unreported fact that one of the subjects in the Good Friday experiment had had a difficult reaction and was administered a major tranquilizer during the course of the experiment (Doblin 1991; Roberts & Jesse 1998). Whatever his motivations, Leary's misleading reports about the success of the Concord Prison experiment serve as an object lesson in what not to repeat. With the current renewal of research into the therapeutic use of psychedelic drugs after three decades of almost total prohibition, psychedelic researchers must hold themselves to the highest ethical standards in order to retain a measure of trust with regulators and the general public.

Conclusion

The failure of the Concord Prison Experiment to generate a reduction in recidivism rates should not be interpreted as proof of the lack of value of psychedelics as adjuncts to psychotherapy in criminals. Rather, the failure of the Concord Prison Experiment should finally put to rest the myth of psychedelic drugs as magic bullets, the ingestion of which will automatically confer wisdom and create lasting change after just one or even a few experiences. Personality change may be made more likely after a cathartic and insightful psychedelic experience, though only sustained hard work after the drug has worn off will serve to anchor and solidify any movement toward healing and behavior change. Psychedelic drug experiences are not sufficient in and of themselves to produce lasting change. Leary, who wrote about the importance of set and setting, knew this as well as anyone, and wrote, "The main conclusion of our two year pilot study is that institutional programs, however effective, count for little after the ex-convict reaches the street. The social pressures faced are so overwhelming as to make change very difficult." (Leary 1969).

Leary took the time during the follow-up interview, conducted shortly before his death, to reiterate what he had previously claimed was the major lesson of the Concord Prison experiment; the key to a long-term reduction in overall recidivism rates might be the combination of the pre-release administration of psilocybin-assisted group psychotherapy with a comprehensive post-release follow-up program modeled on Alcoholics Anonymous groups to offer support to the released prisoners.

Of course, it is likely that post-release programs would be of some benefit to all people released from prison, regardless of whether they had received psilocybin-assisted group psychotherapy, drug abuse counseling, vocational training, non-drug psychological treatment, any other program intended to reduce recidivism, or even no treatment at all. As a result of the profound psychological effects of psilocybin, a post-release program for subjects who had received psilocybin might differ in both content and importance from programs for subjects who had received other interventions. Whether a new program of psilocybin-assisted group psychotherapy and post-release programs would significantly reduce recidivism rates is an empirical question that deserves to be addressed within the context of a new experiment.

Notes

1. This article has benefited from extensive critique by Ralph Metzner as well as thoughtful review by Rick Strassman, Tom Riedlinger, Gunther Weil, Charles Grob, and Bob Forte.

2. Experiential accounts by project leaders can be found in High Priest (Leary 1968), and in the account by Metzner, "From Harvard to Zihuatanejo," in the Leary Festschrift Timothy LearyOutside Looking In, edited by Robert Forte, published by Inner Traditions, New York.

3. These personality changes are discussed in detail in Leary et. al. 1965, and Leary & Metzner 1968. In the California Personality Inventory, significant changes were noted in 12 of 18 scales (including sociability, sense of well-being, socialization, tolerance and intellectual efficiency.) There were generally no significant changes in the MMPI with the exception of the D-scale going down from test one to test three.

4. Some confusion may result from the fact that the first journal article that Leary published about the Concord Prison experiment (Leary *et al*. 1965) contains information about recidivism rates as of July, 1964, which showed no overall reduction. Leary's subsequent books and journal articles (Leary 1969; Leary 1968; Leary & Metzner 1968) and historical reviews written by authors to whom Leary spoke (Stevens 1987; Lee & Shlain 1985; Stafford 1979), report recidivism rates only as of January, 1963, which Leary claimed did show a dramatic reduction, and do not even mention that there had been a later follow-up as of July, 1964 which showed no overall reduction. The normal expectation is that later papers and reports contain the most up-to-date information. As a result of being first exposed to the later papers and reports, this author, as well as many other people, initially obtained the mistaken impressions that there had been no follow-up to the Concord Prison Experiment after January, 1963, and that the experiment had succeeded in reducing recidivism rates. Only in one post-1965 paper did Leary ever mention again that there had been a follow-up after January, 1963 in which the recidivism rates were not lower than expected. Leary was not the lead author in that paper, which was written after almost three decades had passed since the 1965 paper (Riedlinger & Leary 1994).

5. Leary's report of two people returned to prison for new crimes as of July, 1964 conflicts with his report as of January 15, 1963, 18 months earlier, when he claimed that three people had already been returned to prison for new crimes. Subject #9 was returned to prison for parole violations linked to a new crime for which he was not convicted, was released after serving additional time, and then returned for parole violations linked to subsequent convictions for new crimes.

6. Subjects #2, #9, #13, #17, #19, and #21 were returned to prison for parole violations for incidents that subsequently resulted in new criminal convictions. Subject #4 was returned to prison for a new crime. Subjects #5 and #10 were suspected of committing new crimes but were not convicted, while Subjects #12, #15, and #20 were returned for problems related to their use of alcohol.

7. Between the July, 1964 follow-up and 2.5 years post release, three additional subjects were released from

Concord. Subject #3 was returned to prison for skipping parole but was not suspected of committing any new crimes. Subject #6 was returned for a parole violation related to suspicion of involvement in an armed robbery for which he was not convicted. Subject #7 was returned to prison for a parole violation linked to suspicion of involvement in theft, was released after serving additional time, and then returned for a conviction of armed robbery.

8. As of July, 1964, Leary reported that 27 out of the 32 subjects had been released from prison. Of the 27 who had been released, 16 had returned to prison and 11 had not, for a recidivism rate of 59%. In the subsample of 21 subjects, 18 had been released from prison prior to July, 1964. Of those 18 who had been released, 12 had returned to prison and six had not, for a recidivism rate of 67%. Thus, out of the nine subjects who had been released as of July, 1964 and whose file folders were not located, simple subtraction indicates that four must have been returned to prison (16 minus 12) and five were not (11 minus 6). There were also five subjects who had not been released from prison as of July, 1964. In the subsample of 21 subjects, three were released only after July, 1964. Of that three, two were returned to prison for parole violations within 2.5 years post-release while the third was returned to prison for a new crime, but not until after 2.5 years post-release. Therefore, the best possible outcome at 2.5 years post-release would be 56% (18/32; 12 subjects from the subsample of 21 who went back to prison before July, 1964, four subjects from the missing files who Leary reported went back to prison by July, 1964, and two subjects from the subsample of 21 who were released from prison after July, 1964 and who returned to prison within 2.5 years post-release). This lower bound of 56% is exactly what the base rate statistics were for 2.5 years post-release. The worst possible outcome at 2.5 years post-release would be 88% (28/32).

Reflections on the Concord Prison Project and the Follow-Up Study

by

Ralph Metzner, Ph.D.

from Journal of Psychoactive Drugs Vol 30(4)

original source: http://www.maps.org/research-archive/ralphmetzner_concord_follow-up.pdf
backup source: http://www.psilosophy.info/resources/ralphmetzner_concord_follow-up.pdf

Rick Doblin has provided a valuable service to the field of psychedelic research by conducting critical follow-up studies to the Good Friday study of religious experiences as well as the study discussed here on a "behavior change" program for convicts at Concord Prison. I was probably more deeply involved in the project and in the writing-up of the results than anyone besides Leary. I spent the better part of two years out of my four-year graduate program on this project, and though it was not the area in which I did my thesis research, I did also do a clinical internship in Concord prison supervised by Dr. Madison Presnell (who was also the supervising psychiatrist for the psilocybin project).

It is disconcerting, of course, to discover 35 years after the fact that a research project I was involved in and wrote about made quantitative errors and reported erroneous conclusions. As I read Rick Doblin's findings, and re-read our original papers, it did give me occasion to reflect on that period, and what was called the Harvard Psilocybin project - and to come to the depressing conclusion that none of it did any better than chance (as far as one could tell from the tests). Leary was, at that time, a respected, experienced and committed research scientist, who had spent a decade doing statistical evaluations of psychotherapy. The graduate students in the project, such as Gunther Well and myself, were equally committed to doing exacting and rigorous demonstrations. Well and I, for example, spent most of a summer in the archives of the State Department of Corrections, poring through hundreds of prisoner files and assembling the data we needed to calculate an appropriate recidivism base-rate, against which any behavior change program could be measured.

The two dominant paradigms in the Department of Social Relations at Harvard (of which the Center for Research in Personality was a part) were behaviorism and Freudian psychoanalysis. For this reason, Tim Leary was particularly pleased with the prospect of trying the psychedelic insight treatment with convicts. Having just shown that the subtle personality changes that psychotherapists feel sure happen, can't be demonstrated to happen, he pointed out that in the recidivism rate (the rate of return to prison after being released on parole) we had the perfect in controvertible behavioral index of personality change. Personality tests would also be given before and after the therapy, but they were secondary.

It was therefore with some dismay that the members of our project realized, after almost a year of running dramatic, seemingly life-changing psilocybin sessions with convicts in the prison, that we (and the prisoners) didn't have a clue as to what to do for them once they got out of the prison and how to help them make it in society. In the 1965 paper published in *Psychotherapy: Theory, Research and Practice*, which I mostly drafted, I remember sharing the disappointing conclusion that our group's recidivism rate was not different from the base-rate. We did find and report significant changes in several scales on the California Psychological Inventory, and one on the MMPI; as well as some inconclusive behavioral ratings changes. And that is the way I have held the study in my mind ever since - deep personality changes occurred, but in order to maintain changed behavior outside of the prison, some kind of half-way house or rehab program is essential.

This conclusion was stated clearly in our reports. Leary actually devoted a tremendous amount of time and energy to finding ways that our project could somehow help the paroled convicts who had been through our program, "make it" on the outside, i.e., trying to help them find jobs, places to live, and offering them companionship. I remember trips to Boston bars to meet with some of the men, just to keep in touch. Leary has described (in chapter 10 of *High Priest*) his extreme and almost comical efforts on behalf of an uneducated, unskilled, lower class, alcoholic petty thief who was the first to graduate from our program - including eventually giving him a job at the Center for Personality Research (the "job" being to find another job) and renting him a room in his family home, with his kids.

Thirty-five years is a long time from which to recall details of a statistical research project. Although I wrote up the results of the final and longer follow-up in the 1965 paper. I have to say at this point I have no idea how Leary came up with the "finding" that the return rate for parole violations Was up and for new crimes down (hence the over- all rate unchanged). This "finding," which has now turned out to be erroneous, was of course the kind of result we wanted to find - it enabled us to maintain a positive, enthusiastic attitude in talking about this project. We fell victim to the well-known "halo effect," by which researchers tend to see their data in as positive a light as possible. I have myself, in later years, sometimes forgotten the basically negative result we reported in the study, and talked about the project as if we lowered the recidivism rate.

In this sense, I'm grateful to have this late opportunity to acknowledge a chastening correction. Rick Doblin's analysis of the situation shows that most prisoners who were actually returned for parole violations had also committed new crimes - so that the distinction itself is an artifact. Similarly, I have at this time no idea where the 10-month follow-up figure of 32% recidivism in our group came from. In the article in the *British Journal of Social Psychiatry*, which he apparently wrote before the project was completed(though it was not published until 1968), Leary (erroneously) compared this 32% figure to the 30-month base rate figure - thereby arriving at a significant overall reduction. He stated these as "extremely tentative" results, subject to further analysis. Nevertheless, they are clearly inconsistent with our own results (reported in the 1965 article) of no difference in overall rate of return. As Doblin points out, Leary was able to get this seemingly positive finding only by using the wrong control figure. In the paper from *Psychedelic Review*, which was excerpted from the then forthcoming *High Priest*, he repeated the same mistake - and I, as editor, didn't catch it. Clearly we were both under the "halo-effect." Leary was also by this time no longer playing what he called "the scientist game."

Whether Leary made these mistakes consciously, faking the results that he wanted, or whether they were unconscious mistakes of carelessness, motivated by overenthusiasm, is impossible to say at this point. I tend to favor the latter alternative, if only for the reason that our own results clearly show the inconsistencies. Our basic finding remains, then as now: that with psychedelics (and other programs) profound experiences of insight and personality change can be brought about, but criminal behavior patterns take a much more concerted system of rehabilitation and community support to change. The interviews done 30 years later with two of the men document this in a direct and touching way.

The one statement of Doblin's that I would still question is the need for a "higher standard" or "highest ethical standards in order to regain a measure of trust from regulators." In my opinion, the existing accepted standards of honesty and truthfulness are perfectly adequate. We have those standards, not to curry favor with regulators, but because it is the agreement within the scientific community that observations should be reported accurately and completely. There is no proof in any of this re-analysis that Leary unethically manipulated the data. Careless mistakes were made, no doubt; mistakes that made the data look more like we wanted them to look. But to make mistakes is neither unethical nor unscientific. It's an integral part of the scientific method that when mistakes are found, they are reported and corrected. In this sense, I appreciate the better understanding that comes. from this more complete and accurate review of the Concord prison project.

Selective Enhancement of Specific Capacities Through Psychedelic Training

Comments and Speculations

> (This article discusses exploratory work that was interrupted early in 1966 when the Food and Drug Administration, as a strategy in combating the illicit-use problem, declared a moratorium on research with normal human subjects. In view of the preliminary nature of the work, it would not under ordinary circumstances have been submitted for publication. However, because of the significance of the hypotheses, and because they are consistent with experience gained in a previous study of four hundred subjects who received psychedelics in a therapy context, and because of the hope that when it is again possible to resume psychedelic research the non-medical applications will get long-overdue attention, the decision was made to release these results in their present, unfinished form.)

Amid much controversy over the place of psychedelic chemicals in contemporary culture, we have quietly entered a third phase of the research on human uses of these agents.

The first phase, typically identified in the literature by the use of the adjective "psychotomimetic," was characterized by dominance of *a priori* structured models. Seriously underestimating the effects that such preconceptions might have on the content and aftereffects of the subjective experience, researchers variously reported that psychedelics mimicked mental illness (when given in a setting that provoked it), illuminated Freudian theory (when administered by a competent Freudian), evoked Jungian archetypes (when administered by a sensitive Jungian), substantiated the tenets of behavior therapy (by increasing suggestibility and modifiability), and demonstrated the soundness of the existential approach.

The second phase, adopting Osmond's neologism "psychedelic," was characterized by an emphasis on allowing the drug session to run its natural course, in an attempt to minimize the influence of the conceptions and interpretations of the therapist or monitor. Care was taken to provide such expectations, rapport, and environment that the experience would be as non- threatening as possible. Opinions varied as to what constitutes optimum set and setting, and subjects and experimenters varied. As a consequence, reported effects range from ecstasy to psychosis, from community to isolation, from greatly enhanced mental and perceptual abilities to greatly impaired abilities. From this work emerged a variety of psychotherapeutic applications, well summarized by Hoffer (1965), as well as widespread, mainly illicit, use with sensual, philosophical, and transcendental goals.

Growing out of this informal experimentation and clinical research, largely as a consequence of suggestive spontaneous occurrences, the possibility gradually emerged that specific kinds of performance might be selectively enhanced by deliberate structuring of psychedelic-agent administrations. Thus a third phase of psychedelic research began. Whereas, in the first phase, experiences tended to be controlled and delimited-never mind if inadvertently-by preconceptions of experimenter and subject, and in the second phase they tended to be more uncontrolled and wide-ranging in scope, now the emphasis was to be on deliberate selection of specific aspects of the psychedelic experience and of specific parameters of functioning.

As these experiments on specific performance enhancement through directed use of the psychedelics have gone on in various countries of the world, on both sides of the Iron Curtain, and as, furthermore, some, at least, of the informal exploration has been in defiance of existing laws governing use of the psychedelic agents, publicly available information on results is scant and scattered. In the remainder of this chapter we shall discuss one pilot study in which the particular type of performance chosen for attention was creative problem-solving ability. The implications of the work are, we believe, much broader than this particular application. Indeed, the basic assumption underlying setting up the project, and not negated by any of our observations during the course of the research, is that, *given appropriate conditions, the psychedelic agents can be employed to enhance any aspect of mental performance, in the sense of making it more operationally effective*. While this research was restricted to intellectual and artistic activity, we believe the assumption holds true for any other mental, perceptual, or emotional process. The psychedelic agent acts as a facilitator, an adjunct to the situation it facilitates, neither good nor evil, efficacious nor powerless, safe nor dangerous.

Rationale Behind the Creative Problem-Solving Study

Reports in the literature on psychedelic agents that deal with effects on performance are inconclusive or contradictory. Changes in performance levels have been intensively investigated, both during and after the drug session. Instrumental learning has been found to be impaired during the drug experience in some studies, enhanced in others. Similarly, contradictory results have been noted for color perception, recall and recognition, discrimination learning, concentration, symbolic thinking, and perceptual accuracy (Mogar, 1965a).

In some of the research, where impairment was reported, the drug was used as a stresser with the intention of simulating psychotic performance-impairment. Practically all of the formal research in which improved performance was claimed subsequent to the drug experience has been in a clinical context. Performance enhancement during the drug experience has been sporadically reported in both experimental and clinical research, but not in general where the psychotomimetic orientation was dominant.

Our experience in clinical research (Mogar and Savage, 1964; Fadiman 1965; Savage *et al*., 1966) had been amply convincing with regard to the possibility of long-term performance enhancement through employment of the psychedelic agents in a clinical setting. We also had much evidence with regard to the subtlety and pervasiveness of the influence of set and setting. Furthermore, although they had not been deliberately sought, there were numerous spontaneous incidents of what appeared to be temporarily enhanced performance during the drug experience itself. These observations led us to postulate the following propositions:

1. Any human function, as generally elicited, can be performed more effectively. This amounts to an acknowledgement that we do not function at our full capacity.
2. The psychedelics appear to temporarily inhibit censors that ordinarily limit the mental contents coming into conscious awareness. The subject may, for example, discover his latent ability to form colored imagery, to hallucinate, to recall forgotten experiences of early childhood, to generate meaningful symbolic presentations, etc. By leading the subject to expect enhancement of other types of performance-creative problem solving, learning manual or verbal skills, manipulating logical or mathematical symbols, sensory or extrasensory perception, memory and recall-and by providing favorable preparatory and environmental conditions, it may be possible to improve the level of functioning in any desired respect.
3. Both objective and subjective indicators of mental performance are appropriate to use in establishing whether there has indeed been an improvement (or impairment) of performance.

As Table 1 indicates, commonly observed characteristics of the psychedelic experience seem to operate both for and against the hypothesis that the drug session could be used for performance enhancement. In this research we attempted to provide a setting that would maximize those characteristics that tend toward improved functioning, while minimizing those that might hinder effective functioning.

TABLE 1
SOME REPORTED CHARACTERISTICS OF THE PSYCHEDELIC EXPERIENCE
(as found in the literature and in subjects' reports)

Those supporting creativity	Those hindering creativity
1. Increased access to unconscious data.	1. Capacity for logical thought processes diminished.
2. More fluent free association; increased ability to play spontaneously with hypotheses, metaphors, paradoxes, transformations, relationships, etc.	2. Ability to consciously direct concentration reduced.
3. Heightened ability for visual imagery and fantasy.	3. Inability to control imaginary and conceptual sequences.
4. Relaxation and openness.	4. Anxiety and agitation.
5. Sensory inputs more acutely perceived.	5. Outputs (verbal and visual communication abilities) constricted.
6. Heightened empathy with external processes, objects, and people.	6. Tendency to focus upon "inner problems" of a personal nature.
7. Aesthetic sensibility heightened.	7. Experienced beauty lessening tension to obtain aesthetic experience in the act of creation.
8. Enhanced "sense of truth," ability to "see through" false solutions and phony data.	8. Tendency to become absorbed in hallucinations and illusions.
9. Lessened inhibition, reduced tendency to censor own by premature negative judgment.	9. Finding the best solution seeming unimportant.
10. Motivation heightened by suggestion and providing the right set.	10."This-worldly" tasks seeming trivial, and, hence, motivation decreased.

For several reasons we chose to focus our efforts on creative problem solving. One was its obvious utility, an important consideration at that juncture because of the increasing pressure for stricter regulation of the psychedelics by those who doubted that they were good for anything at all. Another factor was that many of the observed spontaneous occurrences had been of this sort. Finally, because of extensive recent research activity in the field of creativity, a number of relevant objective measures were available for use. Interest centered on three questions:

1. Can the psychedelic experience enhance creative problem-solving ability, and if so, what is the evidence of enhancement?
2. Can this result in enhanced production of concrete, valid, and feasible solutions assessable by the pragmatic criteria of modern industry and positivistic science?
3. Working with a non-clinical population and with a non-therapy orientation, would there nevertheless result demonstrable long-term personality changes indicative of continued increased creativity and self-actualization?

Procedure

The subjects in these experiments were twenty-seven males engaged in a variety of professional occupations (sixteen engineers, one engineer-physicist, two mathematicians, two architects, one psychologist, one furniture designer, one commercial artist, one sales manager, and one personnel manager). Nineteen of the subjects had had no previous experience with psychedelics. The following selection criteria were established:

1. Participant's occupation normally requires problem-solving ability.
2. Participant is found to be psychologically stable as determined by psychiatric interview-examination.
3. Participant is motivated to discover, verify, and apply solutions within his current work capacity.

Each group of four subjects met one another during an evening session several days before the experimental day. (In one of the groups, one subject had to be eliminated, which left only three.) The proposed sequence of events during the experimental session was explained in detail. This initial meeting also served the function of allaying apprehension and establishing rapport and trust among the members and the staff.

Subjects were told that they would experience little or no difficulties with distractions such as visions, involvement with personal emotional states, and so on. The instructions emphasized that the experience could be directed as desired. Direct suggestions were made to encourage mental flexibility during the session. An excerpt from those instructions is quoted below:

> Some suggestions on approaches:
>
> Try identifying with the central person, object, or process in the problem. See how the problem looks from this vantage point.
>
> Try asking to "see" the solution, to visualize how various parts might work together, to see how a certain situation will work out in future, etc.
>
> You will find it is possible to scan a large number of possible solutions, ideas, data from the memory etc., much more rapidly than usual. The "right" solution will often appear along with a sort of intuitive "knowing" that it is the answer sought. You will also find that you can hold in conscious awareness a number of ideas or pieces of data processes simultaneously, to an uncommon extent.
>
> You will find it is possible to "step" back from the problem and see it in new perspective, in more basic terms; to abandon previously tried approaches and start afresh (since there is much less of yourself invested in these earlier trials).
>
> Above all, don't be timid in the ambitiousness with which you ask questions. If you want to see the completed solution in a three-dimensional image, or to project yourself forward in time, or view some microscopic physical process, or view something not visible to your physical eyes, or re-experience some event out of the past, by all means ask. Don't let your questions be limited by your notion of what can and what cannot happen.

Approximately one hour of pencil-and-paper tests were administered at this time. Subjects were told that they would take a similar battery during the experimental session. To insure that the problems to be worked on were appropriate for the purpose, each participant was asked to present his selection briefly. By the end of the preparation session, participants were generally anticipative and at ease. They had been given a clear picture of what to expect, as well as information on how to cope with any difficulties that might arise.

The session day was spent as follows:

8:30 Arrive at session room
9:00 Psychedelic material given. Mescaline sulphate (200 mg).
9-12 Music played, subjects relaxed with eyes closed
12-1 Psychological tests administered
1-5 Subjects work on problems
5-6 Discussion of experience; review of solutions.

Participants were driven home after this. They were given a sedative, which they might take if they experienced any difficulty in sleeping. In many cases, however, they preferred to stay up until well after midnight, continuing to work on insights and solutions discovered earlier in the day.

Each subject wrote a subjective account of his experience within a week after the experimental session. Approximately six weeks after the session, subjects were administered questionnaires that related to (1) the effects of the session on post-session creative ability and (2) the validity and acceptance of solutions conceived during the session. These data were in addition to the psychometric data comparing results of the two testing periods.

Subjective Reports

The literature on creativity includes analytical description of the components of creative experience, the personal characteristics of creative individuals, and the distinguishing features of creative solutions. From the participants' reports, it was possible to extract eleven strategies of enhanced functioning during the session. The relationship of these strategies to enhanced functioning should be self-explanatory. Those readers interested in the relationship of these aspects to current research and theory on creativity can refer to the detailed technical discussion in Harman, McKim *et al*. (1966).

The factors are listed below with representative quotations from the subjects' reports.

1. Low Inhibition and Anxiety:
"There was no fear, no worry, no sense of reputation and competition, no envy, none of these things which in varying degrees have always been present in my work."
"A lowered sense of personal danger; I don't feel threatened any more, and there is no feeling of my reputation being at stake."
"Although doing well on these problems would be fine, failure to get ahead on them would be threatening. However, as it turned out, on this afternoon the normal blocks in the way of progress seemed to be absent."

2. Capacity to Restructure Problem in Larger Context:
"Looking at the same problem with (psychedelic) materials, I was able to consider it in a much more basic way, because I could form and keep in mind a much broader picture."
"I could handle two or three different ideas at the same time and keep track of each." "Normally I would overlook many more trivial points for the sake of expediency, but under the drug, time seemed unimportant. I faced every possible questionable issue square in the face."
"Ability to start from the broadest general basis in the beginning ..."
"I returned to the original problem. ... I tried, I think consciously, to think of the problem in its totality, rather than through the devices I had used before."

3. Enhanced Fluency and Flexibility of Ideation:
"I began to work fast, almost feverishly, to keep up with the flow of ideas."
"I began to draw ... my senses could not keep up with my images ... my hand was not fast enough ... my eyes were not keen enough ... I was impatient to record the picture (it has not faded one particle). I worked at a pace I would not have thought I was capable of."
"I was very impressed with the ease with which ideas appeared (it was virtually as if the world is made of ideas, and so it is only necessary to examine any part of the world to get an idea). I also got the feeling that creativity is an active process in which you limit yourself and have an objective, so there is a focus about which ideas can cluster and relate."
"... dismissed the original idea entirely, and started to approach the graphic problem in a radically different way. That was when things started to happen. All kinds of different possibilities came to mind. ..."
"And the feeling during this period of profuse production was one of joy and exuberance. ... It was the pure fun of doing, inventing, creating, and playing."

4. Heightened Capacity for Visual Imagery and Fantasy:
"Was able to move imaginary parts in relation to each other."
"... it was the non-specific fantasy that triggered the idea."
"The next insight came as an image of an oyster shell, with the mother-of-pearl shining in different colors. I translated that in the idea of an interferometer-two layers separated by a gap equal to the wave length it is desired to reflect."
"... As soon as I began to visualize the problem, one possibility immediately occurred. A few problems with that concept occurred, which seemed to solve themselves rather quickly. ... Visualizing the required cross section was instantaneous."
"Somewhere along in here, I began to see an image of the circuit. The gates themselves were little silver cones linked together by lines. I watched the circuit flipping through its paces. ..."
"I began visualizing all the properties known to me that a photon possesses and attempted to make a model for a photon. ... The photon was comprised of an electron and a positron cloud moving together in an intermeshed

synchronized helical orbit. ... This model was reduced for visualizing purposes to a black and white ball propagating in a screw-like fashion through space. I kept putting the model through all sorts of known tests."

5. Increased Ability to Concentrate:
"Was able to shut out virtually all distracting influences."
"I was easily able to follow a train of thought to a conclusion where normally I would have been distracted many times."
"I was impressed with the intensity of concentration, the forcefulness and exuberance with which I could proceed toward the solution."
"I considered the process of photoconductivity. ... I kept asking myself, "What is light?" and subsequently, "What is a photon?" The latter question I repeated to myself several hundred times till it was being said automatically in synchronism with each breath. I probably never in my life pressured myself as intently with a question as I did this one." "It is hard to estimate how long this problem might have taken without the psychedelic agent, but it was the type of problem that might never have been solved. It would have taken a great deal of effort and racking of the brains to arrive at what seemed to come more easily during the session."

6. Heightened Empathy with External Processes and Objects:
"... the sense of the problem as a living thing that is growing toward its inherent solution."
"First I somehow considered being the needle and being bounced around in the groove."
"I spent a productive period ... climbing down on my retina, walking around and thinking about certain problems relating to the mechanism of vision."
"Ability to grasp the problem in its entirety, to 'dive' into it without reservations, almost like becoming the problem." "Awareness of the problem itself rather than the 'I' that is trying to solve it."

7. Heightened Empathy with People:
"It was also felt that group performance was affected in ... subtle ways. This may be evidence that some sort of group action was going on all the time."
"Only at intervals did I become aware of the music. Sometimes, when I felt the other guys listening to it; and it was a physical feeling of them listening to it."
"Sometimes we even had the feeling of having the same thoughts or ideas."

8. Subconscious Data More Accessible:
"... brought about almost total recall of a course that I had had in thermodynamics; something that I had never given any thought about in years."
"I was in my early teens and wandering through the gardens where I actually grew up. I felt all my prior emotions in relation to my surroundings."

9. Association of Dissimilar Ideas:
"I had earlier devised an arrangement for beam steering on the two-mile accelerator which reduced the amount of hardware necessary by a factor of two. ... Two weeks ago it was pointed out to me that this scheme would steer the beam into the wall and therefore was unacceptable. During the session, I looked at the schematic and asked myself how could we retain the factor of two but avoid steering into the wall. Again a flash of inspiration, in which I thought of the word "alternate." I followed this to its logical conclusion, which was to alternate polarities sector by sector so the steering bias would not add but cancel. I was extremely impressed with this solution and the way it came to me."
"Most of the insights come by association."
"It was the last idea that I thought was remarkable because of the way in which it developed. This idea was the result of a fantasy that occurred during Wagner [Note: the participant had earlier listened to Wagner's 'Ride of the Valkyries.']. ... I put down a line which seemed to embody this [fantasy]. ... I later made the handle which my sketches suggested and it had exactly the quality I was looking for. ... I was very amused at the ease with which all of this was done."

l0. Heightened Motivation to Obtain Closure:
"Had tremendous desire to obtain an elegant solution (the most for the least)."
"All known constraints about the problem were simultaneously imposed as I hunted for possible solutions. It was like an analog computer whose output could not deviate from what was desired and whose input was continually perturbed with the inclination toward achieving the output."

"It was almost an awareness of the 'degree of perfection' of whatever I was doing."
"In what seemed like ten minutes, I had completed the problem, having what I considered (and still consider) a classic solution."

11. Visualizing the Completed Solution:
"I looked at the paper I was to draw on. I was completely blank. I knew that I would work with a property three hundred feet square. I drew the property lines (at a scale of one inch to forty feet), and I looked at the outlines. I was blank.
Suddenly I saw the finished project [Note: the project was a shopping center specializing in arts and crafts]: I did some quick calculations ... it would fit on the property and not only that ... it would meet the cost and income requirements ... it would park enough cars ... it met all the requirements. It was contemporary architecture with the richness of a cultural heritage ... it used history and experience but did not copy it."
"I visualized the result I wanted and subsequently brought the variables into play which could bring that result about. I had great visual (mental) perceptibility; I could imagine what was wanted, needed, or not possible with almost no effort. I was amazed at my idealism, my visual perception, and the rapidity with which I could operate."

Results: Subjective Ratings

As mentioned above, several weeks after the experimental session all participants were asked to complete a brief questionnaire. Here they rated their experience with respect to nine characteristics relevant to enhanced functioning. Items were rated on a five-point scale from MARKED ENHANCEMENT (+2) through NO CHANGE (O) to MARKED IMPAIRMENT (-2). The average ratings are listed in Table 2. These data, too, seem to substantiate the hypothesis of enhancement of both verbal and non-verbal skills.

TABLE 2
MEAN SUBJECTIVE RATINGS OF FACTORS
RELATED TO ENHANCED FUNCTIONING
(all ratings refer to behavior during the session) n = 27

Values	Mean	S.D.
1. Lowering of defenses, reduction of inhibitions and anxiety	+1.7	0.64
2. Ability to see the problem in the broadest terms	+1.4	0.58
3. Enhanced fluency of ideation	+1.6	0.69
4. Heightened capacity for visual imagery and fantasy	+1.0	0.72
5. Increased ability to concentrate	+1.2	1.03
6. Empathy with external processes and objects heightened	+0.8	0.97
7. Empathy with other people heightened	+1.4	0.81
8. Data from "unconscious" more accessible	+0.8	0.87
9. Enhanced sense of "knowing" when the right solution appears	+1.0	0.70

Results: Psychometric Data

Test-retest scores on some of the measures used showed dramatic changes from normal to psychedelic-session conditions. Most apparent were enhanced abilities to recognize patterns, to minimize and isolate visual distractions, and to maintain visual memory in spite of confusing changes of form and color. Specific tests used included the Purdue Creativity, the Miller Object Visualization, and the Witkin Embedded Figures. This last test has been reported to be stable under a variety of experimental interventions including stress, training, sensory isolation, hypnosis, and the influence of a variety of drugs (Witkin *et al.*, 1962). With these twenty-seven subjects, enhancement was consistent ($p<.01$), and in some cases improvements were as great as 200 percent. (For a fuller description of the psychometric evaluation, see Harman *et al.*, 1966.)

Long-term Results

The practical value of obtained solutions is a check against subjective reports of accomplishment that might be attributable to temporary euphoria. The nature of these solutions varied; they included: (1) a new approach to the design of a vibratory microtome, (2) a commercial building design, accepted by the client, (3) space probe experiments devised to measure solar properties, (4) design of a linear electron accelerator beam-steering device, (5) engineering improvement to a magnetic tape recorder, (6) a chair design, modeled and accepted by the manufacturer, (7) a letterhead design, approved by the customer, (8) a mathematical theorem regarding NOR-gate circuits, (9) completion of a furniture-line design, (10) a new conceptual model of a photon, which was found useful, and (11) design of a private dwelling, approved by the client.

Table 3 outlines the initial results of attempting to apply the solutions generated in the experimental sessions back into the industrial and academic settings of the subjects. (These data were obtained by questionnaire and follow-up interview six to eight weeks after the session.) A quote for a follow-up report written several months after the session is typical of the relative usefulness and validity of the session-day solutions: "In the area of ionospheric source location and layer tilt analysis, I was able in the weeks following the session to build on the ideas generated to the extent of working out the mathematics of the schemes proposed, and of making them more definite. The steps made in the session were the correct ones to start with ... the ideas considered and developed in the session appear as important steps, and the period of the session as the single most productive period of work on this problem I have had in the several months either preceding or following the session."

TABLE 3
OUTCOME OF PROBLEMS ATTEMPTED IN EXPERIMENTAL SESSION
ONE MONTH AFTER SESSION DATE

new avenues for investigation opened	20
working model completed	2
developmental model to test solution authorized	1
solution accepted for construction or production	6
partial solution obtained being developed further or being applied	10
no further activity since session	1
no solution obtained	4
total number of problems attempted*	44

* Many subjects attempted more than one problem during the session.

Many subjects in the follow-up interview reported changes in their modes of functioning that were continuous with the enhancement reported for the session itself (e.g., continuing visualization ability). Table 4 lists the result of a questionnaire dealing with changes in work effectiveness.

TABLE 4
WORK PERFORMANCE SINCE SESSION (n=16)

key	-2	-1	0	+1	+2
1. Ability to solve problems	0	0	8	8	0
2. Ability to relate effectively to others	0	0	8	5	3
3. Attitude toward job	0	0	7	8	1
4. Productivity	0	0	9	5	2
5. Ability to communicate	0	0	10	5	1
6. Response to pressure	0	0	7	8	1

key: -2 marked impairment; -1 significant impairment; 0 no change;
+1 significant enhancement; +2 marked enhancement

The results given in Table 4 indicate that approximately half the subjects reporting were still noticing some change in their performance level several months after the experimental session. These results are particularly interesting in view of the relatively low dosage and the fact that no suggestion was made at any time that continuing changes of this nature were expected. The deliberate anticipation of enhanced performance level, the incitement to a high degree of motivation, and use of a sheltered and non-critical atmosphere-none of these were directly suggestive of long-term personality changes or permanent therapeutic benefit. Yet a certain amount of such change seems to have occurred. One implication is clear: We are dealing with materials and experimental situations that have long-term effects; it would be foolhardy and irresponsible to treat this kind of research as if it were isolated from the fabric of the subjects' lives.

Comments and Speculations

We had originally intended to follow this pilot study with a controlled experiment employing a double-blind design, in which a fraction of the subjects receive an active placebo. This would have addressed the question of whether suggestion alone could account for the performance enhancement. Because of interruption of the research program by government fiat, this extension was never carried out. The need for controlled hypothesis-testing research in this perplexing area of chemical facilitation of mental functioning has become a common plea, and rightly so. But equally needful of furthering is the exploratory sort of research that aims at invention of conceptual models and hypothesis construction. Because of the controversy surrounding use of the psychedelic agents, this latter type of research is even more likely to be slighted.

In the research described, we employed naive subjects. There are clear methodological virtues accruing from the use of untrained subjects. However, when the central question is not one of pharmacological effects, but rather the degree to which certain processes can be facilitated, the more experience the subjects can gain the more we are likely to learn about the process. Thus we would urge the desirability of further investigations employing a series of sessions for each subject.

A similar comment holds with regard to selection of subjects. Clinical studies already referred to indicate that those subjects who are more stable and productive beforehand 4 tend to "benefit considerably from the psychedelic experience along the lines of self-actualization, richer creative experience, and enhancement of special abilities and aptitudes" (Savage *et al.*, 1966). Subjects for this pilot study were deliberately selected to be persons with known reputations as creative individuals. In general, we would expect the outcomes of this kind of research to be more fruitful with gifted rather than "merely normal" subjects.

In contrast with reports of other researchers, we experienced little difficulty in getting subjects to work on psychological tests. Many studies seem to indicate a temporary debilitating effect of psychedelics on higher cortical processes. It seems to us that variables that affect results on these kinds of tests include attitude and motivation as well as ability. We found that discussing this problem with subjects in the preparatory meetings eliminated any tendency in the experimental session to shrug off the tests as meaningless or to resist them as disconcerting. In short, on the tests, as well as in problem solving, by establishing an anticipation of improved performance, we seemed to obtain results that support it.

Assuming that these findings are eventually substantiated by additional research, they find their most obvious application to problem solving in industry, professional practice, and research. Here the procedure could play a role similar to that played by consultants, brainstorming, synectics, and other attempts to augment and "unstick" the problem solver's unsuccessful efforts. A quote from one of our subjects illustrates the possibilities:

"I decided to drop my old line of thinking and give it a new try. The 'mystery' of this easy dismissal and forgetting did not strike me until later in the afternoon, because I had many times before this session indulged in this line of thinking and managed to work up the whole thing into an airtight deadlock, and I had been unable to break, much less dismiss, this deadlock. The miracle is that it came so easy and natural."

A much more important application in the long run, we believe, is the use of the psychedelic agents as training facilitators to gradually upgrade the performance level of already effective personnel. This would require establishment of accepted training procedures and certification provisions for those qualified to use them. This may seem to be a utopian projection from our present state, but we live in an age of rapid change, and it is perhaps not out of the question within a decade.

Among consequences of this line of exploration, the most significant of all, in our estimation, is the gaining of new knowledge of the mysterious higher processes of the human mind, the framing of new and more productive research questions, and the eventual effect on our image of man-of what he can be, and of what he is, of the vast potentialities he has seemingly only begun to tap.

Implications for psychedelic-assisted psychotherapy: a functional magnetic resonance imaging study with psilocybin

Background

Psilocybin is a classic psychedelic drug that has a history of use in psychotherapy. One of the rationales for its use was that it aids emotional insight by lowering psychological defences.

Aims

To test the hypothesis that psilocybin facilitates access to personal memories and emotions by comparing subjective and neural responses to positive autobiographical memories under psilocybin and placebo.

Method

Ten healthy participants received two functional magnetic resonance imaging scans (2 mg intravenous psilocybin v. intravenous saline), separated by approximately 7 days, during which they viewed two different sets of 15 positive autobiographical memory cues. Participants viewed each cue for 6 s and then closed their eyes for 16 s and imagined re-experiencing the event. Activations during this recollection period were compared with an equivalent period of eyes-closed rest. We split the recollection period into an early phase (first 8 s) and a late phase (last 8 s) for analysis.

Results

Robust activations to the memories were seen in limbic and striatal regions in the early phase and the medial prefrontal cortex in the late phase in both conditions ($P<0.001$, whole brain cluster correction), but there were additional visual and other sensory cortical activations in the late phase under psilocybin that were absent under placebo. Ratings of memory vividness and visual imagery were significantly higher after psilocybin ($P<0.05$) and there was a significant positive correlation between vividness and subjective well-being at follow-up ($P<0.01$).

Conclusions

Evidence that psilocybin enhances autobiographical recollection implies that it may be useful in psychotherapy either as a tool to facilitate the recall of salient memories or to reverse negative cognitive biases.

Declaration of interest

None.

Psilocybin is a classic psychedelic ('mind-manifesting') drug, pharmacologically related to the prototypical psychedelic, lysergic acid diethylamide. Psychedelic drugs were used extensively in psychotherapy in the 1950s to lower psychological defences and facilitate emotional insight.[1] In cognitive terms, the 'lowering of defences' may be thought of as a decrease in top-down emotional control. There are several reports in this literature of spontaneous autobiographical recollections or 'relivings' under psychedelics[2] - similar in some respects to the dream-like sequences seen on stimulation of the medial temporal lobes[3] or to the flashback phenomena seen in post-traumatic stress disorder (PTSD).[4] In a previous psilocybin functional magnetic resonance imaging (fMRI) study by our group,[5] one individual reported a striking reliving under the drug, further motivating us to test this phenomenon in a controlled manner. We also observed large decreases in resting state activity in the medial prefrontal cortex after psilocybin.[5] The medial prefrontal cortex is known to exert top-down inhibitory control over limbic activity,[6] so a psilocybin-induced deactivation of the medial prefrontal cortex - leading to a disinhibition of limbic activity - may explain the occurrence of spontaneous recollections in the psychedelic state.

Thus, the present study sought to test the hypothesis that psychedelic drugs facilitate autobiographical recollection, using psilocybin and a blocked fMRI paradigm involving personal memory cues. Spontaneous relivings under psychedelics are often explicitly linked to past traumata;[2] however, we used only positive memory cues in order to minimise the risk of adverse reactions. We predicted that psilocybin would augment subjective and neural responses to personal memories. Based on previous studies implicating medial temporal and visual association regions in vivid autobiographical recollections,[7-9] we predicted that psilocybin would increase activations in these specific regions.

Method

Design

This was a placebo-controlled cross-over study approved by a local National Health Service research ethics committee and research and development body, and conducted in accordance with good clinical practice guidelines. A Home Office licence was obtained for storage and handling of a schedule 1 drug. The University of Bristol sponsored this research.

Participants

Fifteen healthy individuals were recruited, all via word of mouth. However, only 13 completed the behavioural component of the fMRI study because of presentation software failure for 2 individuals after administration of psilocybin, and three further data-sets were removed because of scanner artefacts, rendering the functional data unusable. Of the ten remaining participants, nine were male, all were physically and mentally healthy, with a mean age of 31 years (s.d.= 7.5), and all had used psilocybin before (average 16.4 uses, s.d.= 27.2), but not within 6 weeks of the study. Participants attended a screening visit during which their mental and physical health was assessed. This included a brief psychiatric interview, routine blood analysis, electrocardiogram, blood pressure and heart rate, and a neurological examination.

Derivation of autobiographical memory cues

After enrolment, participants were given at least 2 weeks to provide 30 or more personal memories for use in the fMRI behavioural paradigm. They were instructed that these should refer to specific life events, and not general periods of time, and that they should be especially positive and emotionally salient. To avoid embarrassment, individuals were advised to encrypt especially personal memories so that they could only be understood by themselves. Cues were abridged to one sentence (e.g. 'Remember being at the altar getting married'). To control for recency effects, participants were asked to estimate the approximate age they were at the time of the event, and to rate the emotionally potency of the memory on a scale of 0-3, with 3 being 'especially potent' (i.e. capable of eliciting a strong emotionally response and/or vivid recollection). The 30 most potent memories were split into 2 groups of 15 memories and balanced for recency and potency. Each group was randomly assigned to either the psilocybin or placebo condition.

Scanning procedure and drug administration

Participants attended two scanning sessions, separated by at least 7 days. Psilocybin (2 mg in saline) was received on one day, and placebo (saline only) on the other, in a balanced order across participants. Solutions (10 ml) were administered during scanning, as 60 s intravenous infusions.

Participants were cannulated and screened for magnetic resonance compatibility. Prior to functional scanning, we obtained an initial three-dimensional SPGR structural scan in an axial orientation, with field of view 256 x 256 x 192 mm and matrix 256 x 256 x 192 mm to yield 1 mm isotropic voxel resolution (repetition time (TR)/echo time (TE) 7.9/3.0 ms; inversion time 450 ms; flip angle 20°). All scanning was performed on 3 T GE HD x MR system.

Blood oxygen level-dependent (BOLD)-weighted fMRI data were acquired using a gradient echo-planar imaging sequence, TR/TE 3000/35 ms, field of view 192 mm, 64 x 64 acquisition matrix, parallel acceleration factor 2, and flip angle 90°. Fifty-three oblique-axial slices were acquired in an interleaved fashion, each 3 mm thick with zero slice gap (3 x 3 x 3 mm voxels). An initial task-free, eyes-closed, resting state scan took place for 12 min in total. The data from these scans will be presented in a separate publication. Sixty-second manual infusions of either psilocybin or placebo began 6 min after the start of the resting-state scan and the behavioural scan began 7.5 min after the start of the infusion. The subjective effects of intravenous psilocybin (2 mg) peak a few minutes after infusion and persist for approximately 25-30 min (online Fig. DS1 and Carhart-Harris *et al.*[10]); thus, the subjective effects of psilocybin were robust throughout the behavioural scan.

The total duration of the behavioural scan was 18.5 min (370 whole brain volumes).

Functional paradigm

Fifteen memory cues were presented in a blocked paradigm, interleaved with rest and an auditory attention task. The attention task was designed to investigate hypotheses unrelated to autobiographical memory and so the results are not included here. For the memory task, participants were instructed to close their eyes and to open them when cued by a loud auditory tone played through stereo headphones. Individuals were instructed to allow their memories to come back to them during a period of eyes-closed recollection, and not to resist any associated thoughts. Visual stimuli were projected onto a screen behind them which was viewed through a mirror attached to the head coil.

Participants performed the autobiographical memory condition with their eyes closed in order to aid recollection; eyes were also closed in the rest blocks to provide an unbiased baseline state, matched for sensory input. In the rest trials, individuals were first presented with an auditory tone and the visual instruction 'relax', which remained on the screen for 6 s followed by 'close your eyes'. Participants closed their eyes for 16 s before hearing an auditory tone which signalled for them to open their eyes. They were then presented with their first memory cue (e.g. 'Remember playing Oliver in the school play'), which was shown for 6 s before the instruction 'close your eyes'. Individuals were given 16 s to recollect the event before hearing an auditory tone signalling for them to open their eyes. They were then presented with the instruction 'count the beeps', which was shown for 6 s, followed by 'close your eyes' and the onset of the attention task. This task consisted of a sequence of auditory tones of different pitch playing in either ear in a random order. Each participant had to decide whether more tones occurred in their left or right ear and gave their response via button press at the end of the 16 s. There was always one more tone in either the left or the right ear. The fixed sequence of rest-memory-attention was repeated 15 times in total. The rationale for the fixed order was to minimise carry-over effects from the memory trials to the rest trials by using the attention paradigm to distract participants from sustained recollection of the memories.

Subjective ratings

Memory ratings were given after the participants exited the scanner. Each memory was rated for vividness ('How vivid was the memory, if 10 is extremely vivid - i.e. as if you are there experiencing it again?'), emotional intensity ('How strong was the emotion you felt, with 10 being extremely intense?'), valence ('How positive was the memory, if 10 is extremely positive, 5 is neither positive or negative, and 0 is extremely negative?') and visual imagery ('How visual was the memory, if 10 is extremely visual, as if you can see it again?'). Ratings were always given on a 0-10 scale. Descriptive statistics were derived and *t*-tests were performed for between-condition comparisons. Participants were followed up 2 weeks after their scans and asked to rate any changes in their subjective well-being or life satisfaction on a scale of +3 (decreased very much) to +3 (increased very much), with 0 as 'no change'.

Imaging analysis

All imaging analysis was carried out using FSL (www.fmrib.ox. ac.uk/fsl). In the first-level analysis, a general linear model with four regressors was fitted to each participant. There was a regressor for the 16 s of eyes-closed attention to beeps and a regressor of no interest for the periods when the task instructions were presented and for when task responses were required. Previous imaging work on autobiographical recollection has found that different neural systems are engaged immediately after the memory cue compared with a few seconds later.[9] Therefore, two regressors were used for the 16 s memory recollection period - one for the first 8 s after the memory cue (early phase) and one for the remaining 8-16 s (late phase). The two primary contrasts of interest were the early memory period *v.* rest, and the late memory period *v.* rest. The regressors were convolved using a double gamma response function, a temporal derivative was added and temporal filtering applied. Data were high-pass filtered with a cut off of 100 s. The functional data were spatially smoothed (6 mm) and registered to each participants' T_1-weighted high-resolution (1 x 1 x 1 mm) structural scan which was itself registered to the Montreal Neurological Institute standard brain (1 x 1 x 1 mm) using non-linear registration.

The results of fitting this model at the first level were combined in a higher-level within-participants analysis to compare brain activation under psilocybin with activation under placebo. A mixed-effects analysis was performed to produce group statistics. Statistical parametric maps were cluster thresholded and a whole-brain cluster significance threshold of $P<0.05$ was used. To determine the mean activation maps for recollection *v.* rest under psilocybin and placebo, group means were derived for each condition. FSL fMRI Expert Analysis Tool (FEAT) query was used to compute BOLD per cent signal change for specific contrasts. Pearson's correlations were used to compare regional BOLD changes with subjective ratings - and specific variables were chosen on a hypothesis-driven basis. Given that recollection and emotion is typically thought to involve medial temporal lobe and limbic structures, anatomical regions of interest were created for bilateral parahippocampal gyrus and the amygdala based on the Harvard-Oxford probabilistic atlas.

Results

Subjective ratings

Memories were rated as more vivid, visual, emotional and positive under psilocybin than placebo (Fig. 1). Individually, only ratings of vivid (*t*-test, $P= 0.049$, two-tailed) and visual (*t*-test, $P = 0.041$, two-tailed) were significantly different, but if the four parameters (which were highly correlated) are grouped, ratings were significantly higher under psilocybin than placebo (*t*-test, $P = 0.0003$, two-tailed).

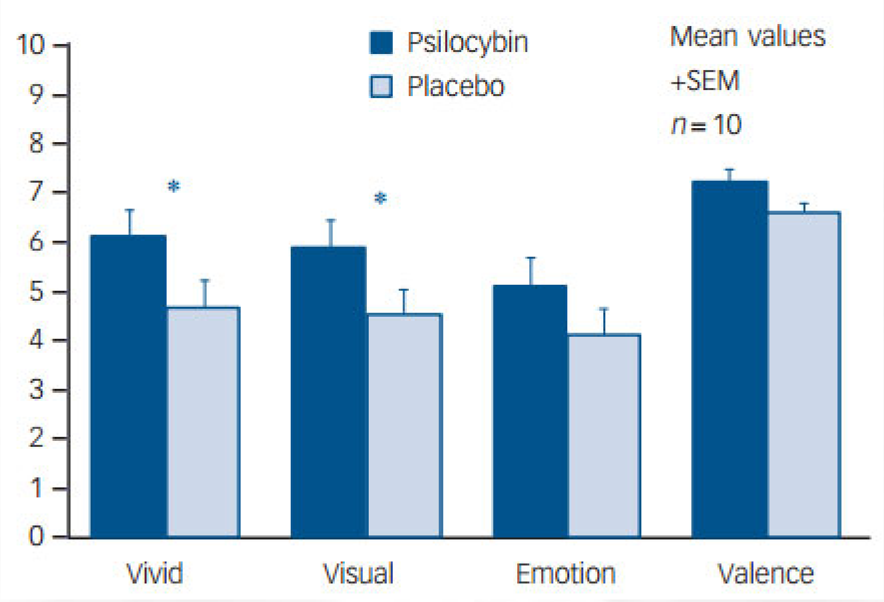

Fig. 1 - Memory ratings after psilocybin and placebo.

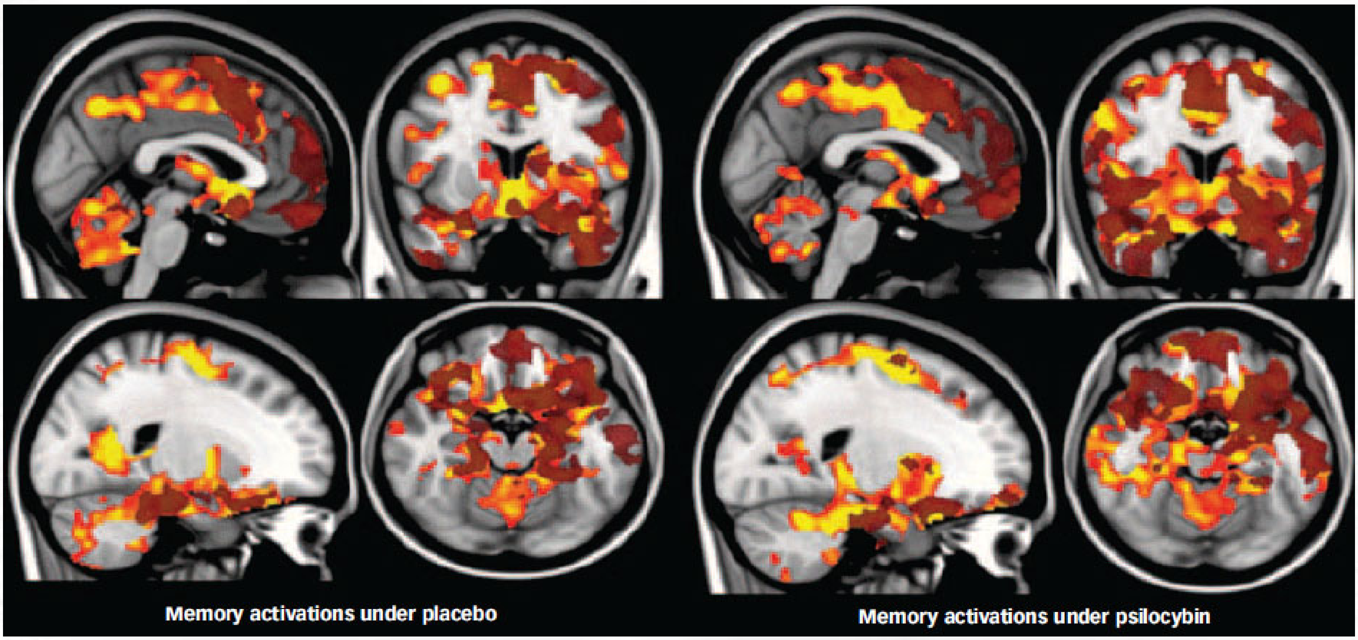
Ratings were significantly higher after psilocybin than placebo for the items 'How vivid was the memory?' and 'How visual was the memory?' (two-tailed *t*-test, $*P<0.05$) and when all four were grouped ($P = 0.0003$).

fMRI results

Activations to memories

Robust activations were observed during cued autobiographical recollection v. rest under both placebo and psilocybin, even with a stringent threshold of $Z = 2$ (whole brain cluster corrected, $P<0.001$; Fig. 2). The contrasts were split up into an early phase recollection period versus rest (orange clusters) and a late phase recollection period *v.* rest (dark red clusters); these were the first and last 8 s of the 16 s recollection period. The early activations were generally more subcortical - and were especially significant in limbic/medial temporal lobe (e.g. amygdala and hippocampus) and striatal regions (e.g. the putamen and nucleus accumbens), as well as the mid-cingulate cortex, pre-sensorimotor area and precuneus. Late activations were seen in limbic (e.g. the amygdala) and paralimbic regions (e.g. the subgenual cingulate cortex and pre-sensorimotor area) and the temporal pole, but there were also large activations in the medial prefrontal cortex and frontal pole that were notably absent in the early recollection period.



Memory activations under placebo
Memory activations under psilocybin

Fig. 2 - Activations during autobiographical recollection v. rest under placebo and psilocybin.

Early phase activations are shown in orange and late phase activations in translucent dark red. Cluster threshold $Z = 2$, whole brain corrected $P<0.001$. The left hemisphere is shown on the right.

Correlations with subjective ratings

Combining the data from each individuals' two scans, there was a significant positive correlation between 'emotion' scores and late phase bilateral parahippocampal activations (Fig. 3, left; $r = 0.4$, $P = 0.04$, one-tailed). There was also a trend-level positive correlation between 'vividness' scores and late phase anterior bilateral parahippocampal activations ($r = 0.35$, $P= 0.07$, one-tailed).

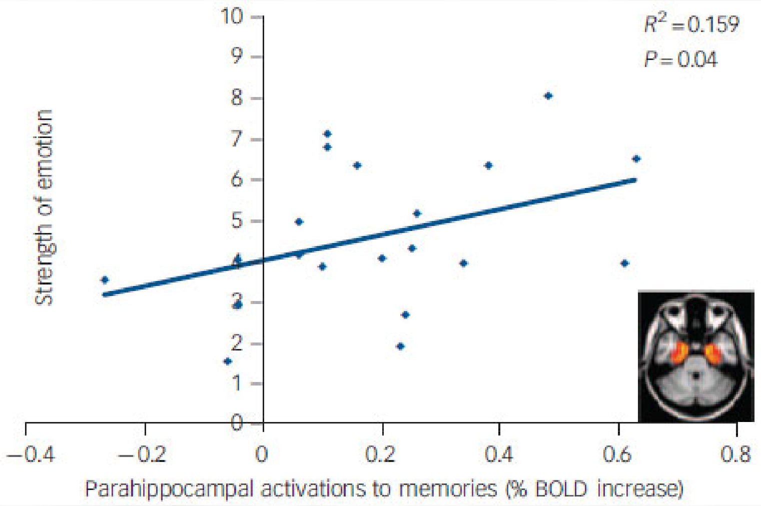


Fig. 3 - Late phase parahippocampal (right) activations correlated positively with how emotional the memories were.

BOLD, blood oxygen level-dependent. Pearson's correlation, $P<0.05$, one-tailed.

Effect of psilocybin on activations to memories

There were no significant differences between early phase activations to memories under psilocybin *v.* placebo. However, there were significantly greater late phase activations under psilocybin than placebo (Fig. 4). These were found in three large clusters, a left occipital pole and visual association region cluster (Fig. 3) and left and right hemisphere clusters that included the mid-insula and primary and secondary auditory cortex, the temporal pole, primary and secondary somatosensory cortex and superior parietal regions (e.g. the superior parietal lobule and supramarginal gyrus). Contrary to prior hypotheses, there were no between-condition differences in medial temporal lobe activations.

Since secondary sensory and high-level attention areas are typically deactivated during periods of introspection,[11] we considered the possibility that the putative activations in these regions under psilocybin were in fact deactivations under placebo. To assess this, we looked at the first-level results for both conditions and calculated the mean percentage BOLD signal change to memories *v.* rest in the three above-mentioned clusters (Fig. 4). One cluster was in the left occipital pole and visual association regions (red in Fig. 4), one was in the left primary and secondary auditory cortex and left somatosensory and superior parietal areas (blue in Fig. 4), and one was in the right primary and secondary auditory cortex and right somatosensory and superior parietal areas (green in Fig. 4). After calculating the mean signal changes in each cluster, large deactivations were evident in the left and right hemisphere clusters under placebo (blue and green, Fig. 4), but true activations under psilocybin were found for all of the clusters - especially the visual one (red, Fig. 4), confirming that visual and other sensory regions are activated by memory cues under psilocybin.

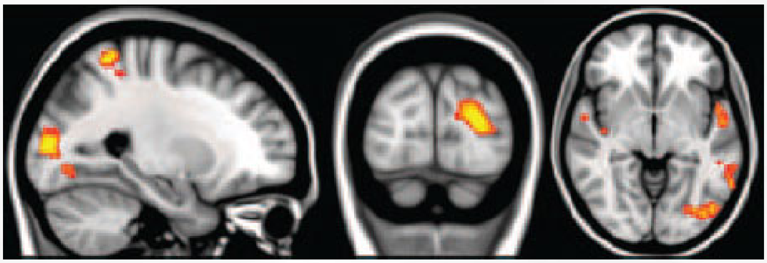

Fig. 4 - Greater late phase activations during autobiographical recollection under psilocybin than placebo.

Cluster threshold $Z = 2$, whole brain corrected $P<0.05$. The left hemisphere is shown on the right.

Follow-up ratings of well-being

When data from the complete sample were analysed ($n = 15$, mean age 30.5 years (s.d.= 7.7), 2 females), reports of well-being 2 weeks after each scan were significantly higher after psilocybin than placebo ($P = 0.03$, two-tailed). To test the hypothesis that participants with the most pronounced subjective responses to positive memories have the largest increases in well-being after psilocybin, we plotted scores of memory vividness against scores of increased well-being post-psilocybin for the 13 participants that completed the memory task in both conditions (Fig. 5). One outlier was removed owing to an explicit non-drug-related event causing him to report an anomalous decrease in well-being post-psilocybin. A significant positive correlation was found between vividness ratings and improved well-being post-psilocybin ($r = 0.72$, $P= 0.004$, one-tailed).

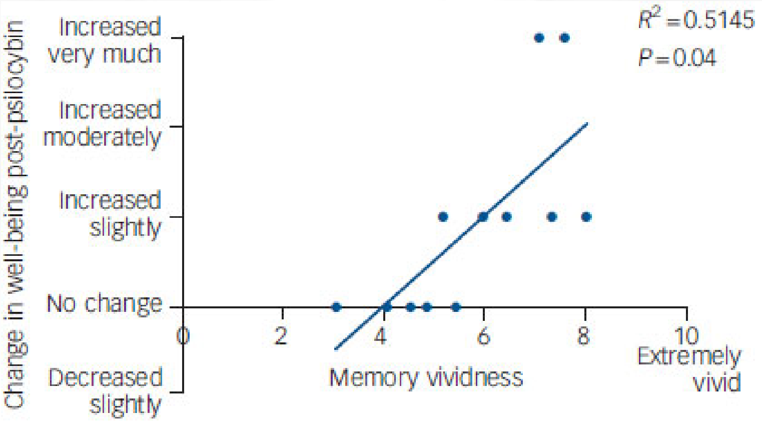

Fig. 5 - Significant positive correlation between ratings of increased well-being post-psilocybin and ratings of memory vividness.

$r = 0.72$, $P = 0.004$, one-tailed.

Discussion

This study sought to test the hypothesis that psychedelics facilitate the neural processes underlying autobiographical recollection using fMRI and the classic psychedelic psilocybin. Robust activations to autobiographical memory cues were found after both placebo and psilocybin, but greater late phase sensory activations and more intense subjective effects were seen after psilocybin. Greater activations were observed in the bilateral auditory cortex, somatosensory cortex, superior parietal cortex, left visual association regions and the occipital pole after psilocybin, and *post-hoc* tests confirmed that visual and other sensory regions were uniquely activated under psilocybin (Fig. 6). This switch in sensory function from a pattern of deactivation under placebo to activation under psilocybin is important and may explain why memories can be felt as especially vivid or 'real' under psychedelics).[2,12,13]

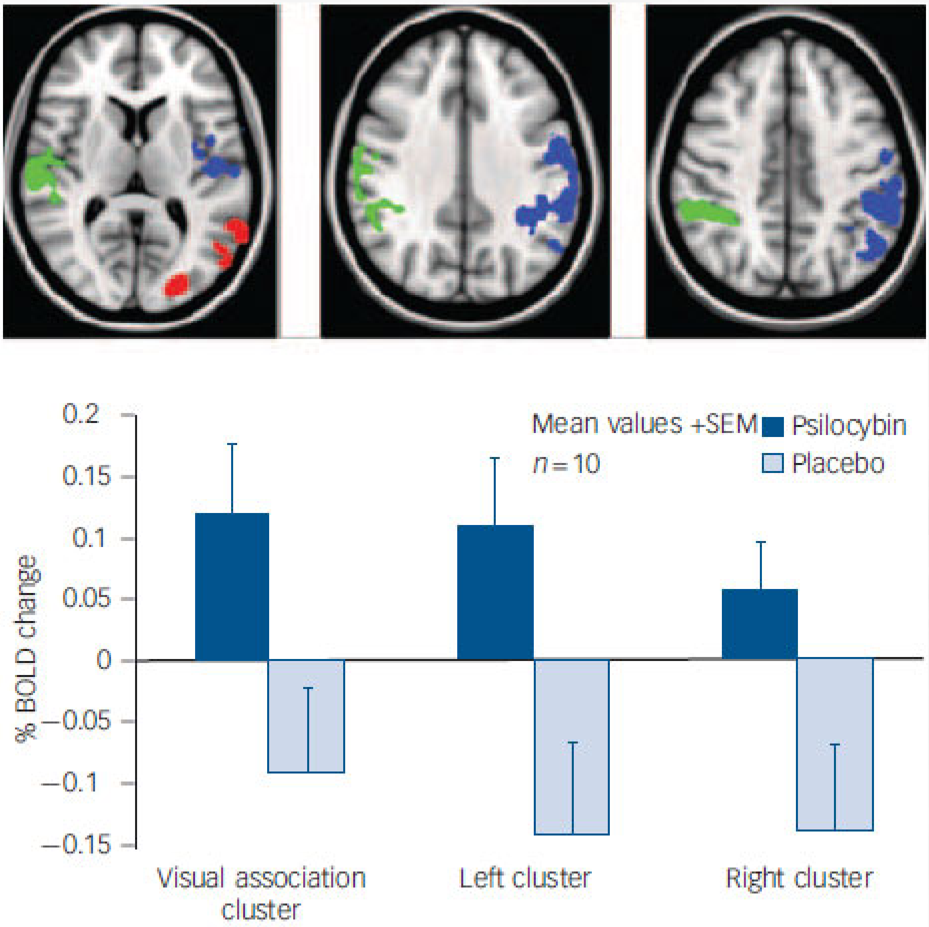

Fig. 6 - Mean per cent blood oxygen level-dependent (BOLD) signal changes to memories v. rest under psilocybin (blue) and placebo (grey).

The left hemisphere is shown on the right.

Relevance to previous studies

Memory activations in both conditions were similar to those found in previous studies. Medial temporal activations are a relatively reliable finding in autobiographical recollection paradigms[6] and have also been shown to correlate with emotional intensity[7] (as shown in Fig. 3). Moreover, early limbic activation followed by a late medial prefrontal component is entirely consistent with previous findings.[9] The early limbic activations are thought to reflect memory retrieval and initial hedonic sensations and the delayed cortical activations are thought to reflect memory elaboration and reliving.[9] Indeed, detailed visual imagery is a hallmark of vivid reliving,[14] and visual cortical activations have been found to correlate positively with ratings of 'reliving' in previous studies.[9] Thus, the greater visual activations in the late recollection phase, when visual imagery becomes more pronounced, plus the reports of more visual and vivid recollections under psilocybin, support the hypothesis that psilocybin augments the neural processes underlying autobiographical recollection.

Subjective experiences

To give a sense of the qualitative difference between the recollective experiences in each condition, one participant commented after his second scan (placebo scan): 'I was focusing on my memories, but there wasn't the same kind of emotional engagement, and I didn't visualise them as realistically as I had done last week [under psilocybin].' When asked whether this meant that he was using his imagination more this time, he said:

> 'I think my imagination had a lot to do with it last time, but it seemed more vivid and real ... I was more attached to the images and putting myself in the scenario than I was today. Today it was like ... I was thinking about it, it was nice, but it was nothing special - nothing new came out of it.'

A number of participants also commented on the brevity of the recollection period and how memories only became more vivid towards the end of the 16 s under psilocybin. For example: 'I think the memories could develop more with more time - you could go deeper with more time'.

Medial temporal lobe involvement in 'relivings'

Despite these positive findings, there were some important negative findings in this study. None of our participants reported anything like the dramatic relivings that are described in the literature on psychedelics.[2,12] We also did not find the hypothesised augmentation of medial temporal lobe responses under psilocybin - despite there being some compelling reasons to expect this: medial temporal lobe activations have been found during flashbacks in patients with PTSD,[15] but the most compelling evidence for a medial temporal lobe involvement in relivings comes from invasive procedures. Wilder Penfield was the first to demonstrate that electrical stimulation of the temporal cortex could produce vivid recollections and reliving,[16,17] and subsequent work has shown that the medial temporal lobes are especially sensitive to this effect.[18] That medial temporal lobe stimulation can generate complex visual imagery is interesting and implies the occurrence of a spreading activation from the site of stimulation to posterior sensory regions. Evidence for this was found in a simultaneous stimulation-depth electroencephalography study, in which stimulation of the anterior medial temporal lobes produced complex visual imagery and a spreading activation to visual association regions in the theta frequency.[19] Thus, our failure to find an exaggerated medial temporal lobe response under psilocybin may explain the absence of relivings, but it would be interesting to explore this issue further with connectivity analyses. For example, using dynamic causal modelling,[20] we might predict an increased medial temporal lobe input to the visual cortex during recollection under psilocybin. We might also predict that connections from the medial prefrontal cortex to medial temporal lobe regions are decreased during recollection under psilocybin. Rostral anterior cingulate cortex blood flow was found to decrease during PTSD flashbacks (and to increase during dissociation),[21] and in a previous psilocybin fMRI study by our group, we found an immediate, marked and sustained drop in medial prefrontal activity after intravenous psilocybin.[5] The medial prefrontal cortex is known to exert a top-down inhibitory control over medial temporal lobe regions;[6] thus, a decrease in medial prefrontal cortex activity may lead to a medial temporal lobe disinhibition.[22]

There are some likely explanations for why we did not observe the predicted relivings in this study. For example, in our efforts to minimise negative drug responses, we used only positive memory cues, but relivings are often linked to painful or conflict-laden memories.[2] An improved design could use conflict-laden memory cues in patients in dynamic psychotherapy, so that any upsetting reactions could be worked through post-session. This would properly test the hypothesis that psychedelics facilitate emotional insight by lowering psychological defences. Also, increasing the duration of the recollection periods would allow a deeper level of introspection. However, despite these limitations, our decision to use only positive memory cues was not without reward; the primary hypothesis that psilocybin augments subjective and neural responses to positive autobiographical memory cues was supported and the experience was well tolerated by all of the participants. Indeed, consistent with previous studies,[23] our sample reported significant improvements in subjective well-being after their psilocybin experience. Moreover, a positive correlation was found between ratings of subjective well-being and memory vividness. The following report from one participant testifies to this:

> 'It being February and having endured the harsh months of a long British winter, I guess I'd been feeling a little blue lately, but right now I feel invigorated, recharged and inspired by the

> experience … What seems to be fuelling my optimism isn't just the drug experience, but the combination of it with refreshing my own memories; it's like I've been reminded of the affirmative aspects of my life.'

Implications for psychedelic-assisted psychotherapy

The primary finding of this study was that psilocybin switched autobiographical memory activations in visual and other sensory regions from a pattern of deactivation to activation (Fig. 6). Participants also reported more vivid and visual recollections under psilocybin - which is consistent with the increased sensory activations. These effects may have implications for the use of psilocybin in psychotherapy. For example, psilocybin could be combined with positive memory cues as a treatment for depression - facilitating the recall of positive life events so to reverse pessimistic mind-sets. Support for such an idea comes from findings of decreased depression scores in patients with anxiety 6 months after a single psilocybin treatment[24] and improvements in well-being and trait openness persisting in healthy volunteers up to 2 years after a single high dose of psilocybin.[23,25] Further supporting the case for psilocybin as a treatment option for depression, we recently observed marked decreases in medial prefrontal cortex activity after psilocybin.[5] Hyperactivity in the medial prefrontal cortex in depression and its normalisation after effective treatment is a highly reliable finding.[26]

Limitations

The sample size in this study ($n = 10$) was small and may have encouraged false negatives. For example, we failed to find significant correlations between between-condition differences in brain activations and subjective ratings, which may have emerged in a larger sample. Another limitation was the self-selecting nature of the sample, which may have biased outcomes. Participants were required to have used psychedelics before, and many held prior assumptions about the positive value of these drugs. This may have contributed to the positive memory ratings, the reports of improved well-being post-administration, and the positive relationship between them (Fig. 6). Importantly, however, such biases cannot easily explain the increased brain activations to memories after psilocybin.

Implications

This study found increased subjective and neural responses to autobiographical memory cues under psilocybin. Greater activations were evident in visual and other sensory regions, which may explain why recollections were rated as more vivid and visual under psilocybin. Psychedelic drugs have a history of use in psychotherapy, linked to the hypothesis that they lower defences to facilitate access to salient emotions and memories. The results of this study provide initial support for this idea and a potential neurobiological mechanism is proposed: decreased medial prefrontal cortex activity leading to disinhibited limbic and sensory activity. We propose that psilocybin may be used in combination with cognitive strategies designed to reverse cognitive biases in depression - and we also suggest that it may be used in more classic dynamic therapy to assist the exploration and understanding of salient emotional themes.

> ... our normal waking consciousness ... is but one special type of consciousness, whilst all about it, parted from it by the filmiest of screens, there lie potential forms of consciousness entirely different.... No account of the universe in its totality can be final which leaves these ... disregarded. How to regard them is the question-for they are so discontinuous with ordinary consciousness.
> William James.[1]

In recent years, how to regard the "forms of consciousness entirely different" induced by mescaline, LSD-25, and psilocybin has posed a seemingly perplexing issue. For articulate self-experimenters from Mitchell to Huxley, mescaline has provided many-splendored visual experiences, or a life-enlarging sojourn in "the Antipodes of the mind"[2]. For Stockings, it may be recalled, mescaline produced controlled schizophrenia[3] - a thesis which earned the Bronze Medal of the Royal Medico-Psychological Association and apparently inaugurated, in conjunction with the advent of LSD-25, a period of concerted chemical activity in the exploration and experimental induction of "model psychoses"[4]. In counterpoint, this same so-called "psychotomimetic" LSD has increasingly found use as a purposeful intervention or "adjuvant" in psychotherapy[5]. The recently arrived "magic mushroom," psilocybin, has been similarly equivocal - "psychotogenic" for some, "mysticomimetic" for others[6]. The present paper will review the literature on drug experience - paying particular attention to the effects of *extradrug* variables, for the realization of the extent of their potential influence has only recently crystallized, and promises to reduce some of the abundant disorder in this area.

The phenomenon of drug-associated rapid personality or behavior change will be discussed in some detail. For example, a number of different alcoholic treatment facilities, especially in Canada, have reported, for many of their patients, complete abstinence after a single LSD session[7]. More generally, neurotic ailments over the full range have been described as practically evaporating[8]. Given this picture, and the present state and practice of the therapeutic art, it is not surprising to find at least one psychiatrist envisioning "... mass therapy: institutions in which every patient with a neurosis could get LSD treatment and work out his problems largely by himself"[9]. James would have been much attracted by the "spectacular and almost unbelievable results"[10] reported on the modern drug scene; and, in fact, their resemblance to the "instantaneous transformations" attendant on "mystical" religious conversions - which he discussed so eloquently - may well be more than superficial and seems worthy of attention.

The Equivalent Action of Mescaline, LSD-25, and Psilocybin

Since the evidence and testimony accumulated over the years on the separate drugs will be treated interchangeably, this raises a preliminary point of some importance. Although the conclusion was delayed by both dissimilarities in their chemical structure and differing modes of introduction to the scientific community, it is now rather commonly adjudged that the subjective effects of mescaline, LSD-25, and psilocybin are similar, equivalent, or indistinguishable. Both Isbell and Abramson have administered LSD and psilocybin in the same study; Wolbach and his co-workers have administered all three. All have found that their subjects were unable to distinguish between the drugs[11].

The reported equivalence in subjective reactions seems quite consistent - or at least not inconsistent - with present pharmacodynamic knowledge. Studies of radioactively tagged mescaline and LSD indicate that the compounds largely disappear from the brain in relatively short order - in fact, at about the same time that the first "mental phenomena" make their appearance[12]. Hence, it has been tentatively suggested that the characteristic effects, which persist for a relatively long period, are to be attributed not to the action of the drug itself but to some as yet unidentified aspect of the chain of events *triggered* by drug administration. Isbell, observing the "remarkably similar" reactions to LSD and psilocybin, hypothesized "some common biochemical or physiological mechanism" to be responsible for the effects - that is, that the various compounds share a final common path[13]. The most direct support for this inference of biological identity in ultimate mechanism of action has come from cross-tolerance studies wherein subjects rendered tolerant to one drug - that is, nonreactive after repeated administrations - have then been challenged by a different drug. Present indications are that cross-tolerance among the drugs does in fact develop[14].

This is not intended to suggest that a drug experience is invariable among subjects - quite the contrary has been the case. In fact, experiences even for the same subject differ from one session to the next[15]. But when relevant extradrug variables are controlled, the within-drug variance is apparently coextensive with between-drug variance, and is attributable to ubiquitous personality differences; in other words, while a range of reactions is reported to *all* of the drugs, there is no reaction distinctively associated with any particular drug. Extradrug variables, which have been uncontrolled and largely unrecognized until recently, are apparently responsible for much of the variance erroneously attributed to specific drug action.

Invariant Drug Reactions

By common consent, the drug experience is paranormal - that is, beyond or outside the range of the normal, the everyday. Exclamations of "indescribable" recurrently appear in the literature. However, whenever descriptions are essayed, there is relative unanimity about certain features. These, it may be said, are attributable to the drug administration, per se, independent of the personality of the subject, the setting, or the experimenter's or subject's expectations. A sampling from the literature of subjective reports and testimony may communicate, or at least transmit the flavor of, these invariant reactions.

First, and perhaps most easily conveyed, is the characteristic of the drug experience called by Ellis a "saturnalia" or "orgy" of vision[16]. Subsequent authors have been only slightly more restrained:

> The predominance of visual experiences in the picture is striking - not only on account of the persistent hallucinations and illusions, but by the impressiveness of seen real objects, their shape and color....[17]
>
> There is a great intensification of light; this intensification is experienced both when the eyes are closed and when they are open.... With this intensification of light there goes a tremendous intensification of color, and this holds good of the outer world as well as of the inner world[18].
>
> When I closed my eyes ... I experienced fantastic images of an extraordinary plasticity. These were associated with an intense kaleidoscopic play of colors[19].

> Changes in the perception of visual form occur in virtually everyone.... Consistently reported [are] the plasticity which the forms of the visual world assume ... the emphasis upon play of light and color, as though light were alive[20].

A second invariant set of drug reactions, more difficult to characterize or communicate, has been called, variously, depersonalization, dissociation, levitation, derealization, abnormal detachment, body image distortion or alteration, and the like:

> There is an awareness of an abnormal distance between the self and what happens in its consciousness; on the other hand, the experience of an abnormal fusion of subject and object[21].

> My ideas of space were strange beyond description. I could see myself from head to foot as well as the sofa on which I was lying. About me was nothingness, absolutely empty space. I was floating on a solitary island in the ether. No part of my body was subject to the laws of gravitation[22].

> What happens in the LSD experience? ... the universe is overtly structured in terms of an identification between the perceiver and the thing perceived. You hear the music way off down in a cavern, and suddenly it is you who is way down in the cavern. Are you now the music, or is the music now at the mouth of the cavern? Did you change places with it? And so on?[23]

> Some degree of depersonalization probably occurs during every LSD experience ... the detachment of the conscious self, a sort of detached ego. This self is in touch with reality and is in touch with the self experiencing the psychic phenomena[24].

Regardless of whatever else a drug experience may be reported to include, alterations in visual experience and in experience of self, as detailed above, may be predicted with considerable confidence[25].

In connection with the so-called dissociation phenomenon - and in view of the connotations of the "psychotomimetic" and "intoxicant" labels - it may be well to emphasize that drug experiences, at least for most nonpsychotic subjects, do not seem to approximate delirium:

> The mescal drinker remains calm and collected amid the sensory turmoil around him; his judgment is as clear as in the normal state....[26]

> It is difficult to classify the state of consciousness during the intoxication which allows such self-observation and, at times, seems to foster detachment and self-scrutiny[27].

> ... in a state of clear consciousness [the subject] ... is able to describe in detail the manifold mental changes daring drug intoxication[28].

The nondelirious condition of normal volunteers, at least with low to moderate drug dosage, has been objectively attested by their ability to perform psychological tests. The most exhaustive series of investigations along this line has been carried out for LSD by Abramson and his associates[29]. Generally, although not consistently, subjects show slight decrements in performance - at least some of which may well be attributable to an altered state of attention-motivation-affect. However, the test setting itself seems to contaminate the drug experience; Savage, among others, has noted "a less profound effect when subjects are kept busy doing psychological tests...."[30]

Another and final set of seemingly invariant reactions concerns the retrospective impressiveness of the drug experience. The succession of testimonials to this effect is a striking and salient feature of the history of research with these compounds:

> In some individuals, the "ivresse divine" is rather an "ivresse diabolique." But in either case ... one looks "beyond the horizon" of the normal world and this "beyond" is often so impressive or even shocking that its after-effects linger for years in one's memory[31].

> The experience of the intoxication, as Beringer also observed, makes a particularly deep

> impression.... The personality is touched to its core and is led into provinces of psychic life otherwise unexplored; light is shed on boundaries otherwise dark and unrevealed and in this some aid may be given to Existenzerhellung (illumination of existence)[32].
>
> ... most subjects find the experience valuable, some find it frightening, and many say that it is uniquely lovely.... For myself, my experiences with these substances have been the most strange, most awesome, and among the most beautiful things in a varied and fortunate life[33].
>
> To be shaken out of the ruts of ordinary perception ... this is an experience of inestimable value to everyone and especially to the intellectual ... the man who comes back through the Door in the Wall will never be quite the same as the man who went out[34].
>
> ... the whole experience is (and is as) a profound piece of knowledge. It is an indelible experience; it is forever known. I have known myself in a way I doubt would have ever occurred except as it did[35].

The "Psychotomimetic" Label

After the above renditions, a querulous reader may be concerned about the appellation "psychotomimetic drugs." So are many contemporary researchers and therapists, too numerous to mention. Holliday has provided a trenchant analysis of "how the semantics in the field of psychopharmacology became so confused and generally misleading"[36]; here, only a few points will be noted.

Early mescaline investigators clearly tempered their comparisons between the mescal-induced state and the hallucinations and dissociations of endogenous psychosis. As far back as 1930, it was found that when chronic schizophrenics suffering from persistent hallucinations were given mescal, they distinguished the mescal phenomena, remarked on their appearance, and usually blamed them on the same persecutors who had molested them before[37]. Kluver, though he foresaw and extensively discussed the "model" values of mescal, persisted in calling it "the divine plant"[38]. It was apparently difficult to consider a sacramental substance - "the comfort, healer, and guide of us poor Indians ... the great teacher"[39] - as unequivocally psychotomimetic.

With LSD, a laboratory-born drug having no history to contend with, the situation changed. The adventurous Hofmann, on that fateful day in 1943, started his self-experiment with 250 micrograms of LSD, thinking, as he put it, that such a small amount would probably be harmless. His response to this quite large dose - in terms of present-day experimental standards - was as follows:

> I noted with dismay that my environment was undergoing progressive change. Everything seemed strange and I had the greatest difficulty in expressing myself. My visual fields wavered and everything appeared deformed as in a faulty mirror. I was overcome by a fear that I was going crazy, the worst part of it being that I was clearly aware of my condition. The mind and power of observation were apparently unimpaired[40].

Hofmann went on to list, as his most marked symptoms, visual disturbances, motor restlessness alternating with paralysis, and a suffocating sensation, and added: "Occasionally I felt as if I were outside my body. My 'ego' seemed suspended in space. ..."[41]

Stoll, who in 1947 reported experimental confirmation of Hofmann's experience, is widely reputed to have warned informally of a case of suicide as the aftermath of an experimental trial. The most common accounts thereafter had a psychotic female subject committing suicide two weeks after the administration; or, in another version, a subject committing suicide after the drug had been administered without her knowledge. At any rate, this story, though itself never appearing in print, is referred to in one form or another in nearly all of the early work with LSD; it apparently influenced experimenter attitudes for a number of years.

For many and varied reasons, too involved to trace here, the initial formulation of the "model psychosis" properties of LSD engendered enormous investigative enthusiasm. In this climate, latent reservations on the score of psychotomimesis tended to go unvoiced. In the more recent, postenthusiasm era, however, reservations have been more or less vigorously expressed - for example:

> There are considerable differences between LSD-induced and schizophrenic symptoms. The characteristic autism and dissociation of schizophrenia are absent with LSD. Perceptual disturbances due to LSD differ from those due to schizophrenia and, as a rule, are not true hallucinations. Finally, disturbances of consciousness following LSD do not resemble those occurring in schizophrenia[42].

Many alternatives to the "psychotomimetic" characterization of "hallucinogenic" agents have recently been proposed. In 1957, Osmond offered, among others, "psychelytic" (mind-releasing) and "psychedelic" (mind-manifesting)[43]. Other investigators have proposed consciousness-expanding, transcendental, emotionalgenic, mysticomimetic, and so forth. It becomes ever more apparent, though, that old labels never die[44].

Variable Drug Reactions and Extradrug Variables

It may probably be stated as a pharmacopoeias commonplace that the effects of a drug administration of any kind are likely to be compounded by factors other than specific pharmacologic action. Often this is attributed to "personality," to individual differences[45]. However, though there have been as yet very few controlled investigations in the case of the drugs considered here, it has become abundantly clear from the *systematic* variability reported in subject and patient reactions - in both the affective and ideational dimensions of drug experience - that factors other than "personality" are also at issue.

Affective reactions attendant on a drug administration have varied, according to reports, all the way from hyperphoric ecstasy to unutterable terror - though not with all investigators. The opinion leader Hoch, through a decade of observations, consistently maintained:

> LSD and mescaline disorganize the psychic integration of the individual....[46]

> ... mescaline and LSD are essentially anxiety-producing drugs... .[47]

The following interchange was recorded at the 1959 conference on the use of LSD in psychotherapy held under the auspices of the Josiah Macy, Jr. Foundation:

> *Hoch*: Actually, in my experience, no patient asks for it [LSD] again.
> *Katzenelbogen*: I can say the same.
> *Denber*: I have used mescaline in the office ... and the experience was such that patients said, "Once is enough." The same thing happened in the hospital. I asked the patients there if, voluntarily, they would like to take this again. Over 200 times the answer has been "No"[48].

Subsequently, Malitz also stated:

> None of our normal volunteers wanted to take it [LSD] again[49].

In contrast, DeShon and his co-workers reported the results of the first LSD study done with normal subjects in this country as follows:

> ... anxiety was infrequent, transient, and never marked.... All subjects were willing to repeat the test[50].

The experience of other investigators has been similar:

> During the past four years we have administered the drug [LSD] hundreds of times to nonpsychotics in doses up to 225 micrograms... . Those who have participated in these groups are nearly always definitely benefited by their experiences. Almost invariably they wish to return and to participate in new experiments[51].

> ... few patients discontinue treatment, in fact, enthusiasm and eagerness to continue are among the features of LSD patients[52].

The rapidly expanding use of LSD in psychotherapeutic contexts has provided highly revealing clues to the patterning of extradrug variability. Busch and Johnson were the first to report administering LSD to neurotic patients whose therapy had "stalled" and whose prognosis was "dim." The result was "a reliving of repressed traumatic episodes of childhood," with "profound" influence on the course of therapy[53]. Sandison and his colleagues also found that LSD "produces an upsurge of unconscious material into consciousness"[54], and that "repressed memories are relived with remarkable clarity"[55] - with therapeutically beneficial consequences.

Since these early reports, whenever psychoanalytically oriented therapists have employed LSD, practically without exception the patient relives childhood memories. The interesting point is that this phenomenon has practically *never* been noted in the experimental literature!

Jungian therapists, on the other hand, have repeatedly found that their patients have "transcendental" experiences - a state beyond conflict - often with rapid and dramatic therapeutic results. As a matter of fact, in an amusing and somewhat bemused account, Hartman has described his LSD-using group comprised of two Freudians and two Jungians, in which the patients of the former report childhood memories, while those of the latter have "transcendental" experiences. In addition, for Jungian patients, the transcendental state is associated with "spectacular" therapeutic results, while for Freudians, should such a state "accidentally" occur, no such spectacular consequence is observed[56].

While not from a therapeutic setting, the reports which have emanated from Harvard are noteworthy on the score of ideational content. Under psilocybin, Harvard subjects do not relive their childhood experiences, but grapple with age-old paradoxes:

> ... the problem of the one and the many, unity and variety, determinism and freedom; mechanism and vitalism; good and evil; time and eternity; the plenum and the void; moral absolutism and moral relativism; monotheism and polytheism and atheism. These are the basic problems of human existence.... We need not wonder that the Indians called the mushroom sacred and gave it a name which means "the flesh of the god"[57].

Without multiplying or belaboring divergences further, it should be apparent that affective reactions and ideational content may be *systematically* variable dimensions of drug experience; in addition, the possible therapeutic uses or consequences, however these are conceived, seem clearly variable. Once these "facts" are arrayed, in Baconian fashion, they nearly speak for themselves. At the Josiah Macy conference, the emerging consensus was perhaps best expressed by Savage:

> This meeting is most valuable because it allows us to see all at once results ranging from the nihilistic conclusions of some to the evangelical ones of others. Because the results are so much influenced by the personality, aims, and expectations of the therapist, and by the setting, only such a meeting as this could provide us with such a variety of personalities and settings. It seems clear, first of all, that where there is no therapeutic intent, there is no therapeutic result... . I think we can also say that where the atmosphere is fear-ridden and skeptical, the results are generally not good.... This is all of tremendous significance, for few drugs are so dependent on the milieu and require such careful attention to it as LSD does[58].

The same conclusion has come from experimental quarters as well - for example:

> [The effect] of hallucinogens is not limited to any single agent since, in addition to psilocybin, we have seen it with LSD-25 and mescaline. The environmental setting in which the drug is administered ... affects the emerging behavior pattern. This factor may account for variations in results with different investigators. Our hospital setting, with the subject, a paid volunteer, receiving an unknown agent, in an experimental framework surrounded by unfamiliar doctors and nurses, differs markedly from the mystical setting which Wasson observed.... Only one of our subjects reported what might be described as a transcendental experience.... The differences in expectation and setting between these two grossly divergent groups may account in part for the disparity in their responses[59].

More specifically, anxiety in the therapist or experimenter about administering the drug, about "inducing psychosis," seems likely to render the experience anxiety-ridden for the subject. Abramson has flatly declared:

"The response of the subject ... will depend markedly upon the attitude of the therapist.... In particular, if the therapist is not anxious about the use of the drug, anxiety in the patient will be much decreased"[60]. Hyde has reported that "impersonal, hostile, and investigative attitudes" arouse hostile and paranoid responses[61]. Sandison has observed that the occurrence of anxiety seems largely to depend on "what the patient is told beforehand [as well as] rumors and myths current among patients and staff, or even in the press, about hallucinogenic drugs"[62]. Huxley had intimated this before it became clarified in the psychiatric literature:

> ... the reasonably healthy person knows in advance that, so far as he is concerned, mescaline is completely innocuous. ... Fortified by this knowledge, he embarks upon the experience without fear - it: other words, without any disposition to convert an unprecedented strange and other than human experience into something appalling, something actually diabolical[63].

That the positive or negative character of the experience can be systematically directed, overriding even personality factors, seems now to have been fairly conclusively demonstrated. With "adequate" preparation - that is, with the specific intent of rendering drug experiences "positive" - approximately 90 percent of the subjects or patients, in each of the two most recent studies, reported at least a "pleasant" or "rewarding" session, and nearly as many called it "an experience of great beauty" or something equally superlative[64].

In content, as in affect, subjects apparently respond to the implicit or explicit suggestion or expectation of the therapist or experimenter. The Harvard subjects were prepared for their metaphysical binges, it may be noted, with such assigned readings as the "Idols of the Cave" parable in Plato's *Republic* and passages from *The Tibetan Book of the Dead*. The preparation of psychotherapy patients hardly needs specification.

Finally, what may be said about therapeutic implications? - given the fact that the compounds under discussion may induce a powerful paranormal experience whose affective and ideational content can be guided. Only perhaps that the extent to which the experience can serve as a useful adjunct to traditional interview therapies, or vice versa, or even as a "compleat therapie" would seem to depend on the particular practitioner of the art - his conceptions of therapeutic gains and consequences, his philosophy and enthusiasm, and his orientation toward "placebo" or "faith" cures[65]. Schmiege has summarized the current state of affairs as follows:

> Those using LSD in multiple doses as an adjunct to psychotherapy feel that it is so useful because of its ability to do the following: (1) It helps the patient to remember and abreact both recent and childhood traumatic experiences. (2) It increases the transference reaction while enabling the patient to discuss it more easily. (3) It activates the patient's unconscious so as to bring forth fantasies and emotional phenomena which may be handled by the therapist as dreams. (4) It intensifies the patient's affectivity so that excessive intellectualization is less likely to occur. (5) It allows the patient to better see his customary defenses and sometimes allows him to alter them. Because of these effects, therapists feel that psychotherapy progresses at a faster rate. Of course this poses the age old problem of what is the essence of psychotherapy.

There are many reports of patients receiving meaningful insight about themselves in an LSD experience without the intervention, participation or even presence of a therapist.... Those who administer lysergic acid in a single dose have as their goal, in the words of Sherwood, *et al.*, an overwhelming reaction "in which an individual comes to experience himself in a totally new way and finds that the age old question 'Who am I?' does have a significant answer." Frequently, this is accompanied by a transcendental feeling of being united with the world.... Some spectacular, and almost unbelievable, results have been achieved by using one dose of the drug[66].

Rapid Personality Change

An increasing number of subjects, patients, experimenters, and psychiatrists - spontaneously or with priming - have declared their drug experiences to be transcendental, mystical, cosmic, visionary, revelatory, and the like. There seems to be difficulty in finding the right name for the experience, even among the professional so-called "mystics":

> There is no really satisfactory name for this type of experience. To call it mystical is to confuse it

> with visions of another world, or of god and angels. To call it spiritual or metaphysical is to suggest that it is not also extremely concrete and physical, while the term "cosmic consciousness" itself has the unpoetic flavor of occultist jargon. But from all historical times and cultures we have reports of this same unmistakable sensation emerging, as a rule, quite suddenly and unexpectedly and from no clearly understood cause[67].

Whatever this type of experience is called, however, a growing body of "expert" testimony apparently confirms the possibility of its induction by drugs. Watts, the dean of current Western Zen scholars, has recently described "cosmic consciousness," courtesy of LSD, in exquisite detail[68]. Seminary students and professors in the Boston area are said to have definitely concluded that their contact with psilocybin was "mystico-religious" (as to whether or not it was "Christian," however, they are still in doubt)[69]. Huxley has been most outspoken about the capacity of the drugs to induce "traditional" mystical-visionary states:

> For an aspiring mystic to revert, in the present state of knowledge, to prolonged fasting and violent self-flagellation would be as senseless as it would be for an aspiring cook to behave like Charles Lamb's Chinaman, who burned down the house in order to roast a pig. Knowing as he does (or at least as he can know, if he so desires) what are the chemical conditions of transcendental experience, the aspiring mystic should turn for technical help to the specialists....[70]

Nearly invariably, whenever dramatic personality change has been noted following the use of these drugs, it has been associated with this kind of experience - that is, one called transcendental or visionary - with the particular name the experience is given seemingly most dependent upon whether the investigator focuses on affect or content. These experiments in drug-induced behavior change will shortly be reviewed in detail.

Examples Not Associated with Drugs

Since accounts of behavior transformations attendant on paranormal experience are not without precedent, it may be helpful to set the stage for present developments by citing some examples not connected with drugs. James reported on the phenomenon in its most familiar and perhaps prototypic context:

> In this lecture we have to finish the subject of conversion, considering it first through striking instantaneous instances of which St. Paul's is the most eminent, and in which, often amid tremendous emotional excitement or perturbation of the senses, a complete division is established in the twinkling of an eye between the old life and the new.

After adducing numerous examples, James continued:

> I might multiply cases almost indefinitely, but these will suffice to show you how real, definite, and memorable an event a sudden conversion may be to him who has the experience. Throughout the height of it he undoubtedly seems to himself a passive spectator or undergoer of an astounding process performed upon him from above. There is too much evidence of this for any doubt of it to be possible. Theology, combining this fact with the doctrine of election and grace, has concluded that the spirit of God is with us at these dramatic moments in a peculiarly miraculous way, unlike what happens at any other juncture of our lives. At that moment, it believes, an absolutely new nature is breathed into us, and we become partakers of the very substance of the Deity[71].

One may also recall to mind the "vision-seeking" American Indians whom Ruth Benedict immortalized. Adapting Nietzsche's designation "Dionysian" to characterize their cultural pattern, she portrayed its fundamental contrast with the "Apollonian" Zuni-Pueblo way of life. The Dionysian "seeks to attain in his most valued moments escape from the boundaries imposed on him by his five senses, to break through into another order of experience." He values "all means by which human beings may break through the usual sensory routine"[72].

Widespread among the western Indians (except in the Pueblos) was what Benedict called the "Dionysian dogma and practice" of the vision-quest - sought by fasting, by torture, and by drugs. The point of interest, of course, is that when the vision came, it could apparently trigger large-scale behavior alterations which had the stamp and reinforcement of social approval.

> ... on the western plains men sought these visions with hideous tortures. They cut strips from the skin of their arms; they struck off fingers; they swung themselves from tall poles by straps inserted under the muscles of their shoulders. They went without food and water for extreme periods. They sought in every way to achieve an order of experience set apart from daily living.
>
> On the western plains they believed that when the vision came, it determined their life and the success they might expect. If no vision came, they were doomed to failure.... If the experience was of curing, one had curing powers; if of warfare, one had warrior's powers. If one encountered Double Woman, one was a transvestite, and took woman's occupations and habits. If one was blessed by the mythical Water-Serpent, one had supernatural power for evil, and sacrificed the lives of one's wife and children in payment for becoming a sorcerer[73].

The final example which will be noted here of rapid personality change not induced by drugs has emerged quite recently from Maslow's studies of "self-actualization." Maslow reports that the occurrence of a dramatic "peak experience" - defined or alternatively described as a "cognition of being," or as "mystic" or "oceanic" - is a major event in the life histories of his "self-actualizing" subjects. Maslow avers "unanimous agreement" among his subjects as to the "therapeutic" after-effects of such peak experiences - for example, that they were so profound as to remove neurotic symptoms forever; or were followed by greater creativity, spontaneity, or expressiveness; or produced a more or less permanently changed, more healthy world-view or view of self, and so on[74].

Drug-Associated Personality Change: A "New Concept" in Psychotherapy

It is an intriguing historical accident that, on the one hand, anthropological studies of the Native American Church (Peyotism) consistently record the peyote-associated reformation of alcoholic and generally reprobate characters[75], and, on the other hand, LSD has been increasingly utilized in the treatment of the white man's "fire-water" ills. LSD was first systematically administered to non-Indian alcoholics in order to explore a putative similarity between the so-called model psychosis and delirium tremens. Two independent undertakings along this line, one in the U.S. and one in Canada, resulted in highly unexpected and sudden "cures"[76].

Investigators in Saskatchewan pursued this serendipitous result aggressively. The outcome, with lately-evolved refinements in technique, has been an explicitly formulated "new concept" in psychotherapy[77]. The following narrative, pieced together from Hoffer's statements at the Macy LSD conference, describes the conditions under which the rapid change phenomenon seems first to have occurred in sizeable numbers:

> ... we have what we call the "businessman's special," for very busy people, the weekend treatment.... They come in because the police or Alcoholics Anonymous or others bring them in. They come in on day *one*. They know they are going to take a treatment, but they know nothing about what it is. We take a psychiatric history to establish a diagnosis. That is on day *one*. On day *two*, they have the LSD. On day *three*, they are discharged.
> Our objective [in using 200-400 gamma doses] is to give each patient a particular LSD experience.
> The results are that 50 per cent of these people are changed [that is, they stop drinking or are much improved].... As a general rule ... those who have not had the transcendental experience are not changed; they continue to drink. However, the large proportion of those who have had it are changed[78].

The only other investigators to report a "weekend treatment" are Ball and Armstrong[79]. They describe a small series of "sex perverts," at least two of whom had had, over a number of years, "a variety of forms of psychotherapy, including psychoanalysis ... [resulting in] no improvement whatever." The large-dose LSD experience, however, is said to have had "remarkable, long-lasting remedial effects"[80].

MacLean and his co-workers in British Columbia, Canada have reported on a series which included 61 alcoholics and 33 neurotics (personality trait disturbance and anxiety reaction neurosis)[81]. Each patient was carefully and intensively prepared for the 400-1500 gamma, "psychedelic LSD-day" - which was jointly conducted by a psychiatrist, a psychologist, a psychiatric nurse, and a music therapist. Their follow-up data (median follow-up was for 9 months) were interpreted to yield a "much improved" or "improved" rating for over 90 percent of the neurotics and 60 percent of the alcoholics, with just under 50 percent of the alcoholics found at follow-up to have remained "totally dry"[82]. The results of this single LSD session with the alcoholic cases seem most impressive, in view of the picture provided:

> These were considered to be difficult cases; 59 had experienced typical delirium tremens; 36 had tried Alcoholics Anonymous and were considered to have failed in that program. The average period of uncontrolled drinking was 14.36 years. The average number of admissions to hospital for alcoholism during the preceding 3 years was 8.07[83].

Since Hoffer's account, procedures in Saskatchewan have apparently been modified to incorporate considerable "psychotherapy" - as an adjunct to, and preparation for, the LSD experience. In a recent report, Jensen has described a greatly expanded treatment method and its results:

> The treatment program includes three weekly A.A. meetings. The patients are strongly encouraged, but not forced, to attend. There are also 2 hours of group psychotherapy, in the course of which those who are not already familiar with the A.A. program are indoctrinated mainly by the other patients' discussion.... Because of the fairly short time available, the group therapy is superficial in nature and primarily educational.
> Toward the end of hospitalization (which averaged 2 months), the patients were given an LSD experience. They routinely received 200 gamma of the drug....[84]
> Of 58 patients who experienced the full program, including LSD, and were followed up for 6 to 18 months, 34 had remained totally abstinent since discharge or had been abstinent following a short experimental bout immediately after discharge; 7 were considered improved, i.e., were drinking definitely less than before; 13 were unimproved; and 4 broke contact.
> Of 35 patients who received group therapy without LSD, 4 were abstinent, 4 were improved, 9 were unimproved and 18 were lost to follow-up.
> Of 45 controls, consisting of patients admitted to the hospital during the same period who received individual treatment by other psychiatrists, 7 were abstinent, 3 improved, 12 unimproved, and 23 lost to follow-up[85].

Among the reservations that might be expressed about Jensen's study, two are outstanding. First, there is some ambiguity about the assignment of patients to the different treatment conditions - it does not seem to have been entirely random. Second, Jensen's assumption that patients who broke or refused follow-up contact with the hospital staff are safely categorized, for statistical purposes, as "treatment failures" would seem somewhat overweening. At any rate, on his count, the difference in percentages of patients "abstinent or improved" between the "full program-LSD" group (41 out of 58, or 71 percent) and the "individual psychotherapy" group (10 out of 45, or 22 percent) was highly statistically significant.

The present "official policy" of the Saskatchewan Department of Public Health may be of interest. A recently issued document, which reviews the results of four such follow-up studies as Jensen's, concludes with the directive that the single, large-dose LSD treatment of alcoholism is to be considered "no longer as experimental," but rather, "to be used where indicated"[86].

There seem to have been only two efforts in the U.S. to explicitly and systematically follow the Canadian model. In quite different contexts, both are reported as at least "doing well." Leary and his co-workers at Harvard, over the last two years, have conducted a research and treatment program at Massachusetts Correctional Institution, Concord, "designed to test the effects of consciousness-expanding drugs on prisoner rehabilitation"[87]. This undertaking, which emphasizes the crucial importance of drug-induced "far-reaching insight experiences" - prepared for, supported, and reinforced by group therapy sessions - has resulted in a recidivism rate considerably reduced from actuarial expectation. The number of post-treatment cases on which this evaluation is based, however, is only 26. The program is ongoing[88].

In a much more familiar setting, a group of workers on the West Coast has been treating the full range of garden-variety neuroses. The patients are intensively prepared over a two- to three-week period for a large-dosage, "transcendental" drug session. The stated intent is to induce a "single overwhelming experience ... so profound and impressive that ... the months and years that follow become a continuing growth process"[89]. Thus far, in over 100 treated cases, at least "marked improvement" in the condition for which treatment was sought has been reported in about 80 percent - after one so-called overwhelming experience[90].

It is a commonplace that new psychiatric treatments seem to effect remarkable cures - at least for a short time and in the hands of their originators. In raising the spectre of the powerful placebo effect[91], it need hardly be pointed out that the results reviewed above should be regarded with healthy skepticism. On the other hand, they are more than merely trifling.

Explanatory Concepts

In addressing a recent international assemblage at Copenhagen, Leary asserted:

> The visionary experience is the key to behavior change. [In its wake] change in behavior can occur with dramatic spontaneity ...[92].

Van Dusen, who bids fair to become the psychologist-philosopher of the "new concept" movement, puts the issue as follows:

> There is a central human experience which alters all other experiences ... not just an experience among others, but ... rather the very heart of human experience. It is the center that gives understanding to the whole.... It has been called satori in Japanese Zen, moksha in Hinduism, religious enlightenment or cosmic consciousness in the West.... Once found life is altered because the very root of human identity has been deepened ... the still experimental drug d-lysergic acid diethylamide (LSD) appears to facilitate the discovery of this apparently ancient and universal experience[93].

Although reminded on all sides of the incommunicableness of "the transport," as James called it, of its ineffability, one may, before following him in the descent toward "medico-materialistic" explanation, inquire further of its nature. James proffered the traditional demurrer "... it is probably difficult to realize [its] intensity unless one has been through the experience one's self ..."[94]. He then proceeded, with seeming aplomb, to describe it:

> The central [characteristic] is the loss of all worry, the sense that all is ultimately well with one, the peace, the harmony, the *willingness* to be....
> The second feature is the sense of perceiving truths not known before ... insight into depths of truth unplumbed by the discursive intellect.... The mysteries of life become lucid ... illuminations, revelations, full of significance and importance, all inarticulate though they remain....
> A third peculiarity ... is the objective change which the world often appears to undergo. "An appearance of newness beautifies every object" ... clean and beautiful newness within and without ...[95].

In James' view, "melting emotions and tumultuous affections" were the constant handmaiden of "crises of change"[96]. Also Benedict, in the context of the vision-quest, remarked on "... very strong affect, either ultimate despair or release from all inadequacy and insecurity"[97]. Chwelos and his co-workers, describing the transcendental drug experience as "mainly in the sphere of emotions or feeling"[98], exemplify this by quoting an alcoholic patient:

> I was swept by every conceivable variety of pleasant emotion from my own feeling of well-being through feelings of sublimity and grandeur to a sensation of ecstasy[99].

Finally now, turning from the poetry of phenomenal experience to medico-materialism, how did James approach the matter of explanation?

> If you open the chapter on Association, of any treatise on psychology, you will find that a man's ideas, aims, and objects form diverse internal groups and systems, relatively independent of one another.... When one group is present and engrosses the interest, all the ideas connected with other groups may be excluded from the mental field.... Our ordinary alterations of character as we pass from one of our aims to another, are not commonly called transformations ... but whenever one aim grows so stable as to expel definitively its previous rivals from the individual's life we tend to speak of the phenomenon and perhaps to wonder at it, as a "transformation."
> Whether such language be rigorously exact is for the present of no importance. It is exact enough, to recognize from your own experience the fact which I seek to designate by it.
> Now if you ask of psychology just *how* the excitement shifts in a man's mental system, and *why* aims that were peripheral become at a certain moment central, psychology has to reply that although she can give a general description of what happens, she is unable in a given case to account accurately for all the single forces at work.
> In the end we fall back on the hackneyed symbolism of mechanical equilibrium. A mind is a system of ideas, each with the excitement it arouses, and with tendencies impulsive and inhibitive, which mutually check or reinforce one another.... A new perception, a sudden emotional shock ... will make the whole fabric fall together, and then the center of gravity sinks into an attitude more stable, for the new ideas that reach the center in the rearrangement seem now to be locked there, and the new structure remains permanent[100].

More modern discussions of rapid personality change seem, in large part, to be variations on the theme of "melting emotions and tumultuous affections." There have been two relatively recent efforts to deal with rapid change associated primarily with conversion. Wallace, who attempted an heroic amalgam of Selye's "stress" theory and cultural anthropology, summed this up as follows:

> ... the physiologic events of the general adaptation syndrome [in situations of massive emotion] establish a physicochemical milieu in which certain brains can perform a function of which they are normally incapable: a wholesale resynthesis that transforms intellectual insight into appropriate motivation, reduces conflict by partial or total abandonment of certain values and acceptance of others, and displaces old values to new, more suitable objects[101].

Sargant has linked along an axis of abnormal "anger, fear, or exaltation" such "abrupt total reorientations" in personality as attend religious and political conversion experiences - as well as violent abreactions in therapy, spontaneous or narcosynthetic. His explanatory scheme derives directly from Pavlov - in the final analysis, sudden alterations in behavior are attributed to "paradoxical" and "ultraparadoxical" brain processes, and the like, induced by extreme emotion[102].
To return to LSD-related developments, Ditman and his coworkers have reviewed a whole range of considerations and theories which might "rationalize" the sudden change phenomenon - including a highly libidinized psychoanalytic formulation[103].

It remains to raise just one final query. Rapid personality change, translated into language more congenial to behavioral psychology, could be taken to describe a situation in which formerly dominant or high-probability responses, overt or mediational, were suddenly greatly reduced in frequency of occurrence; and, vice versa, uncommon responses, or those formerly *low* in a hierarchy, appear with greatly elevated frequency. The only experimental results which even approximate this order of events seem to be those which have arisen with the aid of direct intracranial electrical stimulation. With response-contingent reinforcement of this kind - that is, with electrical "trains" delivered to the hypothalamic, so-called pleasure or reward centers - the repertoires of many rats and monkeys have been dramatically altered in a very few moments: Utterly new behaviors have been shaped, old responses eliminated[104]. The degree to which such "artificially induced" learning has been sustained has been a function, as with all behavior, of the ebb and flow of environmental contingencies. Thus, to point the issue: Do transcendental experiences at the human level, however they are interpreted, tread in this area of *super* reinforcement - with a potential for radically altering the probability of occurrence of "heuristic" mediating processes (for example, positive rather than negative self-concepts) which might channel behavior, at least temporarily, in new directions, toward a "new beginning"?

With Ruth Benedict's "Apollonian" Zuni, the tendency of the modern West is to regard paranormal experiences, indiscriminately and often with little idea of their nature, as "pathological" - to be distrusted, feared, avoided. The Zuni Indian, said Benedict, "finds means to outlaw them from his conscious life... . He keeps the middle of the road, stays within the known map, does not meddle with disruptive psychological states"[105]. It would seem unfortunate were this *Zeitgeist* to unduly prejudice the exploration of therapeutic potential in the drugs here discussed.

In conclusion, let it be noted that the public health implications of drug-associated rapid personality change, should this phenomenon prove not to be a will-of-the-wisp, are apparently great. Intensive investigation would seem a reasonable order of the day. The procedures and time involved are manifestly economical - in truth, there seems little to be lost.

Acknowledgments

Grateful acknowledgment is made of the substantial contributions of Miss Judith C. Marshall and the assistance of Mrs. Linda B. J. P. Moncure in the preparation of this paper.

40. Translated from Albert Hofmann's laboratory report, and quoted in "Discovery of D-lysergic Add Diethylamide - LSD ' *Sandoz Excerpta* (1955) 1:1-2: p. 1.
41. See footnote 40; p. 2. For the record, it may be noted not only that Hofmann recovered, and subsequently synthesized psilocybin, but that he has recently written of the use of "psychotomimetics" in psychotherapy: "... these substances are new drug aids which ... enable the patient to attain self-awareness and gain insight into his disease." See Albert Hofmann, "Chemical, Pharmacological and Medical Aspects of Psychotomimetics," *J. Exper. Med. Science* (1961) 5:31 - 51 p. 48.
42. Translated from B. Manzini and A. Saraval, "L'intossicazione Sperimentale da LSD ed i Suoi Rapporti con la Schizofrenia, *Riv. Sper. Freniat.* (1960) 84:589; and quoted in *Delysid (LSD-25), Annotated Bibliography, Addendum No. 3*, mimeographed, Sandoz Pharmaceuticals, 1961; p. 307.
43. See footnote 33; p. 429.
44. In taking issue with the "psychotomimetic" label, it had best be emphasized that the present intent is hardly to transmit a cavalier attitude toward drug administrations; these are obviously potent agents. On the other hand, they are also apparently "safe" when used with reasonable precaution. For a survey of the outcome of 25,000 administrations, see Sidney Cohen, "LSD: Side Effects and Complications," *J. Nervous and Mental Disease* (1960) 130:30-40.

Abstract

Psychedelic drugs such as LSD and psilocybin are often claimed to be capable of inducing lifechanging experiences described as mystical or transcendental, especially if high doses are taken. The present study examined possible enduring effects of such experiences by comparing users of psychedelic drugs (n = 88), users of non-psychedelic illegal drugs (eg., marijuana, amphetamines) (n = 29) and non-illicit-drug using social drinkers (n = 66) on questionnaire measures of values, beliefs and emotional empathy. Samples were obtained from Israel (n = 110) and Australia (n = 73) in a cross-cultural comparison to see if values associated with psychedelic drug use transcended culture of origin. Psychedelic users scored significantly higher on mystical beliefs (eg., oneness with God and the universe) and life values of spirituality and concern for others than the other groups, and lower on the value of financial prosperity, irrespective of culture of origin. Users of non-psychedelic illegal drugs scored significantly lower on a measure of coping ability than both psychedelic users and non-illicit-drug users. Both groups of illegal drug users scored significantly higher on empathy than non-illicit-drug users. Results are discussed in the context of earlier findings from Pahnke (1966) and Doblin (1991) of the transformative effect of psychedelic experiences, although the possibility remains that present findings reflect pre-drug characteristics of those who chose to take psychedelic drugs rather than effects of the drugs themselves.

Psychedelic drugs are claimed to have the potential to induce profoundly spiritual or mystical experiences (e.g., Bakalar, 1985; Hasler *et al*., 2004; Hofmann, 1983; Horgan, 2003; Huxley, 1956; Maslow, 1964; Leary, 1965; Pahnke, 1966; Shanon, 2003; Strassman, 2001; Watts, 1965). Presumably because of such effects, plant psychedelics such as *psilocybe* mushrooms, peyote, and ayahuasca have been central to the traditional spiritual and healing ceremonies of some indigenous cultures of the Americas. Even today, the Native American Church is permitted to use peyote legally for religious purposes in the United States, and the syncretist religious group União Vegetal is allowed legal use of ayahuasca for similar purposes in Brazil (Shanon, 2002). The most potent of all psychedelics, the semisynthetic ergot derivative LSD, was initially regarded as an agent that induces a "model psychosis" but subsequently LSD was utilized sporadically in depth psychotherapy and alcoholism treatment in the 1950s and 1960s (Grinspoon & Bakalar, 1979; Grof, 2001). Before all use of psychedelics was made illegal in most countries, there were two main models of LSD psychotherapy: "Psycholytic" psychotherapy administered frequent low doses of LSD to facilitate the emergence of material from the personal unconscious and was based on a psychoanalytic paradigm, whereas "psychedelic" psychotherapy administered a limited number of high doses with the goal of inducing a transpersonal, mystical experience that would have longlasting transformative effects on behavior (such as alcohol abstinence in alcoholics). However, clinical research on the efficacy of LSD or other psychedelic agents for psychotherapeutic purposes was generally marred by poor research design (Ludwig, 1970).

In the only published controlled experiment on the spiritual potential of psychedelics in humans, Pahnke (1966) tested claims that psychedelics are capable of inducing religious experiences. In a Boston chapel on Good Friday, drug-naïve divinity students were given either a high dose of psilocybin or an active placebo in double-blind fashion. Most subjects in the psilocybin group reported profound spiritual insights with transformative effects that persisted for decades, according to a follow-up study by Doblin (1991). However, one subject who received psilocybin suffered a psychotic reaction during the experiment, highlighting one of the major risks of psychedelic drug use. Although psychedelics are not addictive, and frequent use is rare due to the intensity of effects (Grinspoon & Bakalar, 1979), these drugs can be dangerous due to the unpredictable and overwhelming mental changes they may induce. Time slows down or stands still, brilliantly colored visions unfold in the mind's eye, and emotions may range from terror and panic to spiritual ecstasy and transcendence. Normal reality may be left far behind as the user seems to enter another dimension, and near-death type experiences are not uncommon. Users often claim to encounter God, to merge with the Cosmos and undergo death and rebirth during a high-dose psychedelic experience.

Reports from some users resemble classic Buddhist or Hindu descriptions of self-realization or enlightenment (Grinspoon & Bakalar, 1979; Horgan, 2003; Watts, 1965). This mystical experience is said to have a universal aspect that transcends cultural context and may cause lasting and profound changes in the user (but see Horgan, 2003, for a critical discussion of this claim). If psychedelic drugs can sometimes induce mystical experiences, as often claimed, then the values and beliefs of psychedelic users should differ in crucial respects from those endorsed by users of other illicit drugs such as marijuana, amphetamines or heroin, as well as those endorsed by non-users of illegal drugs. Further, to be truly universal, the values and beliefs of psychedelic users should transcend cultural context. The present exploratory study examined these hypotheses by comparing users of psychedelic drugs with users of non-psychedelic illegal drugs (as a control for correlates of illicit drug use in general) and non-users of illegal drugs on values, beliefs, coping ability and empathy. Samples were drawn from two culturally distinctive countries, Israel and Australia. We predicted that certain characteristics of psychedelic drug users would distinguish them from the other two groups across the two different nationalities. Mystical beliefs such as oneness with God and the universe, empathy (commonly presumed to follow from such beliefs), confidence in one's ability to handle life stress, and life values such as spirituality, creativity, humility, concern for others, and concern for the environment were all expected to differentiate psychedelic users from the other groups, irrespective of cultural background. Psychedelic users were also expected to be less concerned with financial prosperity and achievement than the other groups, reflecting a less materialistic value orientation. Two values, belonging and loyalty to group, were expected to be higher in Israelis than in Australians irrespective of drug use, on the basis of the presumed ethnic/religious group identification of Israelis.

Method

Subjects

A total of 183 volunteers participated in this study. There were 41 Israeli and 47 Australian users of psychedelic drugs (LSD, psilocybin, mescaline), 18 Israeli and 11 Australian users of other illegal drugs (10 marijuana only, 17 marijuana + amphetamines, 1 amphetamines only, 1 marijuana + heroin) who had never tried psychedelics, and 51 Israeli and 15 Australian non-illegal-drug-using social drinkers. Mean age was 35 years (range 21-70 years). For purposes of this study, participants were classified as psychedelic users only if they reported having had at least one overwhelming high-dose psychedelic experience. This was because some recreational drug users today take low doses of a psychedelic drug (eg., 50 mcg LSD, 1 gm of *psilocybe* mushrooms) to enhance their appreciation of the music and social scene at dance clubs or "rave" venues. As low dose psychedelic use is unlikely to induce a mystical experience, prospective participants who only reported this type of psychedelic use were excluded from the study. For similar reasons, use of marijuana or "entactogens" such as MDMA (Ecstasy) or MDE, which are sometimes considered mild psychedelics, was not sufficient for classification into the psychedelic user group. Use of dissociatives such as ketamine or PCP likewise did not qualify as psychedelic drug use in the context of the present study, as the "psychedelic" category was conservatively restricted to the "classic" serotonergic agonist hallucinogens - the drugs most widely cited as capable of inducing mystical experiences. This study was approved by the Bond University Research Ethics Committee and was funded by a grant from the Multidisciplinary Association for Psychedelic Studies (MAPS).

Materials

Drug Use Questionnaire

Drug Use Questionnaire (DUQ; Barker & Lyvers, 2002). The DUQ assesses personal history of use of alcohol and illegal drugs such as cannabis/marijuana, MDMA/Ecstasy, cocaine, amphetamines, heroin/opiates, and psychedelics (LSD, psilocybin, mescaline), as well as demographic information. A short qualitative section was added asking if the psychedelic user has ever had a profound or overwhelming high-dose psychedelic experience; an affirmative response was necessary for inclusion in the psychedelic user group (see above).

Life Values Inventory

Life Values Inventory (LVI; Brown & Crace, 1996). The quantitative section of the LVI used in this study measures 14 life values by means of 42 items rated for importance to one's life on four-point Likert scales. For purposes of the present study, only 9 of the 14 values were analyzed as they were deemed most relevant to the psychedelic experience and/or to cultural differences between Israel and Australia: Spirituality, Concern for Environment, Concern for Others, Financial Prosperity, Creativity, Belonging, Loyalty to Family or Group, Achievement, and Humility.

Emotional Empathic Tendency Scale

Emotional Empathic Tendency Scale (EETS) (Mehrabian, 1994). The EETS measures one's perceived ability to identify and feel the emotions of others, using 33 items rated on a five point Likert scale.

Mystical Beliefs Questionnaire

Mystical Beliefs Questionnaire (MBQ). Based on Pahnke's (1966) Peak Experience Profile, the MBQ is a 21-item scale developed for the present study. Five point Likert scales are used to rate mystical beliefs such as universal soul, the unity of all things, having no fear of death, the illusory nature of physical existence, the existence of a transcendental reality, and oneness with God, nature and the universe. Cronbach's alpha coefficient in the present study was .94, indicating high internal consistency of this exploratory measure.

Sense of Coherence Scale

Sense of Coherence Scale (SOCS; Antonovsky, 1987). The SOCS measures subjective coping ability in terms of beliefs that stressful events are comprehensible and that one has the resources necessary to cope with them. We expected that psychedelic users would score higher on this than the other groups, due to the presumed buffering effect of a mystical or spiritual perspective against stress. There are 29 items rated on a seven point Likert scale.

Procedure

Participants were recruited by posters in counterculture areas frequented by members of contra-cultural groups and drug users and by word of mouth (snowball method) in Israel (Tel Aviv, Haifa, Jerusalem) and Australia (Nimbin, Byron Bay, Melbourne, Gold Coast). Interested persons contacted the researcher, who sent them a questionnaire packet and a self-addressed stamped envelope for return of the completed forms. Of 212 packets initially returned, 14 were discarded as incomplete, and 22 were discarded because although psychedelic use was reported the respondent denied ever having had an overwhelming or high-dose experience.

Results

Initial examination of groups revealed differences in gender and age composition. There was a significant association between drug group and gender, X^2 (2, N = 183) = 10.15, $p = .006$. There were relatively more males in the psychedelic group (51 males, 37 females) compared to the users of other illegal drugs group (9 males, 20 females) and the non-user group (24 males, 42 females). There were also group differences in age, $F(2, 178) = 4.21$, $p = .016$. Tukey's HSD post-test ($p < .05$) revealed that the non-psychedelic illegal drug user group was younger on average (M = 30 yr) than the psychedelic group (M = 36 yr) and the non-user group (M = 38 yr). Therefore age and gender were used as covariates in all analyses reported below.

Mystical Beliefs

Two-way (drug group X nationality) analysis of covariance (ANCOVA) indicated a significant effect of drug group on the MBQ, $F(2,171) = 73.33$, $p = .000$. As predicted, psychedelic drug users scored significantly higher on the MBQ ($M = 64.22$) than non-psychedelic illegal drug users ($M = 34.84$) and non-users ($M = 34.05$), as revealed by pairwise comparisons using the Bonferroni correction. There was no difference between Israelis and Australians on the MBQ, and no interaction.

Life Values

MANCOVA indicated an overall multivariate effect of nationality on the LVI, $F(9, 164) = 2.51$, $p = .01$. Univariate analyses were significant for Belonging, $F(1, 172) = 6.70$, $p = .01$, Humility, $F(1,172) = 5.72$, $p = .02$, and Loyalty to Family or Group, $F(1,172) = 5.82$, $p = .02$. On Belonging, Israelis ($M = 10.80$) scored significantly higher than Australians ($M = 9.59$). Israelis also rated the value of Humility more highly ($M = 9.59$) than Australians did ($M = 8.71$). Further, Israelis scored higher on Loyalty to Family or Group ($M = 10.80$) than Australians did ($M = 9.74$). There was an overall multivariate effect of drug group on the LVI, $F(18,328) = 4.73$, $p = .000$. Univariate analyses revealed significant effects of drug group on Spirituality,

$F(2,172) = 21.29$, $p = .000$; Concern for Environment, $F(2,172) = 7.72$, $p = .001$; Concern for Others, $F(2,172) = 7.04$, $p = .001$; Creativity, $F(2,172) = 3.42$, $p = .03$; and Financial Prosperity, $F(2,172) = 7.35$, $p = .001$. Pairwise comparisons using the Bonferroni correction revealed that psychedelic users scored significantly higher on Spirituality and Concern for Others, and lower on the value of Financial Prosperity, than the other groups (see Table 1). Psychedelic users also scored significantly higher than users of other illegal drugs on Concern for Environment and Creativity, but only marginally ($p < .10$) higher than non-users on these values (see Table 1).

Table 1. Life Values of Psychedelic Drug Users Compared to Non-Psychedelic Illegal Drug Users and Non-Users of Illegal Drugs.

Life Value	Users of -		
	Psychedelics	Other Drugs	Non-users
Spirituality	12.15	7.59	9.28
Environment	12.16	10.24	11.40
Concern for others	12.25	11.38	11.58
Creativity	11.97	10.59	10.97
Financial Prosperity	8.68	10.38	10.92

Empathy

ANCOVA indicated significant effects of the covariate gender, $F(1, 172) = 62.12$, $p = .000$, and drug group, $F(2, 172) = 14.99$, $p = .000$, on emotional empathy as measured by the EETS. As expected based on past research, females scored higher overall on emotional empathy ($M = 45.87$) than males ($M = 24.96$). According to pairwise comparisons using the Bonferroni correction, psychedelic users scored non-significantly higher ($M = 44.92$) on empathy than users of other illegal drugs ($M = 36.53$), with both groups of drug users scoring significantly higher than non-users ($M = 24.42$). There was no effect of nationality and no interaction.

Coping Ability

SOC total scores were subjected to a two-way (drug group X nationality) ANCOVA. The main effect of drug group was significant, $F(2, 173) = 6.47$, $p = .002$. Post-test (Bonferroni) showed that users of non-psychedelic illegal drugs scored significantly lower on the SOC ($M = 116.78$) than both users of psychedelics ($M = 133.73$) and non-users ($M = 130.88$). Neither the main effect of nationality nor the interaction were significant.

Discussion

The findings, though tentative due to the self-selected nature of the samples, were largely consistent with predictions based on the notion that many users of psychedelic drugs have undergone a mystical or transcendental experience that led to major changes in orientation. Regardless of culture of origin, users of psychedelic drugs scored significantly higher than users of other illegal drugs and non-users on mystical beliefs, such as oneness with God and the universe, the illusory nature of physical existence, and the presence of a transcendental reality. Psychedelic users also scored higher on emotional empathy than the other groups, although only the comparison with non-users was significant. The higher mean empathy score of psychedelic users was consistent with predictions based on the compassionate qualities attributed to those who have had enlightenment experiences according to the mystical traditions of Buddhism and Hinduism. Nevertheless, such claims should be tempered by the fact that, as Horgan (2003) noted, no obvious "psychedelic saints" have yet emerged from the counterculture. Life values that are said to naturally follow from mystical experience - spirituality and concern for others - were rated significantly more highly by psychedelic users than both of the other groups, and concern for the environment and creativity were rated significantly more highly by psychedelic users than by users of other illegal drugs. The value of financial prosperity was rated significantly lower by psychedelic users than by the other groups, indicating a less materialistic orientation in the psychedelic users. However, contrary to predictions, differences were not found on the values of humility or achievement between psychedelic users and the other groups. On the SOC, a measure of belief in one's ability to cope with life stress, users of non-psychedelic illegal drugs such as marijuana and amphetamines scored significantly lower than both users of psychedelics and non-users of illegal drugs. This suggests that in contrast to psychedelic drug use, non-psychedelic illegal drug use may be in part motivated by escapism or as an attempt to cope with stress. Alternatively, use of such drugs may impair the subjective coping ability of some users.

A question that naturally arises from the present findings is whether the above characteristics of psychedelic drug users preceded psychedelic use or resulted from such use. Those who decide to take a psychedelic drug may in some cases do so as part of a personal spiritual quest, based on the reputation such drugs have for inducing mystical experiences; thus the tendency to endorse more spiritual, less materialistic values may have preceded use of psychedelics. However, present results are generally consistent with the earlier findings of Pahnke (1966) and Doblin (1991) of a profound and enduring spiritual influence of the psychedelic experience. The most likely possibility, in our interpretation, is that both pre-drug factors and psychedelic drug effects may have contributed to the distinctive characteristics of psychedelic drug users observed in the present study. That is, people on a spiritual quest may be more inclined to use psychedelics as part of that quest, but in addition the drugs themselves may on occasion have powerful effects on values and spirituality even in those who did not initially take psychedelics for spiritual purposes. Present findings also suggest that the effects of psychedelic drugs may be more important than the cultural differences between Israel and Australia in influencing the life values and spirituality of drug users in these two countries, consistent with the claim of a universal aspect to psychedelic mystical experiences. As predicted, Israelis scored higher on Belonging and Group Loyalty than Australians overall, but also on the value of Humility, which was not predicted.

In recent years a "psychedelic renaissance" seems to be underway, both at the societal level and in terms of renewed scientific interest in these remarkable compounds. In the early 1960s, psychedelics were regarded by many as miracle drugs with the potential to positively transform individuals and society. But the ensuing controversies and problems associated with uncontrolled use quickly led to the illegalization of psychedelics and cessation of scientific research on their clinical and spiritual potential. Given the recent resurgence of scientific interest, and government approval of limited human studies of psychedelic effects (e.g., Strassman, 2001), a less hysterical assessment of psychedelics is likely to emerge in the coming years.

Abstract

Western psychotherapy and indigenous shamanic healing systems have both used psychoactive drugs or plants for healing and obtaining knowledge (called "diagnosis" or "divination" respectively). While there are superficial similarities between psychedelic-assisted psychotherapy and shamanic healing with hallucinogenic plants, there are profound differences in the underlying worldview and conceptions of reality. Four paradigms are reviewed: (1) psychedelic psychotherapy within the standard Western paradigm - here the drug is used to amplify and intensify the processes of internal self-analysis and self-understanding; (2) shamanic rituals of healing and divination, which involve primarily the shaman or healer taking the medicine in order to be able to "see" the causes of illness and know what kind of remedy to apply; (3) syncretic folk religious ceremonies, in which the focus seems to be a kind of community bonding and celebratory worship; and (4) the "hybrid shamanic therapeutic rituals," which incorporate some features of the first two traditions. There are two points in which the worldview of the shamanic and hybrid shamanic ceremonies differs radically from the accepted Western worldview: (1) the belief and assumption (really, perception) that there are multiple realities ("worlds") that can be explored in expanded states of consciousness; and (2) the belief that "spirits," the beings one encounters in dreams and visions, are just as real as the physical organism.

Keywords - hallucinogens, psychedelics, psychotherapy, shamanism, states of consciousness.

By way of introducing a comparative overview of the role of psychoactive drugs in psychological healing practices, a brief personal note might be permitted. As a psychologist, I have been involved in the field of consciousness studies, including altered states induced by drugs, plants and other means, for over 35 years. In the 1960s I worked at Harvard University with Timothy Leary and Richard Alpert, doing research on the possible therapeutic applications of psychedelic drugs, such as LSD and psilocybin (Leary, Metzner & Alpert 1964). During the 1970s the focus of my work shifted to the exploration of nondrug methods for the transformation of consciousness, such as those found in Eastern and Western traditions of yoga, meditation and alchemy (Metzner 1971). I also studied intensively the newer psychotherapeutic methods, many deriving from the work of pioneers such as Wilhelm Reich, that involve deep altered states induced by breathwork and bodywork. During the 1980s I came into contact with the work of Michael Harner (1980, 1973), Joan Halifax

(1982), Peter Furst (1976, 1972), Terence and Dennis McKenna (1975) and others, who have studied shamanic teachings and practices around the globe. These shamanic traditions involve non-ordinary states of consciousness induced by a variety of methods including ingesting hallucinogenic plants, but also drumming, fasting, wilderness vision questing, use of sweat lodges and others.

Realizing that there were traditions reaching into prehistoric times of the respectful use of hallucinogens for shamanic healing and divination, I became much more interested in the plants and mushrooms that have a history of such use. Indigenous people are known to have a profound knowledge of plants and herbs and their effects on the body and mind; they are well able to distinguish harmful from beneficial medicines. For this reason the vision-inducing plants that have a tradition of shamanic usage are much more likely to be safe, in contrast to newly discovered and synthesized drugs, the use of which may often involve unknown long-term risks.

It became clear to me, as a result of these explorations, that while Western psychotherapy and indigenous shamanism may sometimes use the same or similar psychoactive substances for healing and obtaining knowledge (called diagnosis in the West and divination in traditional cultures), there are profound differences between them in underlying worldview and assumptions about the nature of reality. In this article I propose to compare the use of psychoactives, as well as the underlying worldviews, in four systems of consciousness transformation: (1) psychotherapy within the standard Western paradigm, (2) shamanic rituals of healing and divination, (3) syncretic folk religious ceremonies, and (4) what I call hybrid therapeutic-shamanic rituals, which represent a blending of indigenous shamanic and Western psychotherapeutic approaches.

A note on terminology: I use the terms "psychedelic," "hallucinogenic" and "entheogenic" interchangeably. "Psychedelic," the term coined by Humphrey Osmond and Aldous Huxley and popularized by Leary and the Harvard group, means "mind-manifesting." "Hallucinogenic" is the term most often used in the psychiatric research literature for these substances. The main objection to the term hallucinogenic is that these drugs and plants do not in fact induce hallucinations, in the sense of "illusory perceptions." But the term hallucinogen deserves to be rehabilitated. The original meaning of the Latin *alucinare* is to "wander in one's mind"; and traveling or journeying in inner space are actually quite appropriate descriptive metaphors for such experiences, which are referred to colloquially as "trips." The term "entheogen," proposed by R. Gordon Wasson and Jonathan Ott, has the same root as "enthusiasm," and means "releasing or expressing the divine within" (Ott 1995).

Psychotherapy within the Standard Western Paradigm

When the fantastically potent mind-altering qualities of LSD were first discovered, at the height of World War II in a Swiss pharmaceutical lab, they were characterized as "psychotomimetic" and "psycholytic." The prospect of unhinging the mind from its normal parameters for a few hours to simulate madness interested a small number of daring psychiatric researchers as a possible training experience. Predictably, this possibility also intrigued the military and espionage agencies of both superpowers, especially the Americans. Considerable research effort and expense was devoted for about 10 years to determining the most effective surreptitious delivery systems to unsuspecting enemy soldiers, agents or leaders, for maximum confusion, disorientation or embarrassment (Lee & Shlain 1985). Ironically, and fortunately, it was the capacity of LSD to tap into the hidden mystical potentials of the human mind that ruined its applicability as a weapon of war. Rather than making subjects predictably submissive to mind-control programming, LSD had the unnerving propensity to suspend the existing mental programming and thereby release one into awesome worlds of cosmic consciousness. The military was not prepared to have soldiers or espionage agents turn into mystics.

The first research papers that came out of the Sandoz labs, where Albert Hofmann had synthesized LSD and accidentally discovered its astounding properties, described it as bringing about "psychic loosening or opening" (*seelische Auflockerung*). This was the *psycholytic* concept that became the dominant model for LSDassisted psychotherapy in Europe. In psycholytic therapy, neurotic patients suffering from anxiety, depression, or obsessive-compulsive or psychosomatic disorders were given LSD in a series of sessions at gradually increasing doses, while undergoing more or less standard analytic interactions using a Freudian perspective (Passie 1997; Grof 1980). The rationale was that through the *psycholysis*, the loosening of defenses, the patient would become more vividly aware of his or her previously unconscious emotional dynamics and reaction patterns (presumably acquired in early family interactions), and such insight would bring about a resolution of inner conflicts. The Czech psychiatrist Stanislav Grof, working within this model, made the startling discovery that in such a series (involving increasing doses) there could be an even deeper psychic opening - to birth and prebirth memories. After resolving the conflicts stemming from the Freudian dynamics of early childhood, patients would find themselves reliving the significant sensory-emotional features of their birth experience - patterns to which Grof gave the name *perinatal matrices* (Grof 1985).

More or less simultaneously with the psycholytic approach being developed in Europe, the *psychedelic* model became the preferred approach in Anglo-American psychological and psychiatric circles. The English psychiatrist Humphrey Osmond, who worked in Canada with Abram Hoffer on the treatment of alcoholism with LSD (and who provided Aldous Huxley with his first mescaline experience, immortalized in *The Doors of Perception* (Huxley 1954), introduced this term in an exchange of letters with Huxley. First used in the treatment of alcoholics, where it was thought to simulate the often life-changing "bottoming out" experience, psychedelic therapy usually involved one or a small number of high-dose sessions, during which the contents of the unconscious mind would be manifested in the form of vivid hallucinatory imagery, leading to insight and transformation (Passie 1997). A second center for psychedelic therapy and exploration developed in the early sixties in Southern California, where Sidney Cohen, Oscar Janiger and others began providing psychedelic experiences to their clients in the Hollywood film, arts and media community (Novak 1997) - work that brought considerable publicity and notoriety to psychedelics.

The term "psychedelic" was adopted by Timothy Leary, Frank Barron, Richard Alpert and the Harvard research project, which did one of its first research studies on the production of behavior change in convicts, and started publishing the *Psychedelic Review*. Apart from the prison project, Leary's work focused not so much on treatment or therapy, but rather on exploring the possibilities and values of the psychedelic experience for "normals" (mostly graduate students) as well as artists, musicians, poets and writers, when provided in a relatively unstructured but supportive, home-like setting. The concept of "consciousness expansion" was introduced for these experiences, which could be usefully contrasted with the contracted, fixated awareness characteristic of narcotic addictions, as well as obsessions and compulsions in general (Metzner 1994). Leary was also responsible for introducing and popularizing what became known as the "set and setting" hypothesis, according to which the primary determinants of a psychedelic experience are the internal set (intention, expectation, motivation) and the external setting or context, including the presence of a guide or therapist (Leary, Litwin & Metzner 1963).

The psychological research on psychedelics, as well as the psycholytic and psychedelic psychotherapy applications, have been well summarized and reviewed by Lester Grinspoon and James Bakalar (1979/1997) in their book *Psychedelics Reconsidered*. The history of the introduction of LSD and other hallucinogens into American culture with its many extraordinary and unforeseen social and political consequences has been described by Jay Stevens (1987) in his book *Storming Heaven*. Leary's own story of these events in which he was centrally involved is told in his own unique, provocative and tricksterish style in his several autobiographies, most particularly in *High Priest* (1968/1995) and *Flashbacks* (1983).

A significant extension of the field of psychoactive-assisted psychotherapy occurred with the discovery by chemist Alexander Shulgin of a variety of phenethylamines, such as MDA, MDMA, 2-CB and others, which bring about an expansion and centering of awareness primarily on the emotional or heart-level, with minimal or no perceptual changes or other-worldly consciousness (Shulgin & Shulgin 1991). For this reason, to distinguish them from the classical hallucinogens, some have suggested the name *empathogens* ("generating a state of empathy") for this class of substances. In particular, MDMA (which also became known as Ecstasy or E, and as such has come to play a central role in the hugely popular rave culture) was used with impressive success in psychotherapy - often facilitating a significant opening of relationship communication and helping in the healing of disabling trauma (Saunders 1993; Eisner 1989; Adamson & Metzner 1988).

Despite the seeming theoretical and practical differences between the psycholytic and psychedelic approaches, there are a number of significant fundamental conclusions and directions which they share, and which I would now like to summarize. These are all features of psychoactives-assisted psychotherapy that distinguish this modality from other uses of mood-altering drugs such as tranquilizers or antidepressants, in which the patient or client takes a pill and goes home:

1. It is recognized that psychotherapy with hallucinogens invariably involves an experience of a profoundly *expanded state of consciousness*, in which the individual can not only gain therapeutic insight into neurotic or addictive emotional dynamics and behavior patterns, but may come to question and transcend fundamental self-concepts and views of the nature of reality.
2. It is widely accepted in the field that *set and setting* are the most important determinant of experiences with psychedelics, while the drug plays the role of a catalyst or trigger. This is in contrast to the psychiatric or other psychoactive drugs (including stimulants, depressants and narcotics) where the pharmacological action seems paramount, and set and setting play a minor role. The set-and-setting model can also be extended to the understanding of other modalities of altered states of consciousness, involving nondrug triggers such as hypnosis, meditation, rhythmic drumming, sensory isolation, fasting, and others (Metzner 1989).
3. Two analogies or metaphors for the drug experience have been repeatedly used by writers both in the psycholytic and psychedelic paradigms. One is the *amplifier analogy*, according to which the drug functions as a nonspecific amplifier of psychic contents. The amplification may occur in part as a result of a lowering of sensory thresholds, a "cleansing of the doors of perception," and in part be due to not-yet-understood central processes involving one or more neurotransmitters. The other analogy is the *microscope metaphor*: it has repeatedly been said that psychedelics could play the same role in psychology as the microscope does in biology - opening up to direct, repeatable, verifiable observation realms and processes of the human mind that have hitherto been largely hidden or inaccessible.
4. Again in contrast to the use of other psychiatric or psychoactive drugs, it is widely recognized that the *personal experience of the therapist* or guide is an essential prerequisite of effective psychedelic psychotherapy. Without such prior personal experience, communication between the therapist and the individual in a psychedelic state is likely to be severely limited. This principle implies also that a significant role for psychedelic experience could be in the training of psychotherapists. The vast majority of psycholytic and psychedelic therapists would of course not sanction the taking of the drug by the therapist together with the client.
5. *Access to transcendent, religious or transpersonal dimensions of consciousness* can be attained. That mystical and spiritual experiences can and often do occur with the use of psychedelics was recognized early on by most researchers in this field, thereby posing both challenge and promise to the psychological disciplines and professions. Albert Hofmann has testified that his ability to recognize the psycholytic properties of the LSD experience was based on its similarity to his childhood mystical experiences in nature (Hofmann 1979). Stanislav Grof found that after resolving biographical childhood issues, and then the perinatal traumata, individuals would often find themselves in realms of consciousness completely transcendent of time, space and other parameters of our ordinary worldview (Grof 1985). He gave the name "transpersonal" to these realms of consciousness and "holotropic" ("seeking the whole") to the predominant quality of consciousness in these realms, as well as to other means of accessing these realms, such as certain breathing methods (holotropic breathwork).

Timothy Leary, stimulated by his association with Aldous Huxley, Huston Smith and Alan Watts, devoted considerable time and energy to exploring and describing the spiritual and religious dimensions of psychedelic experience. This work resulted in adaptations of the Tibetan Buddhist *Bardo Thödol* (Leary, Metzner & Alpert 1964) and the Chinese Taoist *Tao Te Ching* (Leary 1997) as guidebooks for psychedelic experience. Based on his initiating experience with Mexican magic mushrooms, it would also be true to say that Leary was the first person to recognize and articulate that the fundamental mystical vision that emerges in these states is an *evolutionary remembering* - an experience of reconnecting with our biological and cosmological evolution. In other words, he realized the experience went beyond the personal and cultural developmental issues that usually concern psychologists, and that the language of mystics and shamans in our time was basically going to be the scientific language of evolution.

Shamanic Rituals of Healing and Divination

Synchronistically with the revelations and insights emerging from psychedelic research in psychology and religion, a generation of students and researchers in anthropology and ethnobotany was inspired to explore the roots of humankind's involvement with psychoactive plants in shamanism. These works ranged from Wasson's rediscovery of the pre-Columbian magic mushroom cult, and Harner's early work on the role of hallucinogens in European witchcraft-shamanism, to the work of sober researchers like Weston LaBarre, Richard Evans Schultes, Claudio Naranjo and Peter Furst, as well as the more fantastic and imaginative writings of Carlos Castaneda and Terence McKenna. It is fascinating to realize, in hindsight, that the two texts which seemed to lend themselves most readily to psychedelic adaptation (the *Bardo Thödol* and the *Tao Te Ching*) come from religious traditions in which shamanic elements were strong. In Tibetan Buddhism, as in Chinese Taoism, practices of connecting with spirits of nature through special visionary states were integrated into the teachings concerning spiritual development and liberation.

If we accept the idea, growing out of scientific research, that set and setting are the crucial determinants of the content of a hallucinogenic experience, then the use of these substances in a ritual setting, with careful attention paid to conscious intention, is in fact the logical as well as the traditional approach. Shamanic rituals involving hallucinogens are the intentional arrangement of the set and the setting for purposes of healing and divination. Traditional Western psychotherapy, with or without psychedelics, can also appropriately be seen as a ritual - i.e., an experience formally structured according to the intention of healing or problem-solving. The traditional *shamanic ceremonial* form involving hallucinogenic plants is a carefully structured experience, in which a small group of people (six to 12) come together with respectful, spiritual attitudes to share a profound inner journey of healing and transformation, facilitated by these powerful catalysts. A "journey" is the preferred metaphor in shamanistic societies for what we call an "altered state of consciousness."

There are three significant differences between shamanic entheogenic ceremonies and the typical psychedelic psychotherapy session. One is that the traditional shamanic rituals involve very little or no talking among the participants, except perhaps during a preparatory phase or after the experience to clarify the teachings and visions received. The second is that singing, or the shaman's singing, is invariably considered essential to the success of the healing or divinatory process; furthermore the singing typical in entheogenic rituals usually has a fairly rapid beat, similar to the rhythmic pulse in shamanic drumming journeys (widespread in shamanistic societies of the Northern Hemisphere in Asia, Europe and America). Psychically, the rhythmic chanting, like the drum pulse, seems to give support for moving through the flow of visions, and minimizes the likelihood of getting stuck in frightening or seductive experiences. The third distinctive feature of traditional ceremonies is that they are almost always done in darkness or low light - which facilitates the emergence of visions. The exception is the peyote ceremony, done around a fire (though also at night); here participants may see visions as they stare into the fire. I should point out that the hybrid therapeutic forms that have been developing in the past few decades (to be discussed below) have incorporated these three features from the shamanic model.

As mentioned above, psychotherapists working within the psycholytic and psychedelic model quickly came to the consensus that the therapist working with these substances had to have prior experience with them. This is so widely assumed in shamanic societies that it is hardly even discussed. Typically, a shamanic healer working with entheogenic plants undergoes a lengthy initiation and training (sometimes lasting years) under the guidance of an experienced elder before working with others.

I will briefly mention some of the variations on the traditional rituals involving hallucinogens. In the peyote ceremonies of the Native American Church in North America, participants sit on the ground in a circle around a blazing central fire in a tipi. The ceremony lasts all night and is conducted by a "roadman," with the assistance of a drummer, a firekeeper and a cedar-man (for purification). A staff and rattle are passed around and participants sing the peyote songs, which involve a rapid, rhythmic beat. The peyote ceremonies of the Huichol Indians of Northern Mexico also take place around a fire, with much singing and story-telling, after the long group pilgrimage to find the rare cactus (Pinkson 1995; Myerhoff 1974; La Barre 1964).

The ceremonies of the San Pedro cactus in the Andean regions are sometimes also done around a fire, with singing; but sometimes the *curandero* sets up an altar, on which are placed different symbolic figurines and objects representing the light and dark spirits which one is likely to encounter (Calderon *et al*. 1982).

The mushroom ceremonies (*velada*) of the Mazatec Indians of Mexico involve the participants sitting or lying in a very dark room with only a small candle. The healer, who may be a woman or a man, sings almost uninterruptedly throughout the night, weaving into his or her chants the names of Christian saints, spirit allies and the spirits of the Earth, the elements, animals and plants, the sky, the waters and the fire (Estrada 1981; Wasson 1980).

Traditional Amazonian Indian or mestizo ceremonies with ayahuasca also involve a small group sitting in a circle, in semidarkness, while the initiated healers sing the songs (*icaros*), through which the healing and/or diagnosis takes place. These songs also have a fairly rapid rhythmic pulse, which keeps the flow of the experience moving along. Shamanic "sucking" methods of extracting toxic psychic residues or sorcerous implants are sometimes used (Luna & Amaringo 1991; Dobkin de Rios 1984).

The ceremonies involving the African *iboga* plant, used by the Bwiti cult in Gabon and Zaïre, involve an altar with ancestral and deity images, and people sitting on the floor with much chanting and some dancing. Often, there is a mirror in the assembly room, in which the initiates may "see" their ancestral spirits (Samorini 1995; Fernandez 1982).

Certain common elements can be found in the anthropological literature on the experiences of shamanistic indigenous societies with hallucinogenic plants. These features are also found in accounts of shamanic journey experiences with other modalities, such as drumming, vision questing, or conscious dreaming. It is clear that these experiential features imply the existence of a radically different worldview (than the Western) in entheogenic shamanic practitioners. I will simply list these features, since there is not the space here to document them extensively.

1. The role of the guide, *curandera* or healer is always described as central and essential. This must be a person with extensive personal experience in the use of these medicines, who agrees to provide an initiatory experience to a seeker or training to an apprentice. In virtually all entheogenic rituals, the guide or shaman does much or all of the singing, and this singing profoundly shapes the quality and content of the experience.
2. The experience can be *healing* on physical, psychic and spiritual levels (although traditional shamanic healers do not make such analytic distinctions). Shamanic healing experiences, with entheogens or other means, have three main variations: one is the extraction of a toxin that may have been implanted by means of sorcery; the second is the retrieval of a split-off psychic fragment or "soul"; and the third is the experience of being dismembered or destroyed, and then reconstituted with a healthier, stronger "body."
3. The experience can provide *access to hidden knowledge* - this is the aspect of divination, "seeing," prophecy, intuition or visioning. If the intention or context is healing, then the divination would be equivalent to what Western medicine calls diagnosis - e.g., determining from where and from whom the particular toxic implant came, where has the soul-fragment been "lost," what particular herbs should be used for the person's illness, etc. It is said that there is an intelligence associated with the plant medicine that communicates in an interior way to the person who ingests the medicine. Indigenous healers refer to the entheogenic plants as "plant teachers."
4. There is a feeling and perception of *access to metaphysical realms or worlds*. Such realms have, in shamanic, esoteric or magical traditions, been referred to variously as the "inner world," "spirit world," "upper or lower world," "faerie world," "dreamtime" or "otherworld." Some anthropologists, including Michael Harner, refer to them as "nonordinary reality." The access to these other-worlds may come through a kind of journey to that world, perhaps traveling on the back of an animal or being carried by a large bird. Alternatively, one may feel that one can see into the spirit world without moving, while still aware of the ordinary present world of time-space as well. Scenery and beings of the other world may appear in our world. In any event, the usual boundaries between the worlds seem to become more permeable during such experiences.
5. The experience may involve the *perception of nonmaterial, normally invisible, spirit beings or entities*. Such spirits are recognized as being associated with particular animals (e.g., a serpent or jaguar), certain plants, trees or fungi, certain places (e.g., a river or rainforest), deceased ancestors, and other nonordinary entities (e.g., extraterrestrials or elves). It can include the experiences of actually becoming or identifying with that spirit (e.g., the experience of becoming a jaguar or a serpent). The healing and divination is experienced as being done by or with the assistance of such spirits, also referred to as "allies," "power animals," "guardians" or "helpers." In some healing rituals, there may also be contact with bad or malevolent spirits that need to be exorcised or neutralized in some way.

In comparing Western psychoactive-assisted psychotherapy with shamanic entheogenic healing rituals, we can see that the role of an experienced guide or therapist is equally central in both, and the importance of set (intention) and setting is implicitly and explicitly recognized in both. Healing and insight may take place with both approaches, though the underlying paradigms of illness and treatment are completely different. There is a great deal of as-yet-poorly or not-at-all understood about the processes of illness and healing.

The role of divination is implicitly acknowledged in the Western models through the amplifier analogy and the microscope metaphor. The two elements in the shamanic traditions that pose the most direct and radical challenge to the accepted Western worldview are the existence of multiple worlds and of spirit beings - such conceptions are considered completely beyond the pale of both reason and science. However, we shall see that in the hybrid shamanic-therapeutic rituals and practices, the recognition of multiple dimensions and of the reality of spirit beings is becoming quite common.

Syncretic Folk Religious Ceremonies

The distinction I am drawing here between entheogen-based shamanic rituals and folk religious ceremonies involving plant entheogens is in some ways arbitrary - there is, rather, a continuum of ritual forms and practices. The emphasis in shamanic practices is healing and divination, and they are usually conducted in small groups of around a dozen participants, or sometimes just with one or two afflicted individuals and with apprentices. The folk religious ceremonies often involve fairly large groups of 20 to 40 participants, and in the case of the Brazilian *hoasca* churches several hundred. Here the aspect of healing and divination or visioning tends to recede more into the background, and the primary focus is on group worship and celebration with singing and prayer. Instead of a shaman or healer there are priests and officiants. There is very little or no discussion or sharing of visions or insights, as there would be in the context of a shamanic healing or divination.

The groups coalescing around such entheogenic folk ceremonies in an urban or village society have usually organized themselves into recognized churches, providing their members with a certain degree of social cohesion and protection. An important social function of these religious ceremonies is to strengthen community bonds and give members a sense of participation and belonging. Participation in the Native American Church in the United States, as well as the *hoasca* churches in Brazil, tends to reduce the incidence of alcoholism and drug addiction (McClusky 1997; Grob *et al*. 1996). As has been noted by some anthropologists, a further societal function of these churches is to provide a protective shield of traditional lore against the encroachments of Christian missionaries and the seductions of Western consumer culture in general (Taussig 1987; Fernandez 1982).

The use of peyote by the Huichols of Mexico follows more the traditional shamanic healing model, involving careful and lengthy apprenticeships for the *curanderos*, and a group pilgrimage to the sacred land of Wirikuta to find the sacred cactus. The actual ceremonies are accompanied by much singing and telling of creation myths and other sacred stories (Pinkson 1995; Myerhoff 1974). Native American tribes in the United States legally incorporated the Native American Church (NAC) as an organized religion that uses the peyote cactus as a sacrament. Though their legal protection has been eroded in recent court decisions, for most of this century the NAC has enjoyed legal access to the entheogens in most of the Western states (Peregoy, Echo-Hawk & Botsford 1995). Native American Church ceremonies follow a fairly consistent format, with a "roadman" presiding, and with almost constant singing of traditional peyote songs throughout the night. There is virtually no discussion of healing processes or "visions" during or after the ceremony, although individual participants may of course have healing or visionary experiences. NAC ceremonies are legally limited to persons with 25% or more Indian ancestry, although some ceremonial leaders have opened up their ceremonies to non-Indians as well.

In Brazil there are no less than three organized churches in which ayahuasca is the main sacrament: the Santo Daime, Uniao de Vegetal (UDV) and Barquinia. Each was founded by rubber tappers working in the Amazon region in the 1950s, who came into contact with the hallucinogenic vine through mestizo or Indian *ayahuasceros*. The founder of each of them reported a significant vision which instructed them to organize a church using the brew or "tea" as the principal sacrament. Members of the churches come from all walks of life and both urban and rural environments in Brazil. Each has by now several thousand members in Brazil, and two of the churches have significant satellite centers in North America and Europe. The churches are officially recognized and the use of the ayahuasca is legal in Brazil within that framework.

Typically, the ceremonies are held weekly in specially-built temples, and may range in size from 20 or 30 to several hundred participants. Each of the churches has some differences of emphasis and ceremonial form. The UDV, the largest, is also the most formal: participants sit in rows in straight-backed chairs during the ceremony, listening to sermons and songs given by the *maestres* who sit around a table in the center; there is also a question and answer period. Sometimes testimonials of life-transformations are offered by longer-term members, reminiscent of AA confessions. The Santo Daime, which was founded by a Brazilian of African descent, involves the singing of hymns by the entire congregation, led by a small group of women singers. Some of the Santo Daime ceremonies also involve dancing, in simple rhythmic, swaying steps - the whole somewhat reminiscent of African-American gospel services. The Barquinia church, less well known outside of Brazil, has incorporated elements of Umbanda, an Afro-Brazilian religious movement that involves contact with deceased ancestors and deities known as *orixas*. These ceremonies also involve both singing and dancing. The research of Charles Grob, Dennis McKenna and others has confirmed that membership in these churches and long-term drinking of the tea is associated with no adverse health effects - and indeed with a reduction of addictions and other psychopathologies (Grob *et al*. 1996).

The Bwiti cult among the Fang people in Gabon and Zaire involves the use of the powerful hallucinogen iboga or eboka, from which ibogaine is derived. The use of iboga, like peyote in North America, exists in both shamanic and syncretic religious ceremonial forms. Originally, the Fang, who are village dwellers, say they learned about the iboga brew from the Pygmies, the deep forest dwellers. Initiates are taken through a powerful death-rebirth experience, in which their "head is opened up," after which they are able to converse with their ancestor spirits, who can guide them in their lives. The Bwiti ceremonies are held in temples, with an altar and officiating priests, where the initiate men and women, daubed with white mud, sit and sing in lengthy ceremonies. (Samorini 1995; Fernandez 1982). Pharmacological research has indicated that ibogaine may have a specific action on the receptor sites for cocaine in the brain, raising the possibility that it may be a chemical antidote to addiction (Lotsof 1995). The more plausible assumption is that all the "consciousness-expanding" hallucinogens, including LSD, peyote, ayahuasca and others, can serve to counteract the consciousness-contracting and fixating effect of the addictive narcotics or stimulants (Halpern 1996).

These syncretic religious movements, particularly the ayahuasca churches in Brazil, have brought the use of entheogenic plant substances out of the context of shamanic healing rituals, where only a very limited number of people came into contact with them. They have made profoundly spiritually transforming experiences with entheogenic plant medicines accessible to a large number and wide spectrum of people in all walks of life. As such, we may be seeing the beginnings of a broader cultural transformation movement with significant impact.

Hybrid Shamanic Therapeutic Rituals

There are numerous kinds of set-and-setting rituals using hallucinogens in the modern Western world, ranging from the casual, recreational "tripping" of a few friends to "rave" events of hundreds or thousands, combining Ecstasy (MDMA) with the continuous rhythmic pulse of techno music. My own research has focused on what might be called neoshamanic medicine circles, which represent a kind of hybrid of the psychotherapeutic and traditional shamanic approaches. In the past dozen years or so I have been a participant and observer in over 100 such circle rituals, in both Europe and North America, involving several hundred participants, many of them repeatedly. Plant entheogens used in these circle rituals have included psilocybe mushrooms, ayahuasca, San Pedro cactus, iboga and others. My interest has focused on the nature of the psychospiritual transformation undergone by participants in such circle rituals (Metzner 1999).

In these hybrid therapeutic-shamanic circle rituals certain basic elements from traditional shamanic healing ceremonies are usually kept intact:

- the structure of a circle, with participants either sitting or lying;
- an altar in the center of the circle, or a fire in the center if outside or in tipi;
- the presence of an experienced elder or guide, sometimes with one or more assistants;
- a preference for low light, or semidarkness; sometimes eye-shades are used;
- use of music: drumming, rattling, singing or evocative recorded music;
- dedication of ritual space through invocation of spirits of four directions & elements; and
- cultivation of a respectful, spiritual attitude.

Experienced entheogenic explorers understand the importance of set and therefore devote considerable attention to clarifying their intentions with respect to healing and divination. They also understand the importance of setting and therefore devote considerable care to arranging a peaceful place and time, filled with natural beauty and free from outside distractions or interruptions.

Most of the participants in circles of the kind that I witnessed were experienced in one or more psychospiritual practices, including shamanic drum journeying, Buddhist *vipassana* meditation, tantra yoga and holotropic breathwork, and most have experienced and/or practiced various forms of psychotherapy and bodyoriented therapy. The insights and learnings from these practices are woven by the participants into their work with the entheogenic medicines. Participants tend to confirm that the entheogenic plant medicines, when combined with meditative or therapeutic insight processes, function to amplify awareness and sensitize perception, particularly amplifying somatic, emotional and instinctual awareness.

Some variation of the *talking staff* or *singing staff* is often used in such ceremonies: with this practice, which seems to have originated among the Indians of the Pacific Northwest, and is also more generally now referred to as "council," only the person who has the circulating staff sings or speaks, and there is no discussion, questioning or interpretation (as there might be in the usual group psychotherapy formats). Some group sessions, however, involve minimal or no interaction between the participants during the time of the expanded state of consciousness.

In preparation for the circle ritual there is usually a sharing of intentions and purposes among the participants, as well as the practice of meditation, or sometimes solo time in nature, or expressive arts modalities, such as drawing, painting or journal work. After the circle ritual (sometimes the morning after), there is usually an integration practice of some kind, which may involve participants sharing something of the lessons learned and to be applied in their lives.

The majority of Westerners who have developed an ongoing practice of working with entheogenic plant substances seem to have expanded their belief systems beyond the boundaries of the conventional materialistic paradigm of Western science and psychology. While accepting the validity of many Western psychological insights, including those of Freud, C.G. Jung and Wilhelm Reich, they have come - like indigenous people and devotees of Asian and Western esoteric traditions - to accept the reality of nonmaterial spirit beings and to recognize that we live in multiple worlds of consciousness.

Western psychology may, through such explorations, be finally coming around to the views expressed by William James, after his personal research with the psychedelic anesthetic nitrous oxide, almost 100 years ago:

> Our normal waking consciousness, rational consciousness as we call it, is but one special type of consciousness, whilst all about it, parted from it by the filmiest of screens, there lie potential forms of consciousness entirely different... . No account of the universe in its totality can be final which leaves these other forms of consciousness quite disregarded (James 1901/1958: 228).

Vision inducing plants, commonly referred to as entheogens, hallucinogens, and psychedelics, have played important roles in the therapeutic and religious practices of many societies. Cross-cultural research indicates that their common effects include the induction of powerful emotional, cognitive and therapeutic reactions and interpretations, suggesting these are consequences of similar psychophysiological properties of the substances. Neurophysiological studies illustrate the common physiological effects of entheogens involve psychointegrative effects through intervention in the serotonergic neurotransmitter systems. Psychointegration underlies the entheogens' cross-cultural use as sacred and therapeutic agents. The effects of psychointegrators upon neural, sensory, emotional, and cognitive processes illustrate their adaptive effects in the stimulation of integrative information processing and enhancement of access to lower structures of consciousness. Psychointegrative effects derive from the disinhibition of emotional and social processes and the stimulation of systemic integration of brain functions, particularly the integration of limbic system processes with neocortical processes. Psychointegrators couple nonlinguistic behavioral and social-emotional dynamics with rational processes and functionally integrate different systems of the brain while enhancing spiritual and transcendent experiences by stimulating brain operations supporting basic structures and functions of consciousness (self, other and affect/attachment).

Introduction

The plants with entheogenic effects have played important roles cross-culturally and across history. Where used, they generally have been viewed as central sources of spiritual experience and religious participation, providing inspiration for the institutionalization of religious sentiments and activities (e.g. see Dobkin de Rios 1984, Schultes and Hofmann 1979, Winkelman and Andritzky 1996). These plants are important in understanding cultural and religious development. As La Barre (1972) pointed out, understanding the pharmacological effects illuminates their central roles in many cultures as sources of religious and spiritual inspiration, shamanic ecstasy and visionary experience. An integration of laboratory studies of entheogens' neurophysiological effects and neurotransmitter interactions with ethnographic and cross-cultural studies on their social and therapeutic uses illustrates why they have important personal and cultural functions. Such substances may be also seen as dangerous agents and demonic influences to be prohibited. Understanding why these substances evoke such powerful social reactions requires knowledge of their biophysiological, cognitive and psychosocial effects.

This paper develops a neurophenomenological perspective (e.g. see Laughlin d'Aquilli and McManus 1992; Winkelman 2000) on the institutionalized cultural use of entheogenic plants, addressing their biochemical mechanisms to enhance understandings of their psychodynamic and phenomenal effects upon human experience. This interdisciplinary synthesis provides the rationale for the term "psychointegrator" to refer to the central effects of entheogens, and contributes to a "neurotheological" perspective on the biological mechanisms of sacred experiences (e.g., d'Aquili and Newberg, 1999; Joseph, 2001; Winkelman, 2000). The cross-cultural social and therapeutic uses of entheogens are based in their neurophysiological effects upon the serotonergic neurotransmitter systems. This is the basis for their characterization as "psychointegrators", enhancing processing of fundamental information regarding self, emotions, social relations, attachments, and the overall integration of information in the brain. The neurological foundations explain the widespread common patterns of use of these plant substances in religious and therapeutic practices. Entheogenic plants are generally used along with other means of inducing altered states of consciousness (ASC) in shamanistic healing practices that reflect the universal institutionalization of the psychobiological potentials of ASC (Winkelman 1986a & b, 1990, 1992). This use of ASC is functional, based upon physiological changes that facilitate healing and cognition through a number of physiological and psychological mechanisms (Winkelman

1992, 2000). Shamanic ASC are the quintessential spiritual experience of "ecstasy", providing a neurological basis for the role of chemical agents as sources of spiritual experience.

Cross-Cultural Patterns in Societal Responses to Entheogens

The cross-cultural use of entheogens is consistently associated with the fundamental principles reflected in the etymology of the term - the belief that they are powerful spiritual forces that provide access to internal sacred worlds and have simultaneous therapeutic applications (see Dobkin de Rios 1984; Emboden 1972, 1989; Furst 1972, 1976; Riedlinger 1990; Schultes 1972; Schultes and Hofmann 1979; Wasson 1980; Wasson *et al*. 1974, 1986; Winkelman 1996). Entheogens not only dramatically alter experience, shifting self-awareness to an "other-worldly" sacred or spiritual domain; they also have important applications as therapeutic agents. Furthermore, there are ubiquitous interpretations of these plants' effects, a universal social psychology that involves: personal relations with an animistic world (especially power animals); participation in a mythical time which reaffirms cultural values and beliefs; contact with a spiritual source of power and self identification; ego dissolution and transformation; healing and divination; and enhancement of social solidarity and identity, and interpersonal and community relations (Winkelman 1996).

Alex Grey, *Ayahuasca Visitation*, 2001. Colored pencil and acrylic on paper (11 3/4" x 16 1/4")

Other cross-cultural patterns of entheogen use involve the context of initiation. Grob and Dobkin de Rios (1992) point to the cross-cultural pattern of managed use of these substances in contexts where elders employ them in re-socialization rites. These often constitute collective puberty or initiation rites that channel the individual in transition to adult status. Entheogens are also widely used in the context of shamanic initiation and training (Harner 1973, Furst 1976, Winkelman 2000) and may have contributed to their origins.

The worldwide interpretation of these substances as having simultaneous religious, spiritual and medicinal roles reflects their effects upon basic structures of consciousness. McKenna (1992) documents the worldwide pre-historic practices of using mushrooms as a central part of a cultural ethos relating to the earth and mysteries of nature. He suggests that the mushrooms provoke enhanced self-awareness and a sense of contact with a "Transcendent Other." This reflected an experience of the sentience and intelligence of nature, and an intimate awareness of our interconnectedness with nature, the earth, and the universe.

Societal Differences in the Use of Psychointegrative Plants

Though very widespread, the societal use of entheogens is not universal but varies as a function of social conditions. Different types of societies make varying assessments of their value and potentials. Differences in their use is reflected in the dramatically larger number of hallucinogenic plants used in the New World in comparison to the Old World cultures (LaBarre 1970). This variation has been attributed to cultural factors, since there are many entheogens present but not considered religious in the Old World (Schultes and Hofmann 1979, LaBarre 1970, Furst 1972). Institutional political factors are also responsible for the lack of use of these psychointegrator plants. Hallucinogenic plant use is not typically institutionalized in complex societies (Dobkin de Rios and Smith 1977; Winkelman 1991c). Increasing social and political complexity leads to reduction in the use of psychointegrator plants, with the societal use of hallucinogens negatively correlated with the levels of political integration (Winkelman 1991c). This negative relation to political integration reflects the dynamics of their psychocognitive effects and their inherent conflicts with the political needs of the leadership of hierarchical societies.

The repression of, and restrictions on, the use of entheogens (as a function of increasing political integration) reflects their patterns of use and their effects upon social relations and personal interpretations of the world. Dobkin de Rios and Smith (1977) suggest that hallucinogenic plants are typically repressed in state level societies because they constitute a potential threat to the religious authority and interpretations of those who hold social and religious power. These substances are typically employed in social settings where local idiosyncratic interpretations derived from the set and setting (personal expectations and the local situational influences) play powerful roles in shaping interpretations of the experiences. Local interpretation of the experiences could pose a threat to the centralized hierarchical control of religious consciousness and political authority, and undermine control in religious, political and social arenas. These conflicts could be expected to result from the typical cross-cultural patterns of use of these plants in small group community settings, where they enhance group cohesion and reaffirm immediate values and beliefs (Dobkin de Rios and Smith 1977). They consequently reinforce a traditional community based mythos and social order rather than hierarchical ideological and political ideologies.

The social contexts associated with the use of entheogens also suggest that they are used to provide means of facilitating psychosocial adaptations to social change. Entheogens appear to be most intensely used under conditions of rapid social change, where they serve as a means of facilitating adaptation to changing psychosocial circumstances (e.g. see Andritzky 1989, Aberle 1966), facilitating mediation between conceptual systems. The widespread use of the Banisteriopsis genus (ayahuasca) in the Amazonian basin in collective rituals which strengthen social cohesion and group identity also assist in the management of acculturation problems by mediating between the indigenous world view and the European derived systems (Andritzky 1989). The symbolic synthesis of traditional and new beliefs that facilitate psychosocial adjustment is achieved through the images that appear while under the influence of the plants. Similar dynamics are reported for the selective adoption of the Peyote Religion (Native American Church) among the Navaho (Aberle 1966). The historical development of the Peyote Church illustrates its role in psychosocial adjustment. The early Navajo adherents were primarily those who experienced the greatest relative deprivation due to federally imposed livestock reduction programs. The Native American Church provided a new ethical code that facilitated an adjustment of the Navajo values of collectivism to the broader society's emphasis on individualism. The burgeoning use of hallucinogens in American culture was also associated with periods of rapid social change in the U.S. (i.e., 1960's and 1990's).

Botanical, Chemical Experimental, and Neurological Approaches to Entheogens

The (pre) historical and cross-cultural commonalities in the uses of entheogens, and in particular their similar social and therapeutic utilization patterns, reflect underlying biological mechanisms and require a neurobiological explanation. The specific physiological mechanisms of the general and specific effects of entheogens are derived from the physiological properties of these substances. The commonalities in the experiences induced by entheogens suggest that they should share a common botanical and chemical classification. But there is no single botanical grouping or chemical classification for the diverse plants and substances that produce entheogenic effects, occurring in nearly 100 species and a wide range of genera and families (Schultes and Hofmann 1979). Traditionally, classification of a substance as a hallucinogen was based in non-toxic subjective effects upon human experience, the ability to produce visions, voices, and alterations of perceptions and mood (Siegel 1984).

Because of the subjective basis of the classification of these substances and their effects, social and cultural factors have dominated the labeling of these substances. This is manifested in the medical definition of hallucinogens, which characterizes them as false perceptions and disturbances of thought, experiences without a basis in reality. Similarly, the early psychiatric term "psychomimetic" implies a psychotic and delusional basis for the experiences, but does not reflect their central phenomenological experiences. The cross-cultural use and interpretations of these substances instead reveals that they invoke perceptions of a spiritual realm, a veridical source of important information, in direct contrast with the implications of delusions emphasized by traditional nomenclature.

Recognition of the shortcomings of the medical terms and traditional definitions has prompted the development of new terminology.

The term "psychedelic" developed mainly in the context of LSD experiences, referring to the extraordinary conceptual ("mind-manifesting") impact upon human experience and understanding. The general connotations associated with the term psychedelic, derived as they are from the closely-associated counter-cultural movement, has made the term undesirable to many. The focus on the mental also fails to capture the significant emotional and therapeutic effects. Grof (1989) proposed the term holotropic to reflect the psychodynamic actions of these substances in forcing an orientation towards wholeness. Holotropic does reflect global effects, but does not explicitly emphasize the salient spiritual, emotional, and cognitive elements central to the experiences induced by psychointegrators.

Shultes and Hofmann (1979) referred to these substances as "plants of the gods," reflecting the referents often embodied in indigenous terms for these plants. Many religions throughout history and prehistory and around the world have viewed their practices as inspired by the indwelling spiritual influences of certain sacred plants. In light of these ubiquitous beliefs, Ruck, Wasson, Staples, Bigwood, and Ott (1979) introduced the term entheogen from the Greek *entheos*, referring to "the god within," and gen, "action of becoming." Entheogen reflects many cultural perceptions of these substances and is very appropriate for classification of their beliefs. It can be argued, however, that the concept of entheogen does not reflect other personal and cognitive dynamics of these plants' effects, and implies a strictly spiritual basis that may alienate some who wish to take a more agnostic/scientific approach to the study of these substances.

I have suggested the term psychointegrator as being based both upon the neurological and experimental effects of these substances (Winkelman 1996). Cross-cultural data on traditions utilizing these substances and the neurobiological research on their mechanisms of action concur in seeing these substances as producing psychointegration. Psyche reflects not only the mind, but also the soul and spirit (the broader bases to which psyche once referred), thus it encompasses the spiritual dimensions emphasized in the term entheogen. Psychointegrator implies the stimulation of the mind, emotions, soul and spirit to integrative development (Winkelman 1996) in that they stimulate mental and emotional catalyzing processes, and encourage a holistic developmental integration of the mind, spirit and soul.

The neurotransmitter actions of these substances involve a number of psychointegrative effects and provide a basis for explaining their cross-cultural similarities. Beginning with neurotransmitter processes, and continuing upward, across hierarchical levels of complexity in the brain and mind, psychointegration reflects the effect of entheogens upon processes from neurotransmitter activity, through physiological, behavioral, emotional, cognitive and psychological levels. The basis of an entheogen's activity derives from its intervention in the serotonergic neurotransmitter system, a "neuromodulatory" system whose properties and effects exemplify psychointegration. That is, the modulating effects of serotonin have an overall integrating effect on the dynamics of the neurotransmitter systems.

The introduction of the term psychointegrator is not intended to replace all other terms for sacred plants, nor to preclude further terminological differentiation (e.g., Naranjo 1996, Stafford 1992). Rather, the intent is to supercede inaccurate and value-laden terminology and to provide a neurological basis for explaining the commonalities in the effects of these substances. Such neurological effects can also provide an explanation for the roles of entheogens, activating brain processes that enhance fundamental aspects of sacred experiences. A fundamental aspect of entheogenic and sacred experiences is the generation of a sense of connectedness, oneness and psychological health and healing - perceptions that reflect the effects of psychointegration.

Neurological Perspectives on Psychointegrators

The effects of entheogens upon neurotransmission are responsible for the cross-cultural similarities in physical, emotional, cognitive and sacred experiences and their therapeutic applications. Neurological studies indicate that the major entheogens have common effects upon neurotransmitters (Jacobs 1984a, Mandell 1985). Their effects upon brain function in humans and other animals have been extensively investigated, particularly in the case of LSD (Jacobs 1984a; Mandell 1985). Most of these substances (i.e., indoleamines like psilocybin and LSD, and the phenethylamines like mescaline) have effects that generalize to one another, reflecting similar neurochemical mechanisms of action (Mandell 1985) and global properties involving effects upon serotonin pathways and mechanisms (Jacobs 1984, Aghajanian 1994).

Alex Grey, *Ohio Song*, 2001. Oil on linen (11" x 14")

Laboratory studies of LSD effects have provided diverse findings, derived from various procedures, dosages, phase effects, and "set and setting" factors (Freedman 1984). The basic mechanisms of their action, however, are well recognized, and the LSD-like entheogens are well understood in terms of their effects upon brain mechanisms (Mandell 1985). The primary neurotransmitter system affected by LSD-like entheogens is serotonin. The entheogens most similar to serotonin are: LSD and lysergic acid amide (LSA, e.g., morning glories); psilocybin (e.g., from mushrooms of the genera Psilocybe, Conobybe, Panaeolus and Stropharia; harmine and harmaline from Banisteriopsis caapi and Peganum harmala; and DMT (dimethyltryptamine) and similar substances from the Virola genus and species of Anadenanthera. Mescaline (from peyote) and similar synthetic drugs (STP, DMA, MMDA) resemble norepinephrine, but have end effects similar to the LSD-like substances.

Entheogens' effects upon sensory, behavioral, emotional, cognitive and psychodynamic experience illustrate their stimulation of integrative information processing, providing the rationale for their characterization as psychointegrators. Their systemic effects upon the autonomic nervous system include the induction of limbic system discharge patterns that enhance interhemispheric synchronization and coherence, and limbic-frontal cortex integration (Mandell 1980, 1985; Winkelman 1996). These substances evoke an integration of brain functioning from neurophysiological through cognitive levels, stimulating the integration of pre-linguistic social, emotional and behavioral processes with the frontal cortex's linguistic and egoic functions. The therapeutic roles of psychointegrators derive from the activation of emotional and personal processes of the limbic system and paleomammalian brain that underlie personal identity, attachment and social bonding, emotion, conviction (in beliefs), and their integration with neocortex processes.

Entheogens stimulate the integration of the brain's behavioral and social-emotional processing output with language based ratiomentation, egoic representations, and personal identity. This activation is reflected in the theta wave linkages between the limbic-emotional and the behavioral brain that send ascending impulses into the frontal cortex. These biochemically based physiological effects may produce awareness of repressed memories, integration of emotional and rational processes, and the resolution of conflicts through integration of various functional systems of the brain. I have introduced the term psychointegrator in order to refer to the systemic integrative effects of these substances.

Psychointegrators and Neurotransmitter Functions and the Brain

Neurotransmitters act through a number of mechanisms, exercising inhibitory or excitatory effects and modulating the effects of other neurotransmitters. Entheogens have these roles in the serotonergic system, substituting for neurotransmitters in some receptor locations, and, in others, functioning as antagonists (or blockers) that prevent the normal response.[1] These actions[2] upon neurotransmission mediate their profound effects upon human experience and consciousness.

There are at least four different types of CNS serotonin receptors with different kinds of effects in different parts of the brain.[3] The LSD-like psychointegrators interact with serotonergic neurotransmitters across all major levels of the brain, generally augmenting normal processes in these structures.

Basic commonalities of the LSD-like indole-based psychointegrators involve the blockage of serotonin re-uptake, enhancing action of the brain's serotonergic systems (Mandell 1985). Another mechanism of psychointegrators' effects upon serotonin action is the decreased action of target neurons in the forebrain; LSD exercises a blocking effect upon these serotonin neurons, resulting in the disinhibition of their typical repression. The limbic system's emotional processing areas and the visual areas of the cortex have the most intense disinhibition and therefore greatest activity, resulting in intense visual and emotional experiences. This disinhibition of the structures of the mesolimbic temporal lobe manifests as synchronous high voltage activity in the hippocampus, and as synchronous discharges in the temporal lobe limbic structures (Mandell 1980, 1989; Fink 1978, Aghajanian 1982; Hoffmeister and Stille 1982). Synchronous brainwave patterns result which drive impulses into the frontal cortex, replacing its characteristic desynchronized fast-wave activity with slower, more coherent wave patterns. In turn, these coherent systematic discharges produce synchronous, slow-wave patterns (3-6 cps theta) in the frontal lobes, and ultimately interhemispheric synchronization of the cortex (Fairchild, Alles, Jensen and Mickey 1967, Mandell 1980).

Mandell (1980) suggests that the common neurobiochemical pathway is based in biogenic amine-temporal lobe interaction involving high voltage slow wave EEG activity in the hippocampal-septal area of the limbic system. The limbic system discharge pattern induced by entheogens produces inter-hemispheric synchronization and coherence, limbic-cortical integration, and the synthesis, integration and coherence of thought and emotion (Mandell 1980, 1985; Winkelman 1986a, 1992). Thus the effects of biochemical psychointegration include increases in the coherence of brain discharges, an enhanced integration of feelings and thoughts, and the catalization (of often profound) personal-psychological insights. Driven by the underlying limbic functions, entheogens stimulate the brain to process information in this integrated fashion.

Psychointegrative results derive from a range of biochemical mechanisms upon brain function. These effects on neurotransmission enhance brain activity by reducing habitual repressions while simultaneously stimulating processes that are normally dissociated (such as simultaneous dreamlike mentation with ego awareness). Psychointegrators increase activity of the raphe and reticular formations of the brain stem area, the limbic system, (particularly the hippocampus and amygdala), and the visual and auditory areas of the frontal cortex. This results in the stimulation of memory, emotions, motivation, cognitive processes, attention, awareness and environmental orientation.

Such synthesis of whole brain function enhances the regulation of the autonomic nervous system and the integration of emotions and visual-cognitive representations (Winkelman 1996, 2000). LSD-like compounds also increase arousal, heightening sensory receptivity and responsiveness, which induce a more thorough and random examination of a given environment. This phenomenon, which is almost universal at lower does, again demonstrates the reduction of typical response patterns, habitatuation, which often leads to new behavior patterns and perspectives. High dosages tend to lead to withdrawal (i.e., 'incubate') and a focus upon the internal environment, where limbic activity forces material from the sub- or unconscious into awareness. Elevation of repressed/forgotten memories into consciousness permits catharsis and abreaction, allowing conflicts to be confronted and resolved. The tendency of these substances to elicit distressing personal material (i.e. unresolved conflicts, repressed experiences, and unintegrated aspects of ones psyche) suggests that the stimulation of the limbic system provokes the release of such unresolved issues as it is related to the sense of self and social attachments.

The limbic-frontal driving induced by psychointegrators also produces interhemispheric synchronization, producing integration of unconscious material into the cerebral cortex. This results in an integration of feelings with thoughts, enhancing insight. With an enhanced awareness of repressed memories, personal emotional liability increases, disrupting habitual behavior patterns and dissolving problematic egocentric fixations and repressions. Thus stimulating psyche-dynamic reprogramming by permitting the conscious consideration and expression of repressed aspects of the self.

Psychointegrators primarily enhance the activation of the aspects of the brain that MacLean (1990, 1993) refers to as the R-complex and the paleomammalian brain, or limbic system. The R-complex is a "behavioral" brain that manages motor activities and their routinization, coordinating basic social interaction. The paleomammalian brain manages processes associated with self, identity, species survival, family and social relations, learning and memory, and sexual and aggressive emotions as well as their behavior integration. Entheogens (and ASC in general) enhance systemic integration of the psyche by producing heightened arousal and awareness, and by interfering with habituated behavioral routines. The paleomammalian brain and limbic system provide the social and emotional mentation and behavior. These fundamental cognitive processes involve nonverbal communication, and forms of mental and social representation that manage processes of emotional and social life.

By inducing experiences through the evocation of these underlying structures of consciousness and brain function, entheogens produce experiences that are interpreted and defined as spiritual. Grof 's (1975, 1980, 1992) many years of clinical research with LSD and holotrophic procedures has resulted in new models of the nature of human consciousness. Based on these experiences and research, he has identified the transbiological realms: the perinatal domain of (pre-) birth experiences and the transpersonal domain, of archetypal and mystical structures. The transpersonal domain reveals dimensions of human consciousness that lie beyond the easily encapsulated egoic identity, and provide fundamental or 'primary' spiritual experience. Grof's work on the personal biographical level of the perinatal (domains of-OUT) experience has demonstrated the effectiveness of entheogens in bringing the memories and conflicts embedded at this level into consciousness, and permitting their integration. Naranjo's (1996) studies suggest that entheogens activate "Kundalini phenomena," high levels of organismic self-regulation as a consequence of ego suspension and the activation of mental structures.

The inherent potential of entheogens to induce psychosocial psychointegration is reflected in the wide typology of LSD experiences. These differences result from effects mediated by "set and setting" and the personal, social or transpersonal expectations for the experience. "Set" refers to these beliefs, attitudes, and expectations that one inevitably brings with them, while "setting" refers to the consequences of situational influences upon the experience. Such effects are manifested in the different medical paradigms on the effects of LSD: which include the psychomimetic, psycholytic, and psychedelic (Yensen 1985; Bravo and Grob 1989). The different paradigms of LSD-effects are attributed to extrapharmacological factors derived from expectations and situational circumstances. It is illustrative at the "psychointegrative" effect that the subjects' experiences are understood to also reflect expectations of the researchers.

Psychointegrators, Altered States of Consciousness, and the "Divine Other"

The disinhibition of the serotonergic neurotransmitters systems and the resulting loss of their inhibitory effects upon the mesolimbic temporal lobe structures underlies the common effects of entheogens in producing altered states of consciousness (ASC) and the associated transcendental or transpersonal experience. Systematic changes in brain processes are common to many means of inducing ASC2 (Winkelman

1986a, 1992, 2000) or "transcendent state" (Mandell 1980, 1985) and the basis for the universal application of ASC in healing practices (Winkelman 1986b, 2000). The common psychophysiological changes associated with diverse ASC involve the replacement of normal waking EEG by cortical synchronization (produced by high-voltage, slow-wave discharges originating in the limbic system), which links the levels of the brain with coherent synchronized brain wave patterns. ASC generally replace the normal waking physiological patterns, characterized by the external orientation of attention, with an internally oriented parasympathetic dominant state.

Alex Grey, *Collective Vision*, 1995. Oil on linen (84" x 46")

Elsewhere I have shown that various ASC constitute different means of accessing a common mode of consciousness that represents an optimized homeostatic balance among different functional systems of the brain, permitting the emergence of integrative psycho-physiological operations. This integrative mode of consciousness is as fundamental to human psychobiology as the dream, deep sleep, and waking, and underlies the universality of shamanic healing practices. Since ASC's exemplify the kinds of experiences produced by entheogens, we must conclude that their dynamics be understood in the broader context of ASC experiences.

The fundamental cultural roles of entheogens are shared with other methods of altering consciousness, being represented in shamanism and related ASC based healing practices found in all cultures (shamanistic healers), a universal institutionalization of the psychobiological potentials of ASC (Winkelman 1986a, 1986b, 1990, 1992). Entheogens often serve as a primary means for inducing ASC in the training of shamanic healers and in community rituals for healing. Most shamanic practices do not use entheogens, although these healers still serve the same cultural goals of healing and providing spiritual experiences. The role of these ASC lies in their functional effects, inducing the physiological changes that facilitate healing and divination through the stimulation of integrative brain functioning from the neurophysiological through cognitive levels. This suggests that the cultural roles of entheogens be understood also in the broader context of institutionalized practices for producing spiritual experiences through ASC.

The primary effects of entheogens and ASC are elucidated in reference to the nature of spontaneous religious experience (Stark 1997) and the brain systems elicited by psychointegrators (Winkelman 1996, 2000). Spontaneous religious experiences involve sensations, perceptions and feelings that include some sense of contact with a 'divine' agency that can provide interactive communication with the subject. Religious experience, as essentially a sense of contact with a "Divine Other," and means of developing an enhanced awareness of the divine aspects of self, is found universally because it results from the function of innate brain structures, operators and modules (Winkelman 2000; cf. D'Aquili and Newberg 1996, Joseph, 2001).

The areas of the brain primarily responsible for managing self and external awareness are based in the paleomammalian brain (MacLean 1990). This "emotional brain" is also a "social brain," effecting fundamental aspects of attachment with, and reference to, others. The emotional bonding that first emerged with the paleomammalian brain, evolved to include attachment to others - kin, community, and the unknown spiritual "Other". The major effects of psychointegrators on the paleomammalian brain (and its fundamental processes) provide a basis for an enhanced sense of awareness of self and other (i.e. Buber's 'I and Thou'), which is basic to religious and entheogenic experience. Thus neurophenomenological perspective suggests that the properties of entheogens derive from a general enhancement of specific aspects of brain function that have a role in managing self, other, affect and conviction about beliefs.

Conclusions: Systemic Integration of Brain Function

Spontaneous mystical experiences and those induced by entheogens have similar qualitative and quantitative effects upon both subjective experience and brain functioning. These parallels reflect the manipulation of similar brain processes and aspects of consciousness, indicating that such experiences are endogenous to brain structures and are not dependent on the unique properties of entheogens. Therefore our understanding of entheogens should be placed in the broader context of ASC and integrative mode consciousness models. Conforming to the fact that entheogens derive their characteristic properties from their effectiveness as psychointegrators and from their influences upon the innate structures and modules of the brain (Winkelman 2000, 2002).

The worldwide uniformity of the use of ASC reflects underlying psychobiological potentials. While cross-cultural variation exists in ASC phenomena, this reflects social influences upon the adaptation of these underlying biochemical potentials for ASC (Winkelman, 2000). The psychobiological basis of both shamanic experience and other "natural" ASC derived from the use of entheogens has resulted in the continued re-manifestation of these practices in the contemporary world. This is seen in numerous religio-therapeutic and Neo-shamanic groups active today, as well as the resurgence of indigenous shamanic traditions, the widespread adoption of peyote religion among Native Americans over the past century, most recently the development of a vast international "rave" culture, and the worldwide resurgence in entheogenic religions.

The impact on, and importance of, entheogenic plants in human cultures confirms their important role in facilitating psychointegration, helping to meet needs through the elevation and activation of innate structures, and the stimulation of integrative processes. Humanity's innate drive to seek out ASC's, manifests in a recurrent cycle of "rediscovery" of ASC, within societies. This illustrates a persistent need within all cultures to provide safe and legitimate access to these experiences. The lack of formal societal structures that instruct and accommodate ASC will only assure that the spontaneous discovery and exploration will continue as counter-cultural, (as was seen in the 60's LSD movement and the raves of the 90's).

Cross-cultural patterns of entheogen use illustrate their potential role in meeting a range of psychodynamic needs, in addition to their application for psychointegration. Psychointegration plays a critical therapeutic role in managing the needs of developmental change and crises induced problems that require the integration of conscious, pre-conscious and unconscious processes. This applies particularly to the integration of behavioral routines and socioemotional dynamics into a new gestalt. The conjunction of healing with spirituality reflects an integration of psychophysiological and psychocultural dynamics and has been a fundamental adaptation found universally within traditional societies in the form of shamanistic healing practice. A recurrent emphasis upon entheogens as an important means of achieving this adaptation reflects the need of modern cultures to dramatically reorient psychocultural dynamics to account for the many changes that have occurred in social and cosmological dynamics, producing new patterns of psychointegration. The use of these substances will continue in the rapidly changing world and requires that societies take informed and rational approaches to their managed use (c.f. Winkelman 2001).

Notes

1. Serotonin 5-HT_{1A} receptors in the raphe system mediate responses of the serotonergic neurons with respect to their own transmitters (Aghajanian 1994: 138). These receptors show a strong sensitivity to LSD-like substances (Aghajanian 1994: 140), inhibiting their firing in the raphe area and depressing neuronal firing in lower areas of the brain (the dorsal hippocampus, hypothalamic suprachiasmatic nucleus, amygdaloid cell, caudate-putamen, substantia nigra, trigeminal nucleus, spinal-cord interneurons, spinothalamic-tract neurons and the mesencephalic reticular formation) (Aghajanian 1981: 165). LSD effects the hippocampus by blocking or suppressing the typical depressant functions of serotonin, creating responses conditions similar to dreaming and contributing to production of the typical visual or hallucinatory experiences by disinhibiting postsynaptic neurons in the limbic and visual areas.
   Indoleamine and phenethylamines cause greater activation of 5-HT_2 serotonin receptors relative to other serotonin receptors (Aghajanian 1994). Primary effects of LSD-like psychointegrators are through the action on the 5-HT_2 serotonergic neurons (Glennon 1990: 43). Large concentrations of serotonin 5-HT_2 receptors are in the limbic system in the hypothalamus and basal ganglia; these sensory processing functions are antagonized by LSD (Kruk and Pycock 1991). LSD-like psychointegrators also affect the cerebral cortex and the locus coeruleus 5-HT_2 receptors (Aghajanian 1994). LSD affinity for 5-HT_{2A} and 5-HT_{2C} receptors facilitates the functioning of the locus coeruleus, which receives numerous somatosensory and visceral inputs and projects diffusely to most of the brain (Miller and Gold 1993). These 5-HT_2 serotonin sites play a role in the control of anxiety and reduction of schizophrenic symptomology (Ribeiro 1991).
   LSD-like psychointegrators activate the serotonergic neurons in the locus coeruleus, which serves as a nodal point for convergence of somatosensory and visceral information. The locus coeruleus projections innervate most areas of the neuraxis, principally the thalamus, hypothalamus, cerebellum, basal forebrain, hippocampus and neocortex (Aghajanian 1994, Role and Kelly 1991). LSD-like psychointegrators effect the somatodendritic region of the serotonin autoreceptors in the raphe neuron sites, inducing a selective and potent inhibition of the tonic firing of the dorsal raphe nucleus. This also results in a disinhibition of forebrain targets (Aghajanian 1981, 1982, 1994: 137). LSD-like psychointegrators release the tonic inhibitory serotonin influences upon postsynaptic neurons and increases activity in the lateral geniculate nucleus and amygdala. Jacobs' (1984b) expands the dominant model of presynaptic action of LSD upon serotonergic systems with consideration of the postsynaptic excitatory influences. LSD-like psychointegrators, potentiate serotonin's excitatory effects upon the brain stem and spinal cord (Jacobs 1984b), resulting in excitatory effects on brain stem and spinal cord areas receiving serotonergic input results in excitatory effects at the postsynaptic neurons in the cerebral cortex and brain stem (Jacobs 1984b: 188).
2. The systemic effects of these substances upon neurotransmitters as discussed here is derived from Aghajanian (1994), Jacobs and Gelperin (1981), Jacobs (1984a), Kruk and Pycock (1991), McKim (1991), and Ryall (1989).
3. Derived from Aghajanian (1981, 1993), Glennon (1990), Kruk and Pycock (1991: 121-122), Ribeiro (1991), and Schmidt and Perovtka (1989).
4. A wide variety of agents, procedures, and psychophysiological conditions produce this pattern of limbic driven cortical synchronization. In addition to the entheogens, these include: auditory stimulation such as singing, chanting and clapping; extensive running or other motor behavior; hunger, thirst, and sleep loss; intense sensory stimulation such as physical austerities or temperature extremes; sensory deprivation; sleep states and meditation; and a variety of psychophysiological imbalances or sensitivities resulting from hereditarily transmitted nervous system liabilities, or from epileptic-like states resulting from injury, disease, or other trauma to the central nervous system (summarized from Winkelman 1986a, 1992, 1997, 2000).

Vision-inducing plants ("hallucinogens") are important in many societies, evoking powerful emotional, psychological, cognitive, religious, spiritual, therapeutic and political reactions. These substances' psychophysiological properties shape cross-cultural similarities in patterns of use and experiences, while political factors shape their cultural desirability. Neurological studies illustrate that common effects are based in intervention in serotonergic neurotransmission. Effects upon neural, sensory, emotional, and cognitive processes stimulate integrative information processing, justifying a new term-"psychointegrators." Psychointegrators disinhibit sensory and emotional processes. They stimulate systemic integration of brain information-processing functions, enhancing integration of limbic system self and emotional dynamics with neocortical processes. Their therapeutic applications are reviewed from perspectives of cross-cultural and clinical studies.

The use of hallucinogens or psychedelics as therapeutic and religious agents is reported in many cultures (Dobkin de Rios,1984; Furst, 1972,1976; Harner, 1973; Rdtsch, 1989; Schultes & Hofmann, 1979; Stafford, 1992; Winkelman & Andritzky, 1996). Although broadly prohibited for private and therapeutic use by U.S. and international law in the late 1960s, these substances have a continued importance illustrated by the recent increases in self-application (Beck, 2000; Gold, 1994a & 1994b; Miller & Gold, 1993; Schuster, Lieb, Lamertz

& Wittchen, 1998; Werner, 1993; Zoccolillo, Vitaro, & Trimblay, 1999) and the governmental decisions to renew limited human subject studies (Mathias, 1993). These substances are often viewed as sources of spiritual inspiration, mystical participation and personal transformation, but also as dangerous agents to be controlled or prohibited.

This article integrates ethnographic, cross-cultural, clinical and neurophysiological data to develop a neurophenomenological perspective (Laughlin, d'Aquilli, & Mc- Manus, 1992) for explaining psychotherapeutic and sociocultural patterns of use of these substances. Cross-cultural similarities in social and therapeutic use derive from their effects upon serotonergic neurotransmission, enhancing brain wave coherence (synchronization), emotional processing, and self- and information integration. A review of physiological and psychological data justifies the term "psychointegrator" as more accurately characterizing these substances' effects, avoiding misleading implications and inaccurate assumptions associated with commonly employed terms such as hallucinogen. A cross-cultural review of the use of these substances illustrates similarities in effects and interpretations, and political conditions predicting their use and prohibition. Diverse therapeutic applications attested to cross-culturally are related to different clinical paradigms of the effects of LSD. These are shown to reflect effects upon serotonergic transmission and sensory, emotional, behavioral and cognitive processes. The article concludes with a brief consideration of psychointegrators' continued therapeutic and research applications.

Psychointegration: Hallucinogens' Actions upon Serotonergic Transmission

Cross-cultural similarities in uses and effects of psychointegrators suggest a common botanical and chemical basis for these substances. The so-called hallucinogenic substances do not share a single common botanical or chemical classification, being found in nearly 100 species and a wide range of genera and families (Schultes & Hofmann, 1979). Although hallucinogenic plants are principally fungi and angiosperms, angiosperms are the principal group of plants on the earth, and most are not hallucinogenic (Schultes, 1972; Schultes & Hofmann, 1979). Similarly, most hallucinogenic chemicals are alkaloids, but most alkaloids do not have hallucinogenic effects. Classification as a hallucinogen (or psychedelic) has not been based upon specific chemistry or physiology, but upon effects on human experience, producing visions, voices and effects upon perception, mood, and thought in *non-toxic doses* (Siegel, 1984). This distinguishes them from substances that produce hallucinations because of toxicity.

In spite of the absence of a botanical grouping or chemical classification for these notable plant substances, there are common neurophysiological effects of many of these substances. Lysergic acid diethylamide (LSD), phenylethylamine (e.g., mescaline) and indolealkylamines (e.g., psilocybin) differ in terms of their potency but otherwise have virtually identical clinical effects (Aghajanian, 1994; Hollister, 1984; Jacobs, 1984a; Mandell, 1985). Most[1] substances classified as hallucinogens (e.g., indoleamines such as psilocybin and LSD, phenylethylamines such as mescaline, and tetrahydrocannabinols) have similar neurochemical mechanisms of action involving intervention in serotonin pathways and mechanisms (Aghajanian, 1994; Jacobs, 1984b). Their effects provoke limbic discharge patterns that produce enhanced interhemispheric synchronization and increased communicative interaction between the frontal hemispheres, and between the lower brain areas and frontal cortex (Mandell,1980, 1985). The psychointegrators most similar to serotonin and interacting with it are as follows: LSD, other ergot compounds, and lysergic acid amide found in morning glories (*Ipomoea spp.*); psilocybin (e.g., from mushrooms from the genera *Psilocybe*, *Conocybe*, *Panaeolus*, and *Stropharia*); and DMT (dimethyltryptamine) and similar substances from the genus *Virola* and species of *Anadenanthera*. Mescaline (from peyote), similar synthetic drugs (STP, DMA, MDA, MMDA), and myristicin and elemicin from the genus *Myristica* (e.g., nutmeg) resemble norepinephrine, but their end effects are similar to LSD-like substances.

Because of its availability, standardization and potency, LSD has been the most extensively investigated psychointegrator. Recognition of a primary role of the serotonergic system in the effects of LSD-like substances resulted in extensive studies of their serotonergic interactions. The effects of LSD on neurotransmitters besides serotonin have not been as extensively investigated; although it appears to affect dopamine and norepinephrine systems, the primary effects of LSD do not appear to be mediated by these systems (Freedman, 1984; Jacobs, 1984b). LSD does have significant interactions with other neurotransmitter systems (e.g., GABAergic) (Carlsson, Waters & Carlsson, 1999). Since they interact with serotonin, a neuromodulator with effects on many neurotransmitter systems, psychointegrators affect other systems as well.

Although these substances share physiological and experiential effects, questions have been raised as to the basic nature of the effects and the appropriateness of the terms used. Medical and lay characterizations of their effects as "hallucinations," and therefore false and delusional, are inaccurate and point to the need for new terms. Psychedelic is politicized for many, and its meaning of "mind manifesting" is limited. Grof (1975) proposed *holotropic*, reflecting the psychodynamic actions of these substances in forcing an orientation toward wholeness. Holotropic reflects central experiential effects of these substances, but without emphasizing the spiritual, emotional, and mental experiences. The term *entheogen* was introduced as an alternative, with "*entheos*" referring to the "god within" and "*gen*," "the action of becoming" (Wasson, Kramrisch, Ott & Ruck, 1986). Entheogen accurately reflects the views of many cultures on these substances' effects, but its exclusive focus on the spiritual alienates the scientific and clinical approaches needed to understand these substances.

Common systemic effects of these substances include the stimulation of mental and emotional processes in an integrative personal and spiritual experience. The experiential effects of integration are mirrored in the neurophysiology of the substances, suggesting that *psychointegrator* is a more appropriate characterization. Psyche reflects the meanings of mind emphasized more recently, and the broader and older meanings of *soul* and *spirit* central to the interpretations of these effects in other cultures. Psychointegrator reflects the integration of mind, soul, and spirit as attested to by laboratory, clinical, and cross-cultural research. The term psychointegrator does not preclude further terminological differentiation of the variable effects of these substances (e.g., Naranjo,1996; Stafford, 1992). "Psychointegrator" supersedes valueladen terminology and misconceptions with a neurophenomenological grounding. The justification for this term is provided by the following examinations of cross-cultural, clinical, and neurophysiological data.

Cross-Cultural Patterns of Psychointegrator Use

Cross-cultural use of psychointegrator plants is associated with the belief that they are powerful spiritual forces, provide access to spiritual realities, and have religious and therapeutic applications (see Dobkin de Rios, 1984; Furst, 1972, 1976; Harner, 1973; Schultes & Hofmann, 1979; Winkelman, 1996). Psychointegrators dramatically alter experience, shifting self-awareness to what is interpreted as an "other worldly" sacred or spiritual domain of important personal and social significance. The ubiquitous aspects involve the following: personal relations with the supernatural world; participation in a mythical time; spiritual relationships with animals as a source of power and self-identification; ego dissolution, resurrection and transformation; healing and divination; and promotion of social solidarity and community relations (Dobkin de Rios, 1984). The interpretations of these plants as having therapeutic, religious, and spiritual roles have implications for understanding human consciousness, mystical and spiritual experiences (Smith, 2000), and the pre-historical origins of religion. La Barre (1972) called attention to their potential to stimulate visions and supernatural experiences, giving rise to religious traditions.

Societal Differences in Use of Psychointegrator Plants

Therapeutic use of psychointegrator plants is not universal but varies as a function of social conditions. Different types of societies make different assessments of their value, adaptive functions and potentials. Major regional differences in their use have been reported, with dramatically larger number of hallucinogenic plants used in the indigenous cultures of the Americas in comparison to pre-Christian Eurasian cultures (La Barre, 1970). These differences have been attributed to cultural factors, since many hallucinogens are present but not used in Eurasia (Furst, 1972; La Barre, 1970). Increasing political complexity leads to reduction in the use of psychointegrator plants, which are not typically institutionalized in healing and religion in complex societies (Dobkin de Rios & Smith 1977; Winkelman, 1991). Changes in society and the institutionalized bases and functions of religious healing (Winkelman, 1986b, 1990, 1992) are responsible for cross-cultural differences in institutionalization of psychointegrator plants. Cross-cultural data show their ritual use is negatively correlated with levels of political integration (Winkelman, 1991). The negative relation with political integration reflects inherent conflicts of the needs of hierarchical politically integrated societies with the psychosocial and cognitive dynamics produced by psychointegrators.

Dobkin de Rios and Smith (1977) suggest hallucinogenic plants are typically repressed in state-level societies because they constitute a threat to the interpretations of those who hold social and religious power. Psychointegrators are typically used in social contexts where influences derived from the set and setting (personal expectations and the local situational influences) play powerful roles in shaping the experiences and interpretations. These local set and setting influences on interpretation can pose a threat to the centralized hierarchical control of religious consciousness, and undermine control in religious, political and social arenas. In contrast, typical cross-cultural use of psychointegrators for therapeutic purposes is in small-group community settings, where they enhance group cohesion and reaffirm local social and cultural values and beliefs rather than the state-level ideological and political orders (Dobkin de Rios & Smith, 1977). Repressive legislation enacted against these substances in the 1960s reflects this pattern of political control of threats to the established hierarchy and cosmological orders.

The social context of contemporary psychointegrator use cross-culturally suggests it facilitates psychosocial adaptations required by rapid social change and changing psychosocial circumstances (Aberle, 1966; Andritzky, 1989; Dobkin de Rios, 1984). Psychointegrator plants play a role in mediation between conceptual systems. Ayahuasca is widely used in the Amazonian basin in collective rituals that strengthen social cohesion and group identity and assist in the management of acculturation problems by mediating between indigenous world views and the imposed European systems (Andritzky, 1989). The psychointegrators are used in rituals that serve as a means for mediating between the individual and the cultural systems, integrating the ancient traditions into current adaptations.

The historical adoption of the Peyote religion (Native American Church, NAC) among the Navajo as reported by Aberle (1966) also illustrates its role in psychosocial adjustment, as the early Navajo adherents were primarily those who experienced the greatest relative deprivation due to federally imposed livestock reduction programs. The NAC ethical code facilitated an adjustment of the Navajo values of collectivism to the American society's emphasis on individualism. The NAC fostered resistance to colonizing influences, maintaining socially valued community experiences and religious consciousness (Calabrese, 1997).

Variation in Therapeutic Applications

Review (Schultes & Winkelman, 1996) of therapeutic uses among the indigenous cultures of the Americas of psychointegrators of the families *Strophariaceae*, *Myristicaceae*, *Leguminosae*, *Malpighiaceae*, *Cactaceae* and *Convolvulaceae* illustrates quite a variable action. These substances are used for both physical and spiritual illness, mediation of conflict, treating dysfunctions in social or sexual relations, and directing healing energies. They evoke a range of emotional experiences, including terrifying visions and cathartic reactions. Psychointegrators may be used to prophesize the future, to send messages to others, to contact distant relatives, to discover enemies' plans, and to assist in learning myths, chants, and dances. They are used for all sorts of physical problems, including stomach, bladder, intestinal worms, hemorrhoids, malaria, mouth sores, rheumatism, cuts and wounds, and childbirth difficulties. Diagnostic applications include determination of: the cause of illness, death or other problems; the means of treatment; direction in life; and the meaning of dreams. Social uses include annual harvest festivals, fertility rites, cremation ceremonies, ancestor worship, and inter-village alliances. They are used to treat culture-bound syndromes (e.g., hexes, soul/spirit loss, witchcraft, spirit affliction and exorcisms) and for protection against witches and ghosts. They provide control of emotions and release from guilt and illness caused by resentment and envy, balancing spiritual and natural forces in the patient's life to overcome misfortunes and find peace and harmony.

Highly developed traditional healing systems selectively use variations across species, varying admixtures of species, different doses and routes of administration, and ritual processes to obtain a range of effects. Variable effects also reflect their functions as nonspecific amplifiers of pre- and unconscious content (Metzner, 1998; Riedlinger & Riedlinger, 1994). These substances' effects integrate pharmacotherapy and psychotherapy through interactions of biological and social factors.

Clinical Paradigms in Research on LSD

Since the same plant is used for a variety of purposes, this suggests the same substance can produce a variety of effects. Clinical research revealed a range of effects from LSD (see Bliss, 1988; Bravo & Grob, 1989; Grof, 1975, 1980; Lukoff, Zanger & Lu, 1990; Riedlinger & Riedlinger, 1994; Yensen, 1985, 1996). Legal prohibitions enacted in the late 1960s severely reduced clinical research, but earlier (e.g., see Abramson, 1967) and limited subsequent research (Passie, 1997) provides evidence of the therapeutic effects of LSD. A primary finding is that effects differ as a function of expectations, producing several different medical paradigms-psychotomimetic, psycholytic, and psychedelic (see Bravo & Grob, 1989; Yensen, 1985, 1996;). The different paradigms reflect "set and setting" influences, extra-pharmacological factors derived from expectations and situational circumstances. "Set" refers to personal beliefs, attitudes, and expectations, while "setting" refers to the situational influences upon the experience. These are considered the primary determinants of the psychointegrator's effects.

The psychotomimetic perspective emphasized that LSD induces effects such as dizziness, weakness, tremor, nausea, hallucinations, depression, depersonalization, psychotic reactions, and delusions. This clinical profile better represents side effects rather than the phenomenologically and personally most relevant experiences. While psychosis and disturbed cognitive functioning may occur, particularly under adverse set and setting influences, psychointegrators typically produce positive outcomes, inducing new ways of perceiving and understanding ordinary experience. Induced emotional liability can lead to changes in sense of self, including powerful mystical experiences of union with the universe and oceanic feelings (Cohen, 1971).

These realizations lead to the psycholytic approach, which viewed LSD as a "mind dissolving" agent that facilitates psychoanalytic therapy by altering the relationship between the conscious and unconscious (Yensen,1985). LSD was used as a therapeutic aid for weakening psychological defenses, eliciting conflicts and emotional impulses, releasing unconscious or blocked material, and increasing awareness and emotional responsiveness. The ability to activate and deepen psychoanalytic processes helped shorten psychotherapy, facilitating restructuring of the personality and accelerating the maturation process (Passie, 1997). The psycholytic approach is reflected in the NAC, where peyote plays a role in meaning therapy involving therapeutic emplotment and reinterpretation (Calabrese, 1997).

The last pre-prohibition development in LSD-assisted therapy was the psychedelic approach, based on the recognition that the greatest benefits occurred when mystical experiences resulted. The psychedelic approach used large doses to evoke mystical experiences which produced major personality changes. LSD activated repressed memories, evoking catharsis, enhancing self-awareness, and providing an opportunity for life changes. A significant application of the psychedelic approach was in the treatment of alcoholism and pain and end-of-life management for terminal cancer patients (see Abramson, 1967; Kurland, 1985).

In summary, the cross-cultural patterns in social, religious, and therapeutic applications of psychointegrators and their psychocognitive effects reflect both biological mechanisms and psychosocial effects (set and setting). Even the same substance can induce quite varied experiences since cultural traditions provide integral inputs through ritual, song, myth and other symbolic elements that shape experiences, reactions and outcomes. Cross-cultural commonality in uses of psychointegrator plants in therapeutic activities, and the similarities in experiences and interpretations, nonetheless reflect biological mechanisms and require a neurobiological explanation. The specific neurotransmitter mechanisms through which general and specific effects are achieved illustrate why these pharmacological agents should be called psychointegrators and why they have such important therapeutic applications.

Psychointegrators and Neurotransmitter Functions

The effects of psychointegrator constituents upon neurotransmission produce cross-cultural similarities in physical, emotional, and cognitive experiences. Neurotransmitters act through at least four known mechanisms: stimulating neurons, creating inhibitory or excitatory effects, altering the responsiveness of neurons to other neurotransmitters, and modulating the effects of other neurotransmitters. Psychointegrators interact with neurotransmitters through initiating responses in receptors (agonists) by substituting for neurotransmitters, and by diminishing their effectiveness by functioning as antagonists (or blockers), preventing normal response of a receptor. Studies on these effects in humans have been limited in recent decades, but psychointegrator effects (particularly LSD) upon brain function in humans and other animals have been extensively investigated (Jacobs, 1984a; Mandell, 1985). These studies provide diverse and apparently contradictory findings, derived from different procedures, dosages, phase effects, and set and setting factors (Freedman, 1984). Basic mechanisms of action of LSD-like psychointegrators are fundamentally the same across mammalian species (Jacobs, 1984a; Jacobs & Gelperin, 1981) and are one of the best understood of psychoactive substances (Mandell, 1985). The primary neurotransmitter affected by LSD-like psychointegrators is serotonin (Aghajanian, 1994; Jacobs, 1984b; McKim, 1991). The following section briefly reviews the serotonergic system and effects of LSD-like substances upon neurotransmission. The information about the systemic effects of psychointegrators upon neurotransmitters is primarily derived from Aghajanian (1994), Jacobs (1984a), Jacobs and Gelperin (1981), Kruk and Pycock (1991), McKim (1991), and Ryall (1989).

The Serotonergic System

Serotonin (5-HT) is the most extensive monoaminergic neurotransmitter system in the brain (Role & Kelly, 1991), performing a wide range of functions (Fischbach, 1992; Kruk & Pycock, 1991; Ribeiro, 1991). Serotonin plays an important role in regulating sleep, arousal, thermoregulation, vasoconstriction, blood pressure, growth hormones, hunger, pain, smooth muscles, perception, sensory processing, vigilance, learning, memory, moods, motor activity, cognition, and decision making (Glennon, 1990, p. 39; Kruk & Pycock, 1991, pp. 122-123). Serotonergic dysfunctions are associated with fear, anxiety, depression, sleep disturbances, schizophrenia, pain dysfunctions and psychosomatic complaints (Ribeiro, 1991, p. 37).

The central importance of serotonin in many different processes reflects its role as a modulatory neurotransmitter, a mediator of processes, receiving sensory and internal information, and modulating the strength of responses. The serotonergic neurotransmitter cells are primarily located in the reticular formation, the limbic system and the basal ganglia, with descending projections into the spinal cord and ascending projections to the forebrain; the limbic system and visual areas have the highest levels of serotonin fibers (Ribeiro, 1991). The primary projections are ascending and exert diffuse influences on neuronal systems. The primary concentrations of serotonin neurons in the central nervous system (CNS) are in the midline area of the brain stem, particularly the raphe nuclei; its upward projections into the thalamus, hypothalamus and amygdala of the limbic system; the corpus striatum and basal ganglia; and frontal cortex (Kruk & Pycock, 1991; Parent,1981). The projection systems of the raphe (and reticular activating) systems of the midbrain carry sensory input from axons to the cortex. Interconnected nuclei of the limbic system are responsible for mediating emotion and motivation. Serotonin input to the cortex mediates integration of sensory information and coordination of bodily movements.

Serotonin Receptors

There are at least four different types of CNS serotonin receptors that mediate different kinds of effects in different parts of the brain (Aghajanian, 1981, 1994; Glennon, 1990; Kruk & Pycock, 1991; Ribeiro, 1991; Schmidt & Peroutka, 1989). Serotonin 5-HT$_{1A}$ receptors are primarily in the raphe system and limbic region; they mediate responses of the serotonergic neurons with respect to their own transmitters and have a strong sensitivity to indoleamines (Aghajanian, 1994, p. 140). Primary effects of LSD upon serotonergic systems are on 5-HT$_2$ neurons (Aghajanian, 1994), for which they have a high affinity (Glennon, 1990). 5-HT$_2$ receptors are concentrated in the limbic system in the hypothalamus and basal ganglia, and play a role in the control of anxiety and reduction of schizophrenic symptomology (Ribeiro, 1991). Primary effects of LSD-like psychointegrators upon the cerebral cortex, the locus coeruleus, and other areas of the brain are mediated by the 5-HT$_2$ receptors of postsynaptic neurons (Aghajanian, 1994). LSD has a high affinity for 5-HT$_{2A}$ and 5- HT$_{2C}$ receptors (Miller & Gold, 1993), facilitating the functioning of the locus coeruleus, which receives numerous somatosensory and visceral inputs and projects them diffusely to most of the brain.

Effects of LSD-like Psychointegrators on Serotonergic Receptors

Serotonergic effects of the LSD-like psychointegrators are complex and variable because: the modulatory functions of serotonin are a function of other neural conditions; serotonin has different actions and effects in different areas of the brain, including presynaptic, axon terminal and postsynaptic sites; psychointegrators have different actions upon different types of serotonergic neurons; and psychointegrators have dose-and phase-dependent effects (Aghajanian, 1994, Hamon, 1984; Hollister, 1984). Psychointegrators may act as agonists (serving in the place of serotonin) and as an antagonist, blocking its action. LSD induces sustained hyperpolarization of some serotonergic neurons, but with prolonged effects beyond maximal levels induced by serotonin (Aghajanian, 1984). Uptake and binding of LSD is primarily in postsynaptic serotonin receptors in the visual and auditory areas of the cerebral cortex, and the amygdala, hippocampus, hypothalamus and striatum of the limbic system (Hamon, 1984). Jacobs suggests action at postsynaptic (rather than presynaptic) serotonergic sites is central to hallucinogenic effects. The focus upon hallucinations may undervalue the importance of other effects, such as the stimulation of systemic information integration.

LSD-like psychointegrators' effects upon the serotonin autoreceptors in the raphe neuron sites induce a selective and potent inhibition of the tonic firing of the dorsal raphe nucleus, and results in a dysinhibiting of forebrain neuron targets. LSD blocks the activating effects of the serotonin neurons in the reticular formation and in the cortex, which releases the tonic inhibitory serotonin influences upon postsynaptic neurons, and increases activity in the lateral geniculate nucleus and amygdala. LSD-like psychointegrators also facilitate or potentiate serotonin's excitatory effects upon areas of the brain stem and spinal cord, resulting in excitation of target cells (Jacobs, 1984b, p. 188). Psychointegrators activate serotonergic neurons in the locus coeruleus, a nodal point for convergence of somatosensory and visceral information from all regions of the body. The locus coeruleus' projections innervate most areas of the neuraxis, principally the thalamus, hypothalamus, cerebellum, basal forebrain, hippocampus, and neocortex (Aghajanian, 1994; Role & Kelly, 1991). LSD affects the hippocampus by blocking or suppressing the typical depressant functions of serotonin. This stimulates mesolimbic temporal lobe structures by dysinhibiting postsynaptic neurons in the limbic and visual areas (Mandell, 1985), releasing the habitual blocking on emotional and visual centers, and contributing to production of visual experiences similar to dreaming.

LSD-like psychointegrators interact with the serotonergic system in the brain stem, limbic system, and frontal cortex. They both stimulate and suppress the effects of serotonin, substituting for it in neurotransmission, and blocking it, reducing habitual repressions and stimulating processing centers. Psychointegrators effect: reactivity of the raphe and reticular formations of the brain stem area; the limbic system, particularly the hippocampus and amygdala; and the visual and auditory areas of the frontal cortex. Psychointegrators have effects on: attention, awareness and environmental orientation; motivation, memory, emotions and cognitive processes; visual conceptualization and cognitive representation; and synthesis of information from the entire brain. An effect of serotonin is to depress the action of target neurons in the forebrain; consequently, the blocking effect of LSD upon serotonin neurons is a dysinhibition of their typical repression. This dysinhibition results in synchronous brain-wave patterns that drive impulses into the frontal cortex, replacing the normal desynchronized fast wave activity characteristic of the frontal cortex with slower, more coherent wave patterns. These coherent systematic discharges drive synchronous slow-wave patterns (3-6 cps theta) into the frontal lobes, synchronizing the cortex (cf., Aghajanian, 1982, 1984; Mandell, 1980).

Psychointegrators and Systemic Brain Function

Psychointegrators enhance activation of brain systems that MacLean (1990) refers to as the R-complex (reptilian brain) and the paleomammalian brain (limbic system). Stimulation of the R-complex provides an enhanced integration of information across all areas of the brain, producing heightened arousal and awareness and interference with habituated behavioral routines that the reptilian brain manages. The paleomammalian brain provides social and emotional influences on mentation and behavior involved in species survival, sex, aggression, family and social relations, learning and memory, and self-identity. The activation of the paleomammalian brain and its functions by the psychointegrators (and ASC in general) enhances systemic integration of the psyche through cognitive processes based in nonverbal communication, mentation and social representations that manage processes of emotional and social life.

Psychointegrator Effects Upon Behavior

The macro-level effects of psychointegrators include a range of sensory, behavioral, emotional and cognitive effects (Freedman, 1984; see Winkelman, 1996 for discussion). Psychointegrators heighten sensory receptivity, increasing arousal and responsivity to the environment. They also reduce or reverse habituation of typical response patterns, forcing the organism into new patterns of behavior. While low dosages lead to a more thorough, random and complete examination of the environment, high dosages tend to lead to withdrawal and a focus upon the internal imagetic, emotional, and cognitive environment. The internal focus, alteration of consciousness, and limbic activation forces material from the sub- or unconscious into awareness and brings repressed memories into consciousness where through catharsis and abreaction they are resolved and integrated. Their tendency to elicit distressing personal material, unresolved conflicts, repressed experiences, and un-integrated aspects of self and behavior suggests that psychointegrators provoke manifestations of conflicts and traumas not yet integrated into long-term stable memories. Psychointegrators stimulate emotions and interpretations related to one's sense of self and social attachments.

Cognitive Dynamics: Interhemispheric Fusion

Psychointegrators' neurophysiological effects produce general integration of information from all parts of the body, enhancing significance and meaning, and producing insight and new understandings. The focus on internal experience is often accompanied by an enhanced clarity of consciousness (Freedman, 1984, p. 209) and the maintenance of intact memories subsequent to the experiences that permits reflection and integration. This also reflects activation of paleomammalian brain functions that subserve memory functions and provide the basis for our sense of certainty and conviction (MacLean, 1990). The characteristic cognitive integration found with psychointegrators reflects an "interhemispheric fusion" (Mandell, 1985), a result of the increased coupling (bilateral coherence) in hemispheric oscillations that improves information exchange and integration between the two frontal hemispheres. This integration of the specialized roles in cognition and affect (thought and emotion) of left and right hemispheres, respectively, improves the integration of feelings and thoughts, the right hemisphere intuition and left hemisphere rationality. This underlies the insight experiences and perceptions of wholeness and oneness associated with psychointegrators. The integration of feelings with thoughts enhances insight. Integrative experiences are produced physiologically through high voltage synchronous brain waves generated by hippocampal-septal discharges in the mesolimbic temporal lobe structures (Fink, 1978; Hoffmeister & Stille,1982; Mandell, 1980) that drive synchronization of the cortex. The limbic-frontal driving and interhemispheric synchronization integrates unconscious material into the cerebral cortex. These common patterns have general therapeutic effects, permitting expression and reprogramming of repressed aspects of the self. Enhanced awareness of repressed memories, increased emotional lability, disruption of habitual behavior patterns, and dissolution of egocentric fixations permit an alteration of psychodynamic processes.

Altered States of Consciousness

Dysinhibition of the serotonergic system and the resulting loss of inhibitory effects upon mesolimbic temporal lobe structures underlies common effects of psychointegrators and other means of producing ASC or "transcendent states" (Mandell, 1980). Systematic changes in brain functioning are common to many means of inducing ASC (Winkelman, 1986a, 1992) and the basis for universal shamanistic healing practices (Winkelman, 1986b, 1990). Therapeutic use of psychointegrators reflects the effects of ASC in healing (Winkelman, 1986a, 1992). Healers using ASC are found in all cultures, reflecting the biological basis of ASC and its functional effects that produce physiological changes facilitating healing (Winkelman, 2000). Diverse ASC constitute different means of accessing a common mode of consciousness that represents an optimized homeostatic balance among functional systems of the brain, permitting the emergence of integrative operations. This integrative mode of consciousness is as fundamental to human psychobiology as the dream, deep sleep, and waking modes of consciousness (Winkelman, 2000). Integrative consciousness is manifested in the common patterns associated with ASC (e.g., limbic-frontal integration, interhemispheric synchronization, parasympathetic dominance). It has general therapeutic effects, both physiological and psychological (Winkelman, 2000). ASC in general permit expression of repressed aspects of the self, enhancing right hemisphere processes by inhibiting critical screening by the left hemisphere, permitting expression and reprogramming of normally repressed aspects of brain functioning. These conditions of consciousness are known around the world in contemplative traditions (Laughlin *et al.*, 1992), reflecting high levels of integrative functioning. Psychointegrators are a means of providing experiences within this integrative mode of consciousness, but do not substitute for the rigorous mental discipline necessary for sustained functioning in these conditions of consciousness (Naranjo, 1996).

In summary, the LSD-like psychointegrators have global effects upon awareness, behavior, emotions and cognition. They heighten sensory receptivity, arousal and responsiveness to the environment, reducing or reversing habituation of typical behavior patterns. They force new perspectives and patterns of behavior, phasicly moving from a more random and complete examination of the environment to withdrawal and focus upon internal emotional and cognitive material from the sub- or unconscious. The blocking effect of LSD upon serotonin neurons, whose function is to depress the action of target neurons in the forebrain, results in a dysinhibition of typical repression and therefore more activity. The greatest activity is in the densest serotonin axon terminals in the limbic system's emotional processing areas and the visual areas of the cortex. The dysinhibition of the mesolimbic temporal lobe structures drives synchronous slow-wave impulses into the frontal cortex, replacing the normal desynchronized fast-wave activity with coherent theta wave discharges from the limbic system. The limbic-frontal driving also produces interhemispheric synchronization and an integration of unconscious material into the cerebral cortex. This results in an integration of feelings with thoughts, enhancing insight. Activation of repressed memories permits catharsis and abreaction, facilitating resolution of psychodynamic and interpersonal conflicts. This enhanced awareness, increased emotional lability, disruption of habitual behavior patterns, and dissolution of egocentric fixations permits an alteration of psychological relationships and processes and psychodynamic reprogramming.

Contemporary Applications

The application of these substances as therapeutic agents might seem a mute question given their general illegality. Current classification of many psychointegrators in the Schedule I category inhibits their legitimate use as therapeutic agents. This classification implying no recognized medical use and high abuse potential ignores the substantial clinical and cross-cultural data on their therapeutic applications.

The continued and increasing use of hallucinogens, particularly in the form of new "designer" drugs such as "ecstasy" (MDMA) that have reported adverse consequences, indicates a need for therapists to be able to provide education for their patients. The widespread reports of organic and cognitive dysfunction, brain damage and fatalities associated with "ecstasy" use (e.g., Burgess, O'Donohoe & Gill, 2000; Parrott, Sisk & Turner, 2000) indicate the need for cautionary advice beyond that regarding secondary side-effects (e.g., dehydration). Serotonergic neurotoxicity may result from prolonged and frequent use, a pattern contrary to the sporadic use in traditional societies. Physiological risks may be exaggerated, however, as reports linking hallucinogen use to organic damage and dysfunction lack controls for confounding factors such as comorbidity and polydrug abuse, rendering their conclusion suspect (Halpern & Pope, 1999). There are clear contra-indications for use of psychointegrators (particularly monoamine oxidase inhibitors) with serotonin re-uptake inhibitors (Callaway & Grob, 1998). Serious psychiatric impairments probably should be considered a contraindication.

Clients who use these substances, or have needs that may be served by their use, can benefit from the therapist as educator. Therapists need to be aware that their own attitudes will affect the experiences induced. Clients need to be advised of the need for qualified guidance and appropriate set, setting, goals and support. Traditional patterns of use in non-Western societies provide the richest database for guiding therapeutic use (see Metzner, 1998 for summarization). These traditional approaches have been adapted for the guidance of contemporary people (e.g., see Leary, 1997). Traditional use involved administration by shamanistic healers in periodic sessions, often involving the entire community. This use involved a significantly different worldview and focus than psycholytic and psychedelic therapies (Metzner, 1998).

Information about these substances and their uses and specific effects are widely available (cf., Ott, 1993,1994; Shulgin & Shulgin, 1991; websites at psychedeliclibrary.org, maps.org, geocities.com/psychedelics101, drugtext.org, and csp.org). The pre-prohibition research and limited subsequent clinical studies, particularly in Europe (Passie, 1997), also provide indications of potential applications. The psycholytic approach has usefulness at the beginning of therapy to reduce fear-induced inhibitions and repressions, facilitate communication, and accelerate the formation of therapeutic alliances (Riedlinger & Riedlinger, 1994). Psycholytic therapy has greatest applicability for those with: psychic rigidity and rigid defenses; sexual and severe character neuroses; anxiety, depression, and chronic compulsions; and alcoholism. The ability to overcome strong defensive structures may provide success for those with whom classic psychoanalysis was unsuccessful (Kurland, 1985; Metzner, 1998; Passie, 1997; Zanger, 1989). Users may find benefits through assistance in placing fears and emotional traumas in a more realistic perspective (Greer & Tolbert, 1998). Riedlinger and Riedlinger's (1994) examination of the relationship of serotonergic disorders and depression suggests that the success of psychointegrators reflects effects upon serotonergic mechanisms similar to those of other 5-HT uptake inhibitors used in treating mood disorders, anxiety, aggression, panic and obsessive compulsive disorders (OCD). This may parallel traditional antidepressants' "down-regulation" of serotonin receptors and the normalization of serotonin transmission (Ribeiro, 1991). The usefulness of psychointegrators in treatment of OCD is well enough indicated to warrant clinical trials (Delgado & Moreno, 1998). Earlier work with oncology patients indicates further use is warranted.

Treatment of alcoholism and other forms of drug dependence is a promising area for use of psychointegrators, which often are integrated in non-Western ethnomedical treatments of substance dependence (Heggenhougen, 1997; Jilek, 1994). The incredulity that this suggestion might raise is unsubstantiated since these substances in general appear to be non-addictive (McKim, 1991). Psychointegrators' effectiveness is exemplified in the widespread consensus among Native American rehabilitation counselors that the NAC is the only effective tool against alcoholism in Indian country. Bill Wilson considered his LSD experiences to have had an importance equal to the conversion experience that led to his co-founding of Alcoholics Anonymous (AA) (Smith, 2000). His efforts to have AA endorse LSD as a source of the spiritual experiences for treating alcoholism were, however, rejected by the board. The role of LSD in treating alcoholism and other drug dependence (Abramson, 1967; Kurland, 1985) indicates the use of the psychedelic approach and its large doses for inducing transcendent peak or mystical experiences. Treatment of substance dependence with the psychedelic approach remains inadequately examined in clinical populations (Mangini, 1998), but evidence for its effectiveness continues to accumulate (e.g., see ; Alper, Lotsof, Frenken, Luciano & Bastiaans, 1999; Mabit, Giove & Vega, 1996; Sanchez-Ramos & Mash, 1996).

There is widespread recognition that psychointegrators enhance self-healing effects by allowing a purge of negative affects and memories and activating inherent capacities for psychological integration. There may also be immune system enhancement (Roberts, 1999, 2000). Contemporary applications of psychointegrators typically combine psycholytic and psychedelic approaches, using large doses to induce transformative experiences and a series of low doses in psycholytic sessions for processing psychodynamic material (Passie, 1997).

Research Applications

Psychointegrators induce experiences that facilitate study of the general principles of the brain and consciousness. Grof's clinical research with LSD (1975, 1980, 1992) provided new models of the nature of human consciousness. Psychointegrators elicit experiences in what Grof labels the transbiological realms, the perinatal and transpersonal domains of experience. The transpersonal domain includes the archetypal and mystical structures, dimensions of human consciousness and identity beyond egoic identity. Grof has shown that these substances help elucidate the operations of the brain and mind. They accentuate certain processes (e.g., emotional harmony, connection and integration with nature and humanity, joy and euphoria, alternate identities and sense of self), revealing natural cognitive domains and symbol systems (Shannon, 2000). Naranjo (1996) suggested psychointegrators activate "Kundalini phenomena" (high levels of organismic self-regulation) as a consequence of ego suspension and the activation of latent mental structures. These substances have also been considered a source of veridical mystical and spiritual experiences, as attested to in the recent book by the acclaimed expert on world religions, Huston Smith (2000).

Conclusions

The roles of psychointegrators in many cultures point to their important functions in meeting human needs. Although Western societies have held negative views of these substances and most ASC, they represent responses to innate drives (Siegel, 1990). The innate basis of the drive to seek ASC raises questions about the consequences for a society that views such behavior as aberrant and pathological and attempts to repress it. The recurrent societal "discovery" of ASC (e.g., "ecstasy" and its use at group parties known as raves) illustrates the persistent need to address these issues, as ignoring and prohibiting them has not led to their demise. The numerous biological and chemical sources of these substances with powerful psychological effects suggest that their use will continue. Societies need to take informed approaches to their managed use rather than excluding them to a counter-culture producing ethos. Failure of societies to provide legitimate avenues of access, and instead outlawing these experiences, increases the likelihood that their utilization will contribute to antisocial tendencies.

Typical cross-cultural patterns of psychointegrator use involve management of developmental change or crises-induced problems. Psychointegrators integrate conscious, pre-conscious and unconscious processes into a new gestalt or understanding. Their institutionalized use involves healing and spiritual integration, a "wholing" of the individual. This integrative stimulation is a rationale for the term "psychointegrator" to refer to their functions and effects, reflecting the coupling of the soul or spirit with the mind and emotions. This conjunction of healing with the spiritual reflects an integration of psychophysiological and psychocultural dynamics, a fundamental adaptation found in all human societies in shamanistic healing practices. The use of psychointegrator substances as a means of achieving this psychobiological and psychosocial adaptation reflects the need to reorient psychocultural dynamics to changes in social and cosmological relations. Humanity has many millenniums of use of these substances, and legal prohibitions have not stopped this human drive to experience therapeutic alterations of consciousness. They are, however, powerful and potentially dangerous; only adequate education can help prevent abuse and destructive effects.

Note

[1] Many different plants are loosely classified as hallucinogens because they produce hallucinations through toxic effects upon the body. The plants of the family Solanaceae such as mandrake (*Mandragora officinarum*), deadly nightshade (*Atropa belladonna*), henbane (*Hyoscyamus niger*), and the genus *Datura* (e.g., jimson weed) may be inappropriately classified as hallucinogens. Anticholinergics such as atropine, hyoscyamine, and scopolamine (hyoscine), block acetylcholine's muscarinic receptor sites (McKim, 1991) and can cause cardiac arrhythmia, arrest and death through a reduction in heart rate and contractions, blocking of neurotransmission, and interference with the parasympathetic nervous system (Kruk & Pycock, 1991). This produces delirium, clouded consciousness, interference with basic life-support functions, and possible death, conditions not typically associated with the indoleamine compounds. Deaths due to use of these substances are reported every year in the U.S., but shamanistic traditions have apparently found ritual ways to use these plants safely (Jacobs, 1996).

Biographical Data

Michael Winkelman, PhD, is a Senior Lecturer in the Department of Anthropology at Arizona State University, where he is Director of the Ethnographic Field School, Baja California, Mexico. His research interests are in shamanism, shamanistic healing, altered states of consciousness and ethnomedicine; and in cross-cultural adaptation and inter-ethnic relations. He is the author of *Shamanism: The Neural Ecology of Consciousness and Healing* (Westport, CT: Bergin and Garvey, 2000), *Shamans, Priests and Witches: A Cross-cultural Study of Magico-religious Practitioners* (Anthropological Research Papers #44. Tempe, AZ: Arizona State, 1992), *Ethnic Sensitivity in Social Work and Ethnic Relations in the US: A Sociohistorical Cultural Systems Approach* (1999, 1998, Eddie Bowers Publishing, Dubuque: Iowa). He is also the co-editor of *Sacred Plants, Consciousness and Healing*, and *Divination and Healing* (*Yearbook of Cross-cultural Medicine and Psychotherapy, Volumes 6 & 9*, Berlin: Springer Verlag).

Abstract

Hallucinogenic psilocybin is known to alter the subjective experience of time. However, there is no study that systematically investigated objective measures of time perception under psilocybin. Therefore, we studied dose-dependent effects of the serotonin $(5\text{-HT})_{2A/1A}$ receptor agonist psilocybin (4-phosphoryloxy-*N,N*-dimethyltryptamine) on temporal processing, employing tasks of temporal reproduction, sensorimotor synchronization and tapping tempo. To control for cognitive and subjective changes, we assessed spatial working memory and conscious experience. Twelve healthy human volunteers were tested under placebo, medium (115 µg/kg), and high (250 µg/kg) dose conditions, in a double-blind experimental design. Psilocybin was found to significantly impair subjects' ability to (1) reproduce interval durations longer than 2.5 sec, (2) to synchronize to inter-beat intervals longer than 2 sec and (3) caused subjects to be slower in their preferred tapping rate. These objective effects on timing performance were accompanied by working-memory deficits and subjective changes in conscious state, namely increased reports of 'depersonalization' and 'derealization' phenomena including disturbances in subjective 'time sense.' Our study is the first to systematically assess the impact of psilocybin on timing performance on standardized measures of temporal processing. Results indicate that the serotonin system is selectively involved in duration processing of intervals longer than 2 to 3 seconds and in the voluntary control of the speed of movement. We speculate that psilocybin's selective disruption of longer intervals is likely to be a product of interactions with cognitive dimensions of temporal processing - presumably via 5-HT_{2A} receptor stimulation.

Keywords: psilocybin, 5-HT_{2A} receptor, temporal processing, sensorimotor synchronization, altered states of consciousness, working memory, human study

Introduction

Events are perceived over time, and motor actions evolve over time. The brain, therefore, has to process temporal information adequately for the control of perception and action. Evidence to date suggests that different temporal-processing mechanisms are implemented in distinct circumscribed neural circuitries that can be affected by brain injury and pharmacological treatments (Harrington and Haaland, 1998; Rammsayer, 1999; Wittmann, 1999). Accuracy and precision of time estimation and the exact timing of motor behaviour are intimately linked to overall cognitive functioning. Basic timing processes (internal clocks) are an integral part of the whole cognitive system (Steinbüchel and Pöppel, 1993; Wearden, 2004). Patients with structural damage to the brain such as with right-hemispheric focal brain lesions following a stroke (Kagerer *et al*., 2002) or with traumatic brain injury dominantly affecting frontal areas (Pouthas and Perbal, 2004), patients with dysfunctions related to the dopaminergic system of the brain such as in Parkinson's disease (Pastor *et al*., 1992) or in schizophrenia (Elvevag *et al*., 2003), but also healthy older adults (Block *et al*., 1998) can show substantial impairments in temporal processing. Specifically, these populations show more variability and deviate more strongly from target durations during tasks involving time estimates and the timing of motor acts. These findings are discussed in relation to alterations on several information-processing stages related to time processing, specifically a clock, memory and decision stage (Wearden, 2004) as well to attentional mechanisms (Zakay and Block, 1996). Specifically, recent studies report that schizophrenic patients show deficits in discriminating temporal durations (Volz *et al.*, 2001; Davalos *et al.*, 2002; 2003; Elvevag *et al.*, 2003) as well as recognizing the temporal order of visual and acoustic stimuli (Braus, 2002; Tenckhoff *et al.*, 2002).

Recent research into the pharmacological mechanism of hallucinogens (LSD, psilocybin) and dissociative anesthetics (PCP, ketamine) suggests that a dysbalance between serotonin, glutamate and dopamine neurotransmitter systems may be critical to psychotic symptom formation (Vollenweider, 1998). Specifically, there is increasing evidence that the serotonin 5-HT$_{1A/2A}$ receptor systems are involved in psychotic symptom formation as well as the cognitive and behavioural deficits of schizophrenia (Mita *et al.*, 1986; Arora and Meltzer, 1991; Ngan *et al.*, 2000; Bantick *et al.*, 2001; Roth and Hanizavareh, 2004). Receptor binding studies in rats have shown that psilocin (4-Hydroxy-*N*,*N*-dimethyltryptamine), the pharmacologically active metabolite of psilocybin (Hasler *et al.*, 1997), primarily binds to 5-HT$_{2A}$ receptors (Ki=6 nM) and with a lower affinity also to the 5-HT$_{1A}$ sites (Ki=190nM) (McKenna *et al.*, 1990). Psilocybin induces a model psychosis which mimics certain aspects of acute and incipient stages of schizophrenia (Gouzoulis-Mayfrank *et al.*, 1998; Klosterkötter *et al.*, 2001; Vollenweider, 2001; Vollenweider and Geyer, 2001) and causes deficits in sustained and spatial attention (Gouzoulis-Mayfrank *et al.*, 2002; Umbricht *et al.*, 2003; Hasler *et al.*, 2004). In addition, it is well established, based on early phenomenological and psychological studies, that psilocybin and related serotonergic hallucinogens produce a strongly altered experience of time (reviewed in Heimann, 1994), notably a feeling of slowing down of the passage of time and a subjective overestimation of time intervals expressed in reports that 'minutes appear to be hours' or even that 'time is standing still' (Kenna and Sedman, 1964; Fischer *et al.*, 1966).

To date, alterations in time perception and performance in humans have been linked primarily to the dopamine system (O'Boyle *et al.*, 1996; Rammsayer, 1999), specifically to the cortico-basal ganglia-thalamic-cortical loop representing the neuronal clock (Meck, 1996). Pharmacological studies on animals and humans also support the general hypothesis that fronto-striatal circuits are critical for temporal processing. Dopaminergic antagonists (like haloperidol) that affect the meso-striatal dopamine system disrupt temporal processing in healthy subjects (Rammsayer, 1999). Moreover, animal studies indicate that both dopaminergic agonists and antagonists influence timing processes, presumably by increasing and decreasing clock speed, respectively (Meck, 1996). Patients with Parkinson's disease, who have decreased dopaminergic function in the basal ganglia, and particularly depleting input to the putamen, not only show deficits in motor timing but also in the discrimination of temporal intervals (O'Boyle *et al.*, 1996; Hellström *et al.*, 1997). Thus, intact dopamine neurotransmission within striatal and fronto-cortical sites is important for temporal processing, which is consistent with the notion that a cortico (SMA)-striato-thalamo-cortical system is involved in sensorimotor timing (Harrington *et al.*, 2004). The basic idea in these models is that a pacemaker generates pulses and that the number of pulses represents the subjective estimate of an elapsed interval. The higher the clock rate (presumed to be dependent on the effective dopamine level) the better the temporal resolution will be and the longer subjective estimates of duration (Church, 1984; Matell and Meck, 2004; Harrington *et al.*, 2004; but see Ivry, 1996, who proposes the dominant role of cerebellar mechanisms). Recently, the association of dopaminergic gene loci with endophenotypes of cognitive functioning such as attention and the speed in motor timing was shown (Reuter *et al.*, 2005). Pharmacological manipulations of the serotonin system, applying 5-HT agonists and antagonists, however, have also been shown to affect duration discrimination abilities in humans. Duration discrimination of small intervals with a base duration of 50 ms even improved slightly (Rammsayer, 1989). Given the impairments of patients with schizophrenia in timing tasks, the alterations in subjective time perception in psilocybin model psychosis, and the rather unknown role of the serotonin system in modulating basic timing mechanisms, we designed the present study to elucidate the contribution of the serotonin system to time perception and temporal behaviour. Indications exist that intervals below a time unit of approximately 2 to 3 seconds are processed differently from longer intervals (e.g. Woodrow, 1951; Fraisse, 1984; Pöppel, 1997; Wittmann, 1999). Typically, intervals up to 2 to 3 sec are reproduced accurately, whereas longer intervals tend to be underestimated (Kagerer *et al.*, 2002). Subjects can accurately synchronize their motor actions to a sequence of tones presented with a frequency of approximately 1 to 2 Hz. The ability to synchronize these tones becomes more difficult with increasing inter-tone intervals and finally breaks down when intervals exceed durations of about 2 sec (Mates *et al.*, 1994). Therefore, in the present study we aimed to investigate dose-dependent effects of psilocybin on temporal control of motor performance in sensorimotor tasks on time ranges below and above 2 to 3 seconds. We hypothesized that psilocybin would affect performance on the longer time ranges given the known elicited deficits in attention and working memory and the importance of working memory in longer duration temporal behaviour. Given the lack of any previous data on the phenomena in question, we did not know what to expect regarding possible decrements of timing performance at shorter time ranges which would indicate fundamental influence on the more basic proposed central pacemaker/accumulator mechanism.

For this double-blind, placebo-controlled experimental study of healthy volunteers, sensorimotor tasks were selected that are standard experimental tools in timing research and have proven to be sensitive measures of behavioural differences between brain-injured patient groups and controls. We employed the tasks of sensorimotor synchronization (Mates *et al*., 1994), temporal reproduction of time intervals (Kagerer *et al*., 2002), and personal and maximum tapping speed (Wittmann *et al*., 2001). Concerning the latter tapping tasks, neuropsychological studies point to a specialization of distinct brain networks associated with either voluntarily-chosen speed or with movements at maximum pace (Wittmann *et al*., 1999, 2001). This is the first systematic study of timing tasks performed in pharmacological models of psychoses in healthy human subjects. Former studies on time perception in LSD- or psilocybin-induced states in humans reporting the subjective experience of the passage of time (Kenna and Sedman, 1964), each used a single temporal-processing task to assess time-related psychomotor performance. In the study conducted by Fischer *et al*. (1966) self-paced tapping rate during an 8-minute recording period increased in the two subjects exposed to 115 µg/kg psilocybin as compared to the performance of the same subjects on the next day without the drug. Significantly shortened pause durations between the articulations of words were recorded in 12 volunteers who were under the influence of 123 to 174 µg/kg psilocybin. This result was interpreted as evidence for an increase in the speed of a physiological clock (Tosi *et al*., 1968). However, in a duration identification task with a time range between 300 and 1000 ms, LSD did not affect performance of four subjects (Mitrani *et al*., 1977). Distinct from these limited measures of timing used previously, our study aims to systematically assess timing performance by investigating the impact of psilocybin on standardized measures of temporal processing. Following from this approach, basic neuropharmacological mechanisms of time perception in the normal brain as well as in psychotic disorders may be elucidated.

Methods and Materials

Subjects

Subjects were students from the University of Zürich and a technical college. Volunteers were supplied with oral and written information about the aim of the study and the effects and possible risks of psilocybin administration. All provided written informed consent. Eligible subjects had to have normal or corrected-to-normal vision, no hearing problems, were healthy according to medical history, physical examination, clinical-chemical blood analysis and electrocardiogram. Participants were right handed and instructed to use their dominant hand in all experimental tasks. They were also deemed by psychiatric interview to have no personal or family (first-degree relatives) history of a major psychiatric disorder or evidence of regular alcohol or substance abuse. Subjects were also diagnosed according to the DIA-X computerized diagnostic expert system (Wittchen and Pfister, 1997). Administration of psilocybin to healthy subjects was authorized by the Swiss Federal Office of Public Health, Bern. The study protocol was approved by the Ethics Committee of the University Hospital Zürich. Twelve young volunteers (six men and six women; mean age 26.8 years, SD 3.6) were recruited. Six of these participants reported having had previous experience with psilocybin through the ingestion of psilocybe mushrooms (no more than three times) and seven had used cannabis sporadically. All subjects were reimbursed for their time and were informed that they were free to withdraw from the study at any time without reprisal.

Time measures

Temporal reproduction

Subjects were instructed to reproduce the duration of a sound at 500 Hz that was presented at comfortable loudness via earphones. Six different standard intervals of 1500 ms, 2000 ms, 2500 ms (short intervals), and 4000 ms, 4500 ms, 5000 ms (long intervals) were used. Each interval was presented randomly eight times, resulting in 48 trials per subject. A trial started with the presentation of a randomly-selected standard interval.

After the tone had ended, a fixed-pause interval of 2000 ms duration followed. Then the tone was presented again. Subjects were instructed to reproduce this duration by pressing a key to switch off the stimulus when they believed that the duration corresponded to the previously presented standard interval. After completion of the reproduction phase, a new standard interval was presented. Thus, presentation phases always alternated with reproduction phases. Mean reproduced intervals and the standard deviation of reproduction were calculated over the eight trials per standard interval.

Sensorimotor synchronization

Through headphones subjects heard a regular sequence of tonal stimuli that had to be synchronized precisely by tapping the index finger on a key. The intervals between tone onsets were constant. Four different durations of inter-onset intervals were presented in different trials: 700 ms, 1000 ms, 2000 ms and 4000 ms. The number of tones in each trial was varied to achieve a constant trial duration of 56 sec: 80 (700 ms), 56 (1000 ms), 28 (2000 ms), and 14 (4000 ms). Tones had a frequency of 500 Hz and duration of 100 ms. A software program (Mates, 1990) controlled the stimulus presentation and the registration of the inter-tap intervals, as well as recording the asynchrony between the tone onset and the tap onset. As a measure of accuracy of synchronization, the mean asynchrony between tap and tone onset per trial was registered. As a measure of impaired synchronization ability the number of reactions to the tones per trial was calculated. A reaction to a tone or 'missed synchronization' was defined as a tap onset following a tone with an interval of at least 120 ms. If recorded human reaction times to acoustic stimuli occur less than approximately 120 ms after a stimulus has been presented, they are considered as 'false start', e.g., they were initiated before the stimulus actually occurred (Najenson *et al.*, 1989). Therefore, we defined positive asynchronies (taps occurring after the tone) of more than 120 ms as reactions to the stimulus, that is, as failed attempts to anticipate and synchronize with the repeatedly occurring tone.

Tapping speed

Subjects were instructed to tap constantly on a key with the index finger in a personally chosen constant tempo that was neither too fast nor too slow (personal tapping tempo). Then, in a second task, subjects had to tap at maximum speed (maximum tapping tempo). The program by Mates (1990) registered every single inter-tap interval and terminated the program after 20 taps in each task. The median inter-tap interval per trial is calculated as the measure of tapping speed and a coefficient of variance (Interquartile/ Median x 100) per trial is taken as a measure of stability of the tapping performance for each person and tapping task.

Cognitive test

Spatial Span test

Spatial working memory was assessed using the spatial span (SSP) test taken from the Cambridge Neuropsychological Test Automated Battery (CANTAB) (Robbins *et al.*, 1994). The spatial span test is a computerized version of Corsi's block tapping task measuring the spatial working memory span. For this test, up to nine white boxes arranged irregularly on a black background were presented on a touch screen. During each trial a set number of the boxes were sequentially highlighted by a change in their colour, before returning back to white. Each box was highlighted for the duration of 3 sec. The period between each subsequent box highlighting was 0.5 sec. For each trial the subject was instructed to remember the order in which the boxes were highlighted and then reproduce these changes at the end of the trial by touching the respective boxes in the appropriate sequence. Subjects were initially presented with a sequence of two boxes. After this trial one additional box was added to the sequence after every correct response, up to a maximum of nine boxes. When the subject made a mistake the following trial would repeat the previous number of boxes in a different sequence. After three incorrect responses on any number of boxes, the test was terminated. The final number of boxes that the subject was able to accurately reproduce (Span Length) was recorded.

Psychometric measures

The Altered State of Consciousness rating scale (5D-ASC) (Dittrich, 1998) and the Adjective Mood Rating Scale (AMRS) (Janke and Debus, 1978) were used to assess the subjective effects under placebo and psilocybin. Both the AMRS and 5D-ASC have previously been shown to be sensitive to the psychological effects of psilocybin in humans (Vollenweider *et al*., 1997, 1998, 1999; Hasler *et al*., 2004).

5D-ASC

The Altered States of Consciousness rating scale 5D-ASC (Dittrich, 1998; Dittrich *et al*., 1999) consists of 94 items that are visual-analogue scales of 10 cm length. These items measure alterations in mood, perception, experience of self in relation to environment, and thought disorder. Scores of each item range between zero ('No, not more than usually') and ten ('Yes, much more than usually'). The ASC items are grouped into five main factors comprising several items. (1) 'oceanic boundlessness' (OB) measures derealization and depersonalization accompanied by changes in affect ranging from heightened mood to euphoria and/or exaltation as well as alterations in the sense of time. The corresponding item clusters are 'positive derealization', 'positive depersonalization', 'altered time sense', 'positive mood', and 'mania-like experience'. (2) 'anxious ego dissolution' (AED) measures ego disintegration associated with loss of self-control, thought disorder, arousal, and anxiety. The item clusters are 'anxious derealization', 'thought disorder', 'delusion', 'fear of loss of thought control', and 'fear of loss of body control'. (3) 'visionary restructuralization' (VR) includes the item clusters 'elementary hallucinations', 'visual (pseudo-) hallucinations', 'synesthesia', 'changed meaning of percepts', 'facilitated recollection', and 'facilitated imagination'. (4) 'auditory alterations' (AA) refers to acoustic hallucinations and distortions in auditory experiences and (5) the dimension 'reduction of vigilance' (RV) relates to states of drowsiness, reduced alertness, and related impairment of cognitive function.

AMRS

The Adjective Mood Rating Scale (AMRS) (Janke and Debus, 1978) consists of 60 adjectives representing different mood states. Subjects were instructed to rate the extent to which each adjective was applicable to their current mood from the options: 'not at all' (1), 'a little' (2), 'quite' (3) and 'strongly' (4). The AMRS consists of the following main factors: 'concentration', 'inactivation,' 'tiredness,' 'dazed state', 'introversion', 'heightened mood', 'emotional excitability', 'anxiety,' 'depressiveness,' and 'dreaminess.'

Experimental procedure

Substance and dosing

Psilocybin (4-phosphoryloxy-*N,N*-dimethyltryptamine) was obtained through the Swiss Federal Office of Public Health, Bern. Psilocybin capsules (1 mg and 5 mg) were prepared at the Pharmacy of the Cantonal Hospital of Aarau, Switzerland. Quality control comprised tests for identity, purity and uniformity of content. Psilocybin and lactose placebo were administered in gelatine capsules of identical appearance. After oral uptake, psilocybin is rapidly transformed to the pharmacologically active metabolite psilocin (Hasler *et al*., 1997; Lindenblatt *et al*., 1998). Usually, first subjective effects of psilocybin are perceived 20 to 40 min after oral administration and peak at about 60 to 90 min to last for another 60 to 120 min. All psilocybin-induced symptoms usually wear off 6 to 8 hours after drug administration (Vollenweider *et al*., 1997; Hasler *et al*., 2004).

Study design

We conducted a double-blind, placebo-controlled, within-subject design with three experimental arms: placebo, medium and high doses of psilocybin were administered with a counterbalanced order of administration. Subjects were tested on 3 days separated by at least 14 days to avoid carry-over effects. The medium dose (MD) psilocybin (115 µg/kg; mean body weight of subjects 70.3±12.5 kg; absolute doses 8.2±1.4 mg psilocybin) and the high dose (HD) psilocybin (250 µg/kg; absolute doses 17.6±3.2mg psilocybin) were selected for this study due to observations from a previous investigation (Hasler *et al.*, 2004). These selected doses produced perceptual alterations without producing profound thought disturbances or complete loss of ego control. One week ahead of the first experiment, subjects underwent a somatic and psychiatric examination and were familiarized with the sensorimotor tasks. Subjects arrived at the research unit of the University Hospital of Psychiatry at 8.30 AM on each experimental day, and psilocybin or placebo capsules were administered at 10.00 AM.

Performance on the sensorimotor tasks was assessed just prior to administration of drug/placebo (t_0; baseline measures), at 90 minutes during the anticipated peak effects (t_1), and 240 minutes after drug intake (t_2), when effects had decreased substantially. Subjects also underwent psychometric measurements using the AMRS (at 0, 80 and 280 min after drug/placebo administration) and the 5D-ASC (at 110 min). The SSP of the CANTAB battery was accomplished at 0, 100 and 360 min after drug/placebo intake. Subjects were examined by the principal investigator approximately 7 to 8 hours after drug intake and released from the hospital only when the psychotropic effects had completely subsided. The presented results are part of a study that also comprised tests of binocular rivalry (sampled at 100 min, 180, 270 and 360 min), these results are reported separately (Carter *et al.*, 2005).

Statistical analysis

Psychometric data were analysed using a one-, two- or three-way repeated measures ANOVA. Analysed factors were (1) treatment (placebo, MD psilocybin, HD psilocybin), (2) time of measurement (t_0, t_1, t_2) and - where applicable - (3) measures or subscales (different temporal intervals in a timing task or subscales on a questionnaire). The interaction of treatment x time of measurement was considered as the main source of information since the effect of psilocybin should occur at t_1 and to a lesser degree at t_2, in contrast to the placebo condition. In cases where a significant interaction effect was observed, simple *a priori* contrasts compared differences between placebo and both MD and HD psilocybin. These drug dose effects were considered in respect to changes over time from both t_0 to t_1 and t_0 to t_2 (four contrasts). In some cases we looked at the three treatment conditions separately. Then, time of measurement (t_0, t_1, t_2) was the main factor in three drug conditions followed by two contrasts each (t_0 to t_1 and t_0 to t_2). Pearson's correlation analysis was used to compare relative change in performance on the temporal-processing tasks, the spatial span working memory test and the 5D-ASC rating scale. Only those correlations found to be significant at both medium and high doses were considered. For these cases, the low and high dose data were pooled to calculate a single Pearson's r value for that measure.

To minimize the possible effects of non-normal distribution in the data sets, we transformed all data prior to analysis by applying a natural log transform. In the case that negative values had to be transformed, a constant was added to the variable to make sure that all values were positive. Additionally, Greenhouse-Geisser adjustment of degrees of freedom was applied to the data set when, according to the Mauchly test, sphericity of the sample distributions could not be assumed. Significance levels were set to values of $p<0.05$. However, since multiple comparisons were planned for each measure, the risk of Type I error increases (incorrect rejection of null hypothesis). To ensure overall protection level, only those planned contrasts associated with the decisive interaction for hypothesis testing (e.g. time of measurement x treatment) on each measure are reported. Nevertheless, we adjusted the alpha level for each measure to the amount of contrasts that were applied (e.g. two contrasts: $p<0.025$, four contrasts: $p<0.0125$) as well as for the number of ANOVAs that were calculated for different subscales of a task.

Results

Temporal reproduction

To test for an effect of psilocybin on temporal reproduction, three-way repeated measure ANOVAs were calculated separately for the short (1500 ms, 2000 ms, 2500 ms) and the long intervals (4000 ms, 4500 ms, 5000 ms). The three main factors included were interval duration (three intervals for the short and the long intervals, respectively), measurement time (t_0, t_1, t_2) and treatment (placebo, MD and HD psilocybin). For the short intervals, interval duration was the only factor to show a significant effect [F(2,16)=600.2, *p*<0.001], reflecting a linear increase in reproduction intervals as a function of the presented interval duration (see Figs 1a-1c). No other main factors or interactions showed significant differences. For the long intervals, significant main effects of interval duration [F(2,16)=130.0, *p*<0.001] and measurement time [F(2,16)=6.9, *p*=0.007] were revealed. The interaction treatment x measurement time, the decisive interaction to reveal differential drug effects between peak and baseline, proved to be significant [F(4,32)=3.2, *p*=0.025]. No other interaction revealed a significant effect.

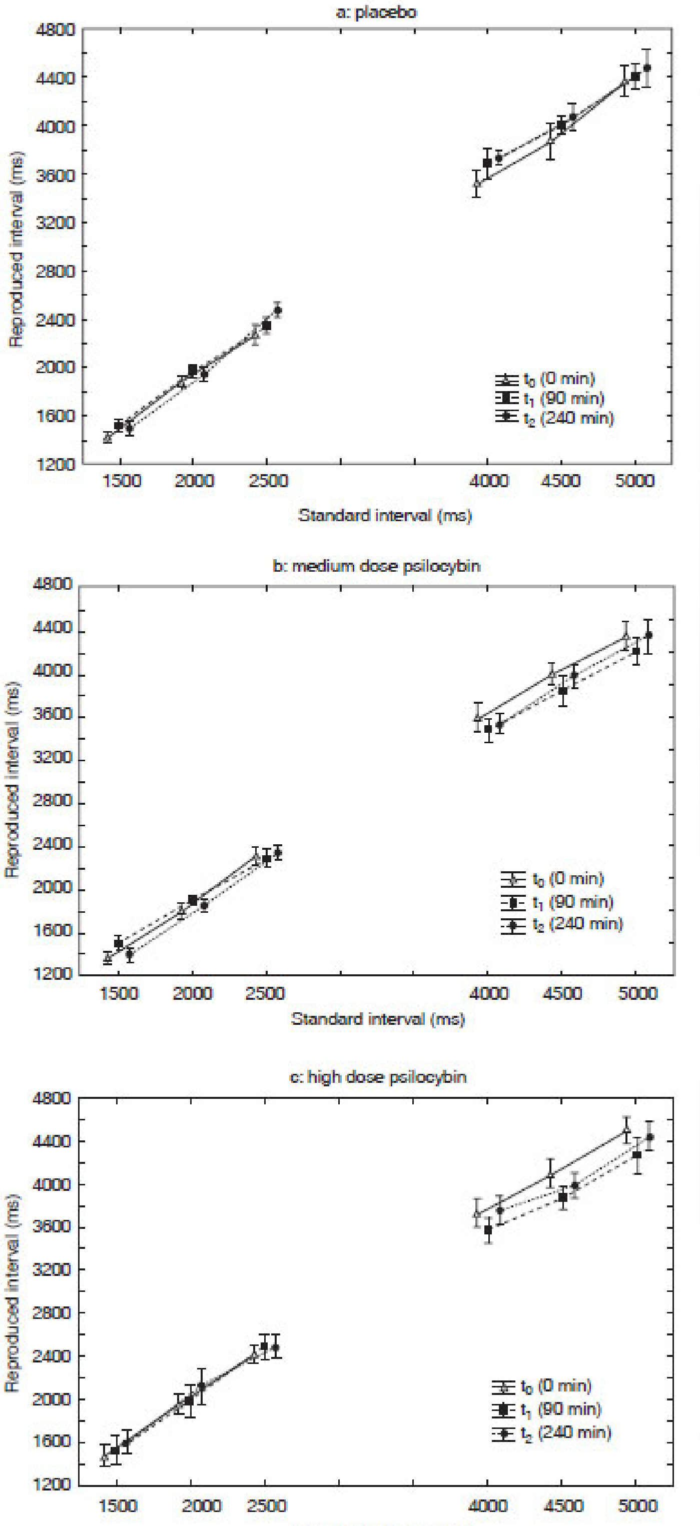

Figure 1 - Mean reproduced intervals ± SE for six different stimulus durations over three measures (t(0) = baseline, t(1) = peak effect 90 min after drug intake, t(2) = post-peak effect) are compared for the conditions of high dose psilocybin (250 µg/kg), medium dose psilocybin (115 µg/kg) and placebo.

To discern the treatment x measurement-time interaction at the long intervals, we looked separately at the three treatment conditions that were tested at the three measurement times. For every treatment condition, a two-way ANOVA with the interval duration (4000 ms, 4500 ms, 5000 ms) and measurement time (t_0, t_1, t_2) was calculated. In the placebo condition (Fig. 1a), we found a significant difference for the factor interval [$F(1,8)=98.1$, $p<0.0001$], but no significant effect of measurement time and no significant interaction of measurement time x interval duration. A similar result was obtained for MD psilocybin (Fig. 1b): a significant difference was only revealed for the factor interval [$F(2,20)=122.7$, $p<0.0001$] and measurement time did not reach the significance level ($p<0.1$). The interaction between interval duration and measurement time also revealed no significant effect. In the treatment condition HD psilocybin (Fig. 1c), however, the ANOVA revealed significant effects for both main factors, interval duration [$F(2,22)=49.5$, $p<0.001$] and measurement time [$F(2,22)=7.0$, $p=0.004$]; no significant interaction effect was found. As depicted in Fig. 1c, temporal reproductions at the long intervals showed a stronger tendency toward underestimation at peak time of HD psilocybin as compared with baseline. Contrasts for the effect of measurement time in the HD-psilocybin condition showed significant differences for the contrast between t_1 and t_0 [$F(1,11)=13.0$, $p=0.004$] but no significant difference between t_2 and t_0 [$F(1,11)=0.36$, $p=0.561$]. Thus, HD psilocybin leads to a significant under-reproduction of time intervals of 4 seconds and longer.

To assess the stability of performance, we compared the standard deviation of the reproduced interval for the three factors: interval, measurement time and treatment. A three-way ANOVA for the short intervals did not reveal any significant effects. For the long intervals, measurement time showed a significant effect. However, for both, the long and short interval durations, the treatment x measurement time interaction failed to reach the significance level.

Sensorimotor synchronization

Asynchrony (Mean)

To assess the subjects' ability to temporally synchronize to a regularly occurring external stimulus, a three-way ANOVA with the main factors: treatment, measurement time and interval (700 ms, 1000 ms, 2000 ms, 4000 ms) was calculated for the dependent variable asynchrony. Whereas the effect of treatment failed to reach significance [$F(2,22)=3.0$, $p=0.069$], measurement time [$F(2,22)=10.1$, $p=0.001$] and interval [$F(1.2,13.5)=16.7$, $p<0.001$; Greenhouse-Geisser adjusted] showed significant differences. Moreover, the measurement time x treatment interaction was found to be significant [$F(4,44)=3.9$, $p=0.009$]. The interaction between interval and measurement time failed to reach significance [Greenhouse-Geisser adjusted]. The interaction of interest (measurement time x treatment) only tended towards significance for the contrast between HD psilocybin and placebo between t_1 and t_0 [$F(1,11)=4.5$, $p=0.057$] but a significant difference was observed for the contrast between MD psilocybin and placebo between t_1 and t_0 [$F(1,11)=14.5$, $p=0.003$].

To take a closer look at the treatment x measurement-time interaction, we calculated two-way ANOVAs separately for the three treatment conditions with the two main factors: measurement time and interval. In the placebo condition, only the main factor interval [$F(1.2,13.2)=13.6$, $p=0.01$; Greenhouse-Geisser adjusted] proved to be significant. No significant differences were found for either measurement time or the interval x measurement-time interaction (Fig. 2a). In the MD-psilocybin condition both factors interval [$F(1.27,33)=12.4$, $p=0.002$; Greenhouse-Geisser adjusted] and measurement time [$F(2,22)= 10.2$, $p<0.001$] revealed significant differences, but not the interaction of the two. Contrasts for the effect of measurement time in the MD-psilocybin condition showed a significant difference for the contrast between t_1 and t_0 [$F(1,11)=16.9$, $p=0.002$] but no significant difference between t_2 and t_0 [$F(1,11)=0.669$, $p=0.431$] (Fig. 2b). In the HD psilocybin condition, interval [$F(1.4,15.9)=9.9$, $p=0.003$; Greenhouse-Geisser adjusted] and measurement time [$F(2,22)=8.1$, $p=0.002$] as well as the interval x measurement-time interaction [$F(2.5,27.7)=4.7$, $p=0.012$; Greenhouse-Geisser adjusted] reached the significance level. Contrasts for the effect of measurement time in the HD-psilocybin condition revealed only a marginally significant difference (adjusted p value) for the contrast between t_1 and t_0 [$F(1,11)=5.5$, $p=0.039$] and no significant difference between t_2 and t_0 [$F(1,11)=1.844$, $p=0.202$] (Fig. 2c). It is to note that the smaller mean asynchrony between tap and tone onset does not reflect a more precise synchronization ability but instead an increase in reaction times, that is, more missed synchronizations (see below).

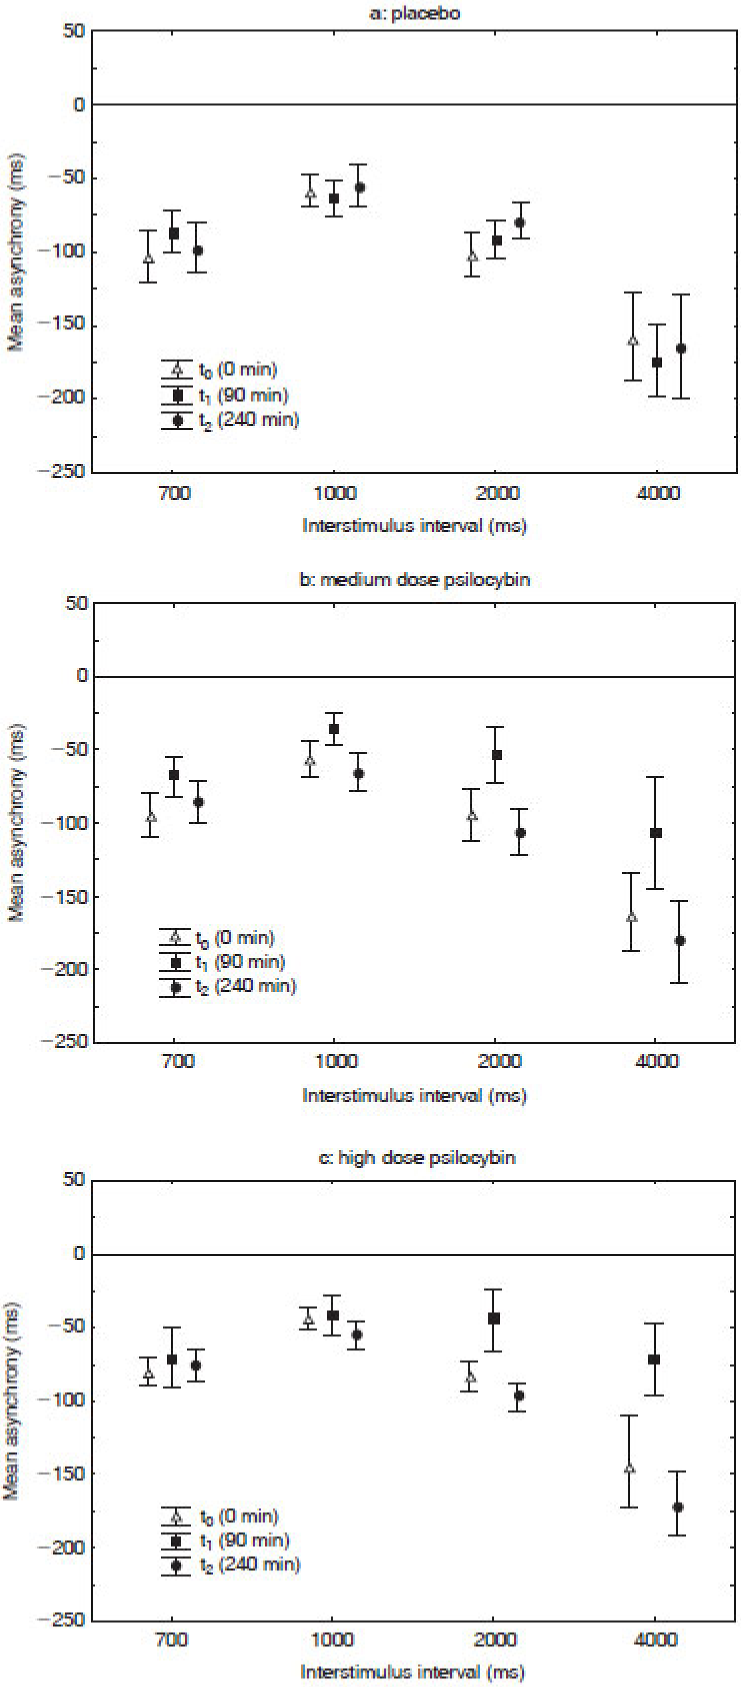

Figure 2 - Mean asynchrony (± SE) between motor response (tap onset) and tone onset over four different interstimulus intervals in the sensorimotor synchronization task over three measures (t(0)= baseline, t(1) = peak effect 90 min after drug intake, t(2) = post-peak effect) are compared for the conditions of high dose psilocybin (250 µg/kg), medium dose psilocybin (115 µg/kg) and placebo.

Asynchrony (standard deviation)

To measure the stability of synchronization performance, the standard deviation of the asynchrony between the tap and the tone was taken as the dependent variable in a three-way ANOVA with the main factors: treatment, measurement time and interval. Treatment [F(2,22)=1.4, *p*=0.874] and time of measurement [F(2,22)=1.6, *p*=0.229] showed no effect on performance. The length of the inter-beat interval had a significant influence on tapping variability [F(3,33)=227.5, *p*<0.001] - the standard deviation getting bigger with increasing intervals. However, the important interaction measurement time x treatment [F(4,44)=1.4, *p*=0.268] was not significant.

Per cent missed synchronization

As can be seen in Fig. 3a-c, it was only for the 2- and 4-seconds intervals that a considerable amount of reaction time asynchronies (> 120 ms) were detectable. Therefore, only these two intervals were taken for further calculations. A three-way ANOVA comparing the per cent missed synchronization for the factors - treatment, measurement time and interval (2000 ms, 4000 ms) - showed a significant main effect only for treatment [F(2,22)=4.9, *p*=0.018] and interval [F(1,11)=16.5, *p*=0.002]. The interaction in focus of our hypotheses treatment x measurement time showed not to be significant [F(4,44)=1.1, *p*=0.37] although - descriptively - subjects show more reaction times under psilocybin at peak-time than at baseline or at post peak (see Fig. 3a-c).

Personal tapping speed

A two-way ANOVA (treatment and measurement time) revealed that psilocybin significantly slowed tapping tempo. There was a main effect of measurement time [F(2,20)=3.5, *p*=0.05], treatment [F(2,20)=4.9, *p*=0.019], and the measurement time x treatment interaction [F(4,40)=3.1, *p*=0.026]. Subjects tapped slower during peak effects of HD psilocybin (949.0 ms, SD: 390.0) than at baseline (692.2 ms, SD: 274.6) and post-peak effects of drug (772.1 ms, SD: 280.7). Following a one-way ANOVA with the factor measurement time in the HD condition [F(2,20)=8.7, *p*=0.002], subsequent contrasts reveal a significant difference between t_1 and t_0 [F(1,10)=13.6, *p*=0.004] but no significant difference between t_2 and t_0 [F(1,10)=2.7, *p*=0.133]. No effect of measurement time was seen in the MD condition [F(2,20)=1.5, *p*=0.247]. The coefficient of variance, the measure for tapping stability in the personal tempo, revealed a significant main effect of measurement time [F(2,20)=5.7, *p*=0.01], but no effect for treatment or the interaction of the two main factors.

Maximum tapping speed

Over the different experimental conditions, subjects' maximum tapping speed was registered with mean inter-tap intervals of approximately 150 ms. Two-way ANOVA for the factors measurement time [F(2,22)=10.9, *p*=0.001] and treatment [F(2,22)=4.3, *p*=0.026] showed significant main effects. However, the important measurement time x treatment interaction was not significant. Since the main effect of treatment includes the t_0 and t_2 measurement times in addition to the t_1 measurement time, the treatment effect was probably due to by chance different performance on the psilocybin administration day. Furthermore, a two-way ANOVA on the coefficients of variance for the inter-tap interval showed no significant main effects or interaction, suggesting that tapping stability at maximum speed is unaffected by psilocybin.

Spatial span task

Two-way ANOVAs (factors treatment and measurement time) were calculated to elucidate the effects of psilocybin on the spatial span length. We found no overall effect for treatment [F(2,22)=1.33, n.s.], a significant effect to measurement time [F(2,22)=4.05, *p*=0.032], and - decisive for the question of concern - a significant interaction effect [F(2,22)=4.66, *p*=0.003]. A priori contrasts (alpha level adjusted to *p*<0.0125 for four contrasts) revealed a significant difference only for the contrast between placebo and HD psilocybin between t_1 and t_0 (*p*<0.011). Thus, at the peak of effects, HD psilocybin (and not MD psilocybin) impaired spatial span task (SSP) performance as indexed by span length (see Fig. 5).

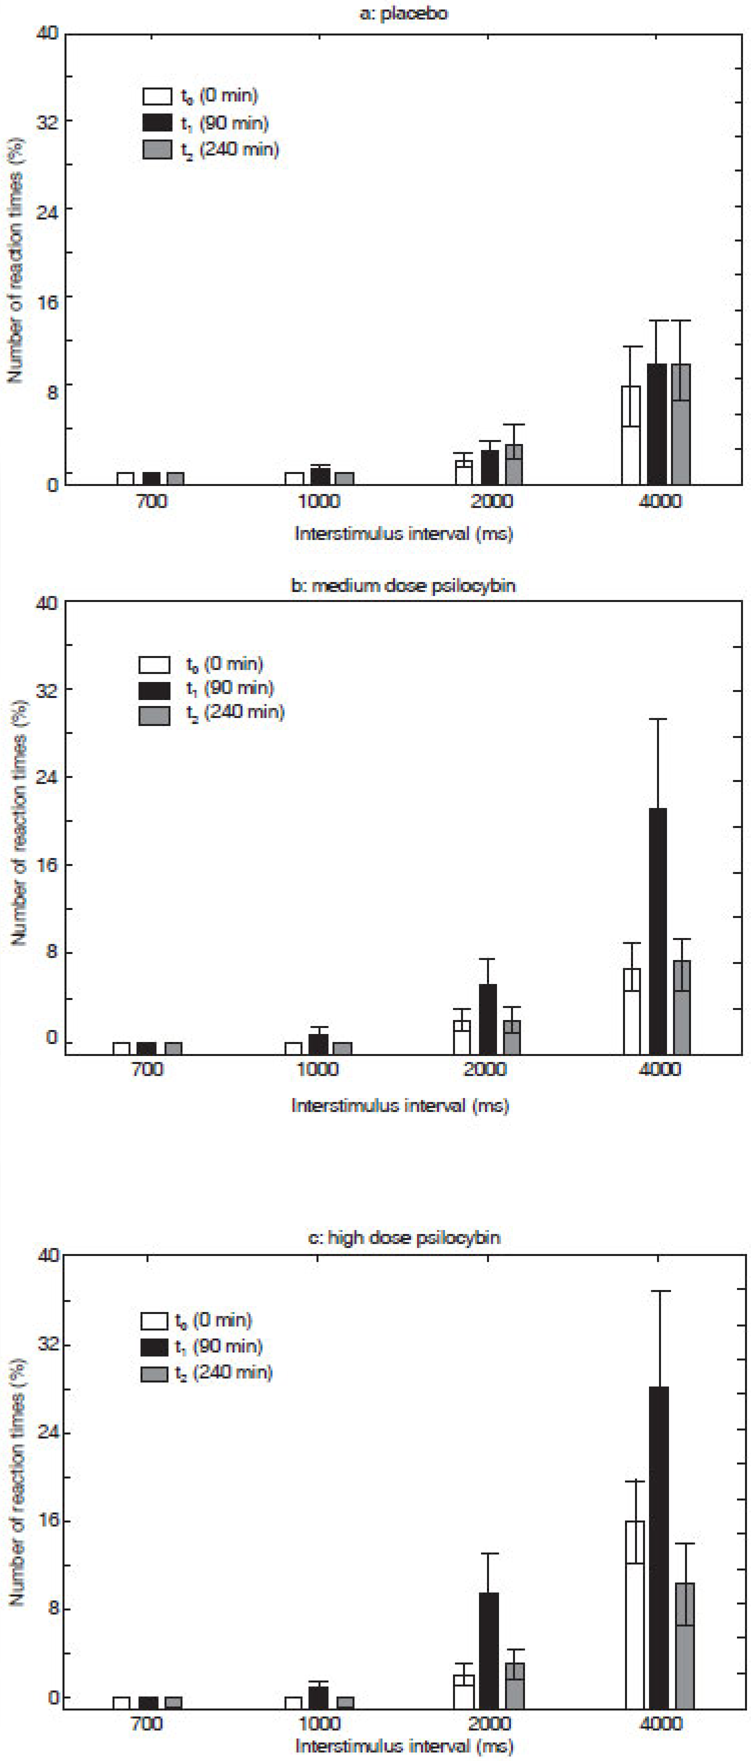

Figure 3 - Mean number of reaction times (in per cent; ± SE) of four different interstimulus intervals in the sensorimotor synchronization task over three measures (t(0) = baseline, t(1) = peak-effect 90 min after drug intake, t(2) = post peak effect) are compared for the conditions of high dose psilocybin (250 µg/kg), medium dose psilocybin (115 µg/kg) and placebo.

Altered States of Consciousness rating scale (5D-ASC)

As shown in Fig. 4, psilocybin increased the scores of the 5D-ASC dimensions (as assessed at peak time) in a dose-dependent manner. There was a main effect of treatment [F(2,22)=14.2, *p*<0.001]. The main effect for subscale did not reach the significance level [F(2.22,24.2)=4.38; *p*=0.064; Greenhouse-Geisser adjusted] but the treatment x subscale interaction did [F(8,88)=2.53, *p*=0.016]. Subsequent one-way repeated measures ANOVAs comparing the three treatment conditions at peak time were performed for each of the five subscales (adjusted alpha level for five comparisons is *p*<0.01). A significant effect of treatment could be seen in all five subscales: OB [F(2,22)=13.54; *p*<0.001; contrast for MD psilocybin vs placebo: *p*=0.01; contrast for HD psilocybin vs. placebo: *p*<0.001], AED [F(2,22)=7.08; *p*=0.004; MD psilocybin vs. placebo: *p*=0.046 (n.s.); HD psilocybin vs placebo: *p*=0.005], VR [F(2,22)=11.2; *p*<0.001; MD psilocybin vs placebo: *p*=0.006; HD psilocybin vs placebo: *p*=0.003], AA [F(1.368,15.05)=9.79; *p*=0.004; Greenhouse-Geisser adjusted; MD psilocybin vs placebo: *p*<0.167 (n.s); HD psilocybin vs placebo: *p*=0.007], RV [F(2, 22)=7.67; *p*=0.003; MD psilocybin vs placebo: *p*=0.004; HD psilocybin vs placebo: *p*=0.003].

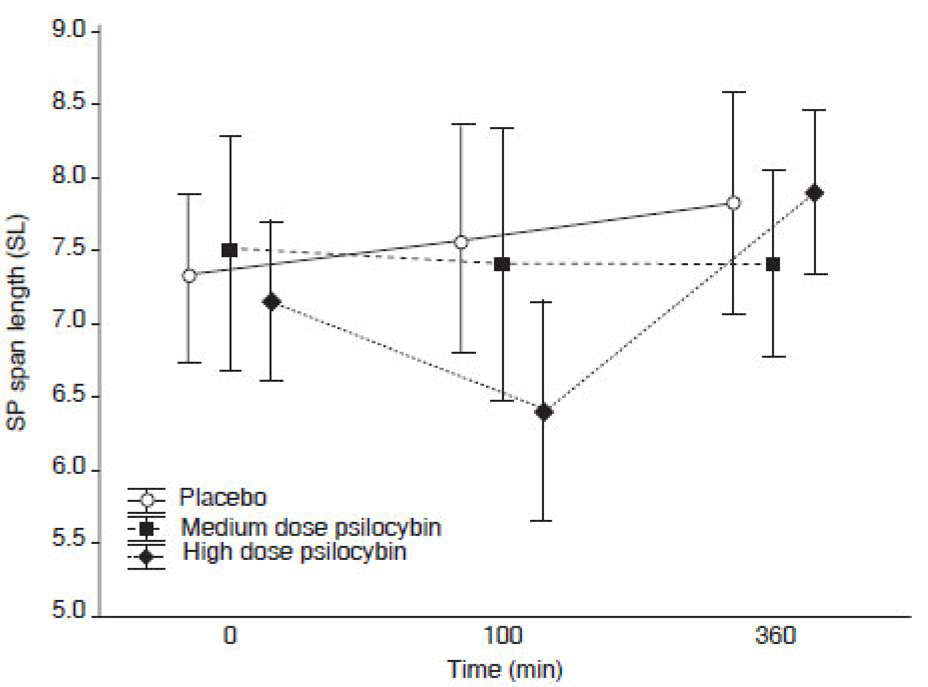

Figure 4 - Dose- and time-dependent effects of psilocybin on working memory performance as indexed by spatial span length (SL; mean ± SE).

A subsequent exploration of the ASC item clusters in each subscale revealed that the increase in OB after high-dose psilocybin was mainly due to moderate increases in (positive) 'derealization phenomena' (30.8±18.7% of scale maximum), 'heightened mood' (30.1±18.9%) and 'mania-like symptoms' (26.0±18.5%). The item of special interest, 'altered time sense', also showed a significant effect of psilocybin [F(1.33,14.61)=7.9; *p*=0.009; contrast for MD psilocybin vs placebo: *p*=0.083 (n.s.); contrast for HD psilocybin vs placebo: *p*=0.017]. The increase in AED was attributable to moderate 'thought disturbances' (45.0±29.8% of scale maximum) followed by slight increases in 'loss of body control' (20.1± 21.0%), 'loss of thought control' (15.9±28.5%) and 'anxious derealization' (15.0±23.4%). Furthermore, the analysis of the VR item-cluster revealed that only the high dose, but not the medium dose of psilocybin significantly produced 'complex hallucinations' and increased 'facilitated recollection and imagination,' and that increase in VR after medium dose of psilocybin was mainly due to visual illusions and elementary hallucinations, such as light flashes or geometric figures.

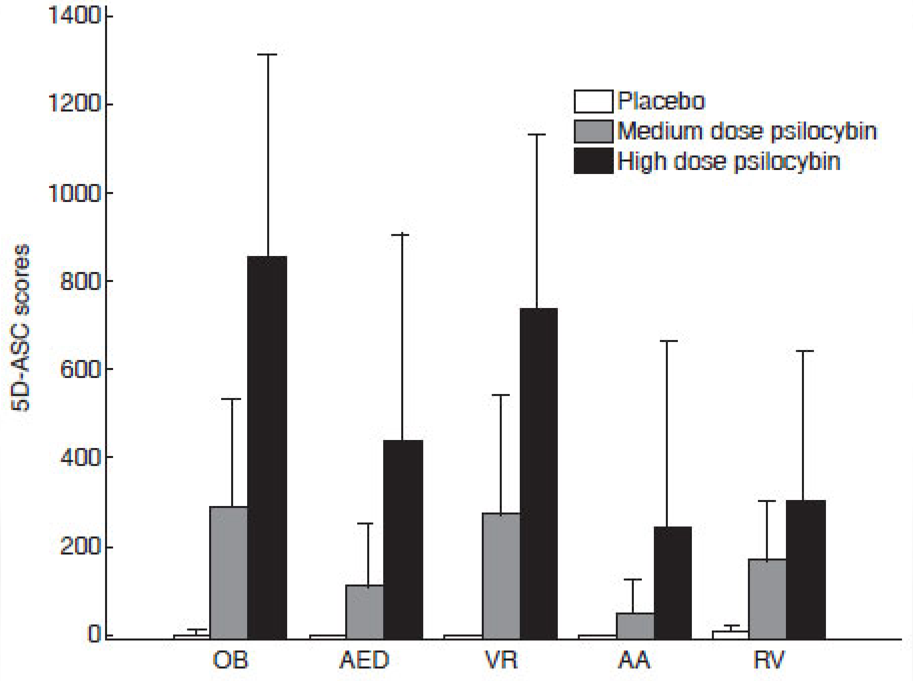

Figure 5 - Mean scores ± SE of the Altered States of Consciousness Rating Scale (5D-ASC) during the peak effect of high dose psilocybin (250 µg/kg) compared to medium dose psilocybin (115 µg/kg) and placebo (*n* = 12). OB= oceanic boundlessness, AED=anxious ego dissolution, VR = visionary restructuralization, AA= auditory alterations, RV = reduction of vigilance.

Adjective Mood Rating Scale (AMRS)

Two-way repeated measures ANOVAs were performed for each of the ten subscales (adjusted alpha level: $p<0.005$). A significant interaction between treatment and measurement time, was found for the subscales of inactivation [F(4,44)=7.89, $p=0.001$; significant contrast for MD psilocybin vs placebo between t_0 and t_1 ($p<0.001$) as well as between HD psilocybin and placebo between t_0 and t_1 ($p=0.019$)], tiredness [F(4,44)=6.6, $p<0.001$; MD psilocybin vs placebo between t_0 and t_1 ($p<0.001$)], dazed state [F(4,44)=6.51, $p<0.001$; MD psilocybin vs placebo between t_0 and t_2 ($p<0.001$)], introversion [F(4,44)=9.84, $p<0.001$; MD psilocybin vs placebo between t_0 and t_2 ($p<0.001$)], emotional excitability [F(4,44)=5.36, $p<0.001$; MD psilocybin vs placebo between t_0 and t_1 ($p=0.015$)], and dreaminess [F(4,44)=12.4, $p<0.001$; MD psilocybin vs placebo between t_0 and t_1 ($p=0.009$) as well as t_0 and t_2 ($p<0.001$)]. A tendency for a treatment x measurement-time interaction was found for the subscale of 'concentration' [F(4,44)=4.12, $p=0.006$]. No significant interaction effect appeared for the subscales of heightened mood, anxiety and depressiveness. The effects of psilocybin on the AMRS mood scales during peak time, comparing the three treatment conditions, are presented in Fig. 6.

Correlations between working-memory performance, time measures and psychometric scores

Correlational analyses revealed no significant correlation between spatial span length and temporal reproduction for the longer intervals (4000, 4500, 5000 ms; where significant drug effects were found) (*r* ranged from -0.17 to 0.16). However, there was a strong negative correlation between spatial span length and the OB subscore (r=-0.73, $p<0.001$). Further multiple regression analysis revealed that the two OB items 'depersonalization' and 'altered time sense' contributed most to this effect (r=-0.83, $p<0.0001$ and r=-0.69, $p<0.001$, respectively). Importantly, the other factors on the 5D-ASC did not show significant correlations with spatial span length, indicating that this effect was specific and not a generalized association between the drug-induced altered state of consciousness and working-memory decrement. There were no significant correlations between any of the temporal-processing measures and the 5D-ASC subscales, however a trend towards correlation between the OB subscore and the time reproduction underestimation at longer time intervals was found. Specifically, the item 'altered time sense' showed moderate correlation coefficients with the longer time intervals in temporal reproduction at peak time under the influence of MD and HD psilocybin: the larger the underestimation of the 4500 and 5000 ms interval, the higher the score on the 'altered time sense' item (*r* between 0.4 and 0.6). However, these associations failed to reach the significance level.

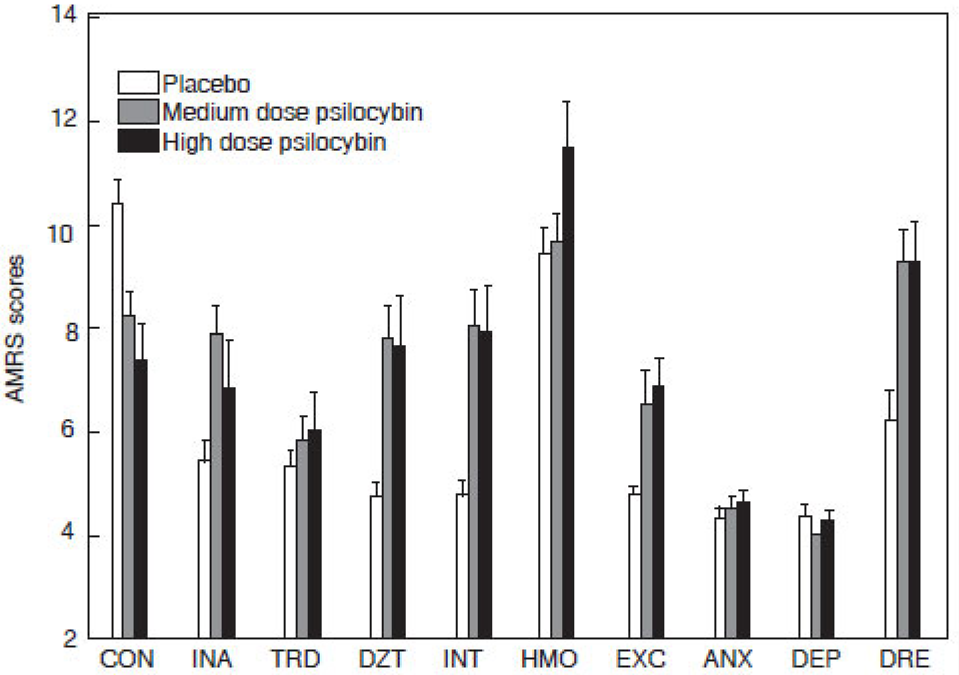

Figure 6 - Mean scores ± SE of the Adjective Mood Rating Scale (AMRS) during the peak effect of high dose psilocybin (250 µg/kg) compared to medium dose psilocybin (115 µg/kg) and placebo (*n* = 12). CON = concentration, INA = inactivation, TRD = tiredness, DZT = dazed state, INT = introversion, HMO = heightened mood, EXC = emotional excitability, ANX = anxiety, DEP = depressiveness, DRE = dreaminess.

Discussion

Our investigation clearly revealed that the 5-HT$_{2A}$/5-HT$_{1A}$ mixed agonist psilocybin alters time perception and temporal control of behaviour in humans. These results confirm self-reports that hallucinogens cause strong alterations in spatial and temporal perception (Vollenweider *et al*., 1997; Hasler *et al*., 2004) and extend these psychometric findings by showing the specific ways in which objective measures of temporal processing can be affected. Psilocybin was found to affect an individual's capacity to accurately reproduce interval lengths longer than 3 seconds, synchronize a motor response (finger tap) to regular auditory beats with intervals longer than 2 seconds, and to slow down the personal tapping tempo (preferred tapping rate). No impairment of performance was observed for shorter lengths on the sensorimotor synchronization and the reproduction task. This indicates that the effects found at the longer intervals were likely a product of interactions with cognitive dimensions of temporal processing instead of interactions with the proposed basic pacemaker/accumulator mechanisms of the brain (Rammsayer, 1999; Wearden, 2004).

Several studies on timing point to a temporal-integration interval of approximately 2 to 3 sec that can be found in perception and motor performance (for reviews, see Fraisse, 1984; Pöppel, 1997; Wittmann, 1999). Durations of temporal intervals in the temporal-reproduction task are estimated precisely with intervals up to approximately 2 to 3 sec, whereas longer intervals are substantially underestimated (Kagerer *et al*., 2002). A temporal limitation of anticipatory planning is also observed in the sensorimotor synchronization task. The ability to synchronize accurately becomes substantially weaker when the inter-stimulus interval is longer than 2 sec (Mates *et al*., 1994). Our pharmacological approach contributes to these findings, as psilocybin mildly affects only those intervals of longer duration in each task. One of the few time perception studies under LSD in humans adds to our results (Mitrani *et al*., 1977): subjects did not show distortions in the ability to identify durations of visual stimuli in the range between 300 ms and 1 sec although they reported changes in the subjective passage of time.

In respect to the current model of timing with multiple processing stages (Wearden, 2004), the disturbed timing abilities for sensorimotor synchronization and duration reproduction we show here could reflect impairments of short-term memory, attention or decision-making mechanisms (Zakay and Block, 1996; Pouthas and Perbal, 2004), rather than the alteration of the pacemaker-accumulator clock (the basic internal timing mechanism). This is especially supported by the concurrent deficits observed in working memory in the present study. Converging evidence exists for the involvement of working memory in temporal reproduction. Processing of a secondary task that influences working-memory capacity interferes with the encoding and reproducing of durations in the domain of seconds (Fortin and Rousseau, 1998). Miyake *et al*. (2004) showed that a secondary working-memory task affected the accuracy of synchronization only with inter-stimulus intervals above 2 seconds. With inter-stimulus intervals below 2 seconds the memory task had no influence on performance. In a group of elderly subjects, working memory capacity correlated with performance in a temporal reproduction task with durations of 5 and 14 seconds (Baudouin *et al*., 2006). Frontal regions known to be closely linked with working-memory function, particularly dorsolateral and frontomedial cortices (Postle *et al*., 2000; Cabeza and Nyberg, 2000; Owen, 2000) are active during temporal reproductions of time intervals of a few seconds (Elbert *et al*., 1991; Volz *et al*., 2001; Monfort and Pouthas, 2003). Given the selective effect of psilocybin on the longer duration intervals in both the temporal reproduction and sensory synchronization tasks it seems that the temporal disturbance observed is induced through interference with cognitive processes like attention and working memory. The fact that no correlations were found between performance on the working-memory and temporal-processing tasks, should not be considered as evidence against this hypothesized role of working memory in the observed timing impairments. Rather it is likely to reflect the small sample size combined with the relatively small effect sizes seen in both the timing measurements and the working memory. In fact, the small impairments observed for the timing measures may reflect a relative insensitivity of working memory performance to psilocybin, a claim supported by the finding that psilocybin had no significant effect on working memory at either the median dose used in this study (115 µg/kg) or a higher dose (215 µg/kg) used in a separate study (Carter *et al*., in press). However, further studies are warranted to corroborate this interpretation. Moreover, it is also possible that other working-memory functions such as verbal working memory might be more significantly associated with the timing tasks.

Whereas the maximum-tapping speed was unaffected by psilocybin, the tapping tempo in a voluntarily chosen tempo was significantly slower during peak effects of HD psilocybin as compared to baseline and post-peak time of that condition. This finding is consistent with several lines of evidence showing that the control of motor speed can basically be characterized by two distinct sensorimotor processes functioning with different frequencies. For example, movements with a frequency of 1 to 2 Hz are under voluntary control and allow the collection of somatosensory information (feedback control), while movements at maximum speed with frequencies of 5 Hz and above require only coarse pre-attentive control (feed-forward control) (Peters, 1989; Kunesch *et al*., 1989; Wittmann *et al*., 1999). These two sensorimotor modes appear to be controlled by distinct neural networks. Injury of the cerebellum can lead to dysdiadochokinesia, the inability to alternate agonist and antagonist muscles with maximum speed (Dichgans, 1984). In contrast, metabolic dysfunction of the basal ganglia such as in Parkinson's disease can lead to the inability to tap at a slower pace, patients showing the so-called hastening phenomenon (Nakamura *et al*., 1978). In another study, tapping in a self-paced tempo was slowed down in patients with left-hemispheric lesions to the brain, whereas maximum-tapping speed was not influenced by lesions in either side of the cortex (Wittmann *et al*., 2001). The effect of HD psilocybin on personal tapping tempo, leading to a slower pace of the regular finger taps at peak time, could be the result of the drug influencing cortical sites of the brain, including those of the left hemisphere. In partial support of such a hypothesis we have previously found that psilocybin caused left-over-right sided dorsolateral overactivation that significantly correlated with depersonalization phenomena using FDG-PET imaging (Vollenweider *et al*., 1997; Vollenweider, 2001).

Psilocybin-induced dose-dependent changes to subjective measures of conscious state, i.e. the loosening of ego boundaries, changes in affect and perceptual distortions as previously reported in detail (Vollenweider *et al*., 1997; Hasler *et al*., 2004), included the expected changes in time perception as indexed by the 5D-ASC item 'altered time sense'. Although we found no correlation between working-memory deficits and the objective timing measures used, we did find significant correlations between working-memory impairment and subjective measures of altered time sense and depersonalization experiences measured by the OB subscale of the 5D-ASC. The trend towards correlations for the duration underestimation above 3 seconds and the OB item 'altered time sense' merits further studies seeking to investigate the relationship between alterations in temporal processing and experiences of self.

The pharmacological basis of the experience of time and temporal processing is only vaguely understood.

Pharmacological manipulations in animal and human studies indicate that dopaminergic agonists and antagonists influence timing processes - supposedly by increasing and decreasing (respectively) clock speed (Rammsayer, 1989; Cevik, 2003). The detrimental effect of the DA antagonist haloperidol on duration discrimination with base intervals of 50 ms has been interpreted as resulting from a slowing down of the clock rate (Rammsayer, 1989). Studies in patients with Parkinson's disease show that dopaminergic agonists can improve motor timing (O'Boyle *et al.*, 1996). It appears that dopaminergic neurotransmission within striatal and cortical sites is strongly connected to temporal processing, leading to the postulation of a cortico-striato-thalamo-cortical system involved in sensorimotor timing (Matell and Meck, 2004). The present results indicate that the serotonin system is also involved in temporal processing, either directly as a component of one of the basic processing stages in the model of timing or indirectly by influencing dopaminergic or glutaminergic transmission as we have previously shown in PET studies of psilocybin model psychosis (Vollenweider *et al.*, 1999). When taking into account the different levels of the timing model that are an integrative part of the cognitive system (Pouthas and Perbal, 2004), several neurotransmitter systems play a decisive role in temporal processing in the range of seconds. Rammsayer (1999), for example, discovered that the dopamine receptor antagonist haloperidol as well as benzodiazepine midazolam had detrimental effects on duration discrimination of intervals ranging around 1 second whereas processing of 50-ms intervals was only affected by haloperidol. These results were discussed as influences via disruption of transmitter-guided cognitive processes such as attention and working memory. The author concluded that any pharmacological treatment that affected working-memory capacity would interfere with temporal processing of intervals in the longer time range. It has to be noted that we did not find effects of psilocybin on durations below 2 seconds. This discrepancy can only be resolved in future studies that consider task-specific and pharmacological factors. In addition to comparing possible task-related differences between the duration discrimination task and the sensorimotor tasks used in our study, selective effects of individual pharmacological substances will probably be accounted for by the inconsistencies found over different studies. In the study presented here, the 5-HT$_{2A/1A}$ receptor agonist psilocybin affected time intervals in sensorimotor synchronization and temporal reproduction only above 2 to 3 seconds and only self-paced tapping (and not maximum tapping). These effects can also be interpreted as following the disruption of cognitively mediated temporal-processing stages. Moreover, as we are reporting the specific effects of the drug concerning the time domain, we can rule out the possibility that a generally decreased capacity of subjects to interact with the environment or a decreased interest for the experimental task produced the effects shown.

Our main goal was to elucidate whether psilocybin induced specific effects on temporal control of behaviour and, if so, whether these would be a function of the duration of the processed time interval - an effect we did find. In future studies the possible relationship between duration processing and underlying cognitive functions including different aspects of working memory - for example, taking into account differences between spatial and verbal working memory - needs to be further investigated by concurrently probing other dimensions of attention and working memory. Further studies with specific 5-HT$_{1A}$, 5-HT$_{2A}$ and dopamine receptor antagonists are needed to tease out the relative contribution of each of these receptor systems to the observed effects. In respect to the use of psilocybin in modelling endogenous psychosis, temporal processing deficits have been observed in chronic medicated schizophrenics at both short and long intervals (Davalos *et al.*, 2002, Davalos *et al.*, 2003, Elvevag *et al.*, 2003) whereas our current findings indicate that only longer interval processing is affected by psilocybin. It would be of interest to see whether the use of the same paradigm in healthy subjects with psilocybin and unmedicated acute schizophrenic subjects would show the same disparity of effects. Moreover, as some effects could be seen on a descriptive level but differences failed to reach the significance level it would be interesting to investigate whether increasing the number of participating subjects may yield further effects of the psilocybin intervention.

Acknowledgments

This study was supported by the Heffter Research Institute, Santa Fe, NM, USA, and the Swiss Federal Office of Public Health (BAG contract No. 00.001023) through grants to FXV. The authors especially thank G. Greer, MD, for critical comments on the manuscript.

Preliminary report on the experience with psychosomimetic drugs in the treatment of alcoholism

by

Z. Rydzyński, S. Cwynar, L. Grzelak, W. Jagiełło

Psychiatric clinic of Military Medical Academy, Łódź

original report: http://www.beckleyfoundation.org/bib/doc/ah/1968/1968_rydzynski_4745_1.pdf
backup source: http://www.psilosophy.info/resources/1968_rydzynski_4745_1.pdf

Encouraged by the world literature reports on good effects of therapy of alcoholics with help of psychosomimetic drugs we started to use this method in 1965. We used two drugs: Psylocybin and Delysid, both produced by Sandoz. In two years and a half we treated 14 men aged 25 do 55. All of them had been treated previously as out- or in-patients, with no results. They belonged to a group of excessive chronic drinkers, majority in conflict with their nearest families and strongly connected with the "alcoholic environment" of their town. We injected psylocibin intramuscularly in doses of 9 mg and so we did with LSD-25, depending on the patient's tolerance and on his body weight, in doses of 100 to 800 µ. As a rule we started the cure with psylocibin, next LSD was used, and then for every 3 delysid injections we gave a psylocibin one. It seems to prevent from getting used to the same drug and allows to avoid increasing the dosage during cure. Psychosomimetic shocks were given, as a rule, one a week, exceptionally twice weekly. Towards the end of the procedure, in 3-4 hours time after the drugs were injected, the doctor taking care of the group had some exploratory talks with the patients during the first 2-4 sittings, later talks took the form of individual psychotherapy. On the days when no drugs were given, individual psychotherapy was systematically continued and half the patients had a group - psychotherapy one the day succeeding the psychosomimetic sitting. The leisure time of the patients was continually organized (work therapy, amusements, etc). Attempts were also made at improving their family relationships. During the hospitalization the patients received 6-8 psychosomimetic shocks. Thereafter all of them were offered to continue the cure as out-patients. Only 4 of them accepted it; they received totally 30 shocks.

The results are the better when the number of shocks is greater. The effects of 6-8 shocks were as follows: 2 men without any improvement, 7 with moderate improvement (they returned to addiction in 3-6 months), 3 with good improvement (ret. to the addiction in 12-18 months) and 2 have not returned to the addiction, for 18 months.

Beneficial effect of psychosomimetic drugs depend on 1st - their transforming influence upon the structure of personality, 2nd - making easier the psychotherapeutic contact with the doctor, 3rd - remission already after 2-3 shocks of the craving for drinking. Really good effects can be obtained by giving 30 or more psychosomimetic shocks in out-patient clinic at intervals of 1-2 weeks. Shorter treatment do not assure remission longer than half a year.

Usually, already after the first two shocks and before the leading doctor starts active psychotherapy, the alcoholic changes his cynical attitude to the environment, loses his desire for drinking, begins to believe in the possibility of getting rid of his habit and to accept attentively the doctor's suggestions.

We have not seen any somatic nor psychic complications.

Human hallucinogen research - guidelines for safety

Abstract

There has recently been a renewal of human research with classical hallucinogens (psychedelics). This paper first briefly discusses the unique history of human hallucinogen research, and then reviews the risks of hallucinogen administration and safeguards for minimizing these risks. Although hallucinogens are relatively safe physiologically and are not considered drugs of dependence, their administration involves unique psychological risks. The most likely risk is overwhelming distress during drug action ('bad trip'), which could lead to potentially dangerous behaviour such as leaving the study site. Less common are prolonged psychoses triggered by hallucinogens. Safeguards against these risks include the exclusion of volunteers with personal or family history of psychotic disorders or other severe psychiatric disorders, establishing trust and rapport between session monitors and volunteer before the session, careful volunteer preparation, a safe physical session environment and interpersonal support from at least two study monitors during the session. Investigators should probe for the relatively rare hallucinogen persisting perception disorder in follow-up contact. Persisting adverse reactions are rare when research is conducted along these guidelines. Incautious research may jeopardize participant safety and future research. However, carefully conducted research may inform the treatment of psychiatric disorders, and may lead to advances in basic science.

Key words: 5-HT$_{2A}$ agonists; adverse reactions; DMT; entheogens; hallucinogens; human research; LSD; mescaline; psilocybin; psychedelics; safety guidelines

Introduction

After several decades of dormancy, research involving the administration of classical hallucinogens to humans has been recently renewed (Sessa, 2005; Frecska and Luna, 2006; Harvard Mental Health Letter, 2006; Lancet, 2006; Morris, 2006; Winkelman and Roberts, 2007). Although nonhuman animal research during the intervening decades has substantially advanced our understanding of underlying neuropharmacological mechanisms of the hallucinogens, the fact that human research with this historically important and widely used class of compounds remained inactive is remarkable (Nichols, 2004). Renewed human administration research began with the work of Rick Strassman, who initiated research on the effects of *N,N*-dimethyltryptamine (DMT) at the University of New Mexico in the early 1990s (Strassman, 1991, 1996, 2001; Strassman and Qualls, 1994; Strassman, *et al.*, 1994, 1996). Subsequently, investigators both in the USA and in Europe have developed human research programmes with hallucinogens. This new research has included basicscience studies that have administered hallucinogens as tools for investigating cognitive neuroscience and perception (Gouzoulis-Mayfrank, *et al.*, 1998a; Gouzoulis-Mayfrank, *et al.*, 2002; Umbricht, *et al.*, 2003; Carter, *et al.*, 2004; Carter, *et al.*, 2005a,b), time perception (Wittmann, *et al.*, 2007), hallucinogen pharmacokinetics and metabolism (Hasler, *et al.*, 1997, 2002), model psychosis (Vollenweider, *et al.*, 1997, 1998, 1999, 2007; Gouzoulis-Mayfrank, *et al.*, 1998a; Vollenweider and Geyer, 2001; Gouzoulis-Mayfrank, *et al.*, 2005, 2006), and, recently in our laboratory, hallucinogens' reported facilitation of experiences having enduring personal meaning and spiritual significance (Griffiths, *et al.*, 2006). Recent clinical studies have administered hallucinogens to evaluate their safety and efficacy in the treatment of psychiatric disorders: specifically, anxiety related to advanced-stage cancer (Grob, 2005) and obsessive-compulsive disorder (Moreno, *et al.*, 2006). In addition, several studies have examined the effects of *ayahuasca* (also known as *hoasca* or *yagé*; an admixture containing DMT) in human volunteers outside of the USA (Grob, *et al.*, 1996; Riba, *et al.*, 2001). Because the United States Supreme Court has recently ruled in favour of the União do Vegetal (UDV; a syncretic Brazilian church that uses *ayahuasca* in the context of religious ceremonies) in their claim that the UDV's use of *ayahuasca* is protected under the Religious Freedom Restoration Act (Gonzales v. O Centro Espirita Beneficiente União do Vegetal, 2006), *ayahuasca* use within this church setting may receive increased scientific investigation within the USA.

We use the word 'hallucinogen' herein to refer to the classical hallucinogens, sometimes called 'psychedelics', 'psychotomimetics' or 'entheogens' (Grinspoon and Bakalar, 1979; Ruck, *et al.*, 1979; Ott, 1996; Metzner, 2004). Admittedly, the term 'hallucinogen' is not ideal for these substances, because perceptual changes are only one domain of their effects, and the typical perceptual changes engendered by hallucinogens at typical doses rarely include frank hallucinations (Grinspoon and Bakalar, 1979; Nichols, 2004; O'Brien, 2006). However, we use this term because it is the most widely used in the scientific literature. Although the term 'psychedelic' is widely used, it has the disadvantage of carrying considerable cultural connotation (i.e. its use as a descriptor of a style of music or art associated with Western counter-culture of the 1960s). The terms 'psychotomimetic' (emphasizing model psychosis) and 'entheogen' (emphasizing mystical-type experiences, i.e. phenomenologically indistinguishable from classically described mystical experiences) highlight only a single aspect (which may not occur reliably) of the much broader range of hallucinogen effects.

Hallucinogens can be divided structurally into two classes of alkaloids: the tryptamines, including psilocybin (prodrug constituent of *Psilocybe* and several other mushroom genera), the semi-synthetic d-lysergic acid diethylamide (LSD), and DMT; and the phenethylamines, including mescaline (principle active constituent of peyote) and certain synthetic compounds (Grinspoon and Bakalar, 1979; Shulgin and Shulgin, 1991, 1997; Metzner, 2004, Nichols, 2004). The effects of these substances are primarily mediated by agonist action at 5-HT$_{2A}$ receptors (Glennon, *et al.*, 1984; Nichols, 2004; González-Maeso, *et al.*, 2007) and produce a generally similar profile of subjective effects (Hidalgo, 1960; Hollister and Hartman, 1962; Wolbach, *et al.*, 1962a,b; Shulgin and Shulgin, 1991, 1997). Other classes of substances have sometimes been identified as 'hallucinogens', including 3,4-methylenedioxymethamphetamine or MDMA [perhaps more appropriately labelled an entactogen (Nichols, *et al.*, 1986) or empathogen (Metzner, 1985)]; dissociative anaesthetics such as ketamine, phencyclidine and dextromethorphan; and anticholinergic agents such as scopolamine and atropine (Nichols, 2004). However, this paper uses the term 'hallucinogen' to refer specifically to classical hallucinogens.

The purpose of this paper is to provide guidance in the safe administration of high doses of hallucinogens (e.g. ≥25 mg psilocybin or 200 μg LSD). Some aspects of these recommendations may also apply to studies employing lower doses, although, as with other drug classes, the likelihood of potential adverse effects will be related to dose. Similarly, some aspects of these recommendations may also apply to studies administering the other drug classes mentioned in the preceding paragraph: entactogens, dissociative anaesthetics and anticholinergic agents. However, the clinical effects and mechanisms of action of these agents are sufficiently different from the classical hallucinogens that safety recommendations concerning their administration are beyond the scope of this manuscript.

First, so that the historical context in which current human hallucinogen studies are conducted will be clear, we will briefly discuss the history of sacramental hallucinogen use by indigenous cultures, and the history of human hallucinogen research before it became dormant in the 1970s. The decades-long virtual dormancy of human hallucinogen research stands as a unique case in the history of modern clinical pharmacology. It is important for researchers going forward to understand the role that safety factors, as well as sociological and political factors, played in the history and cessation of human hallucinogen research. Moreover, because of the historical legacy of sensationalism surrounding hallucinogens, researchers should appreciate the precarious position of current human hallucinogen research, and recognize that very high safety standards will help to ensure that human research continues into the decades to come. Next, we will provide a detailed description of the unique risks of hallucinogen administration. We will then present the proposed guidelines for conducting high-dose hallucinogen research in each of several domains, including volunteer selection, study personnel, physical environment, preparation of volunteers, conduct of sessions, and post-session procedures.

Relevant history

Hallucinogen use by indigenous cultures

Hallucinogens have been used by indigenous cultures for millennia (Schultes, 1969; Lowy, 1971; Schultes, *et al.*, 2001). These cultures have restricted hallucinogen use to sacramental and healing contexts, with these two often being inseparably intertwined. Remarkably, apparently without exception, such cultures view hallucinogenic plants and fungi as being of divine origin (Schultes, *et al.*, 2001). Given this orientation, it is not surprising that their ingestion is often tightly restricted, with use controlled by ceremonial guidelines, including taboos against improper use (Schultes, *et al.*, 2001; Weil, 2004). Indigenous cultures restrict use of hallucinogens to highly ritualized, sacred ceremonies such as those designed to serve as rites of passage, or to set the occasion for divination and spiritual or physical healing. Even in cases in which certain use extends beyond the shaman and may be more recreational in nature (e.g. use of the DMT-containing *epená* by the Waiká cultures of Brazil and Venezuela), the hallucinogen is prepared and taken in a highly ritualized context (Grinspoon and Bakalar, 1979; Schultes, *et al*. 2001; Weil, 2004). Modern, urban syncretic religions, such as the UDV, which have developed in South America and have been influenced by indigenous use of ayahuasca, also incorporate a high degree of structure and guidance into their *ayahuasca* use, which may minimize adverse reactions (Gonzales v. O Centro Espirita Beneficiente União do Vegetal, 2006).

However, indigenous cultures should not be regarded as absolute role models in the clinical use of hallucinogens for at least two reasons. First, some of these cultures also engaged in practices considered unethical in our culture. For example, the Aztecs, who used psilocybin mushrooms and morning glory seeds (containing LSD-related agents), practiced human sacrifice, and even incorporated hallucinogen use into sacrificial rituals (Ott, 1996). As another example, the Jivaro in Ecuador who use *ayahuasca* practice sacramental headhunting, and *ayahuasca* may be used by the shaman in that society for malevolent intent (i.e. bewitching) as well as for healing (Harner, 1962, 1968; Grof, 1977). Second, risk/benefit tradeoffs that may be acceptable in various religious contexts may fall short of what is expected in the domain of contemporary scientific research with human participants.

Nonetheless, some important themes have emerged in the use of hallucinogens by indigenous cultures that may have bearing on the appropriate use of hallucinogens in clinical research. Indeed, some of the safeguards developed for clinical hallucinogen research and expressed in the guidelines presented herein are similar to important aspects of hallucinogen use by indigenous cultures. These common themes are structured use (expressed as ritual in indigenous use), restrictions on use including the need for guidance and appreciation of hallucinogens' powerful psychological effects (expressed as reverence in indigenous use). We believe that these commonalities are more than coincidence. The unique pharmacology of classical hallucinogens may have shaped convergent practices across independent cultures. Likewise, the guidelines expressed herein for human clinical research with hallucinogens may also be viewed as having been developed in reaction to these same aspects of hallucinogen pharmacology. As an example, some of the unique effects and safety concerns for hallucinogens may be related to their ability to set the occasion for deeply meaningful, even spiritual experiences (Richards, 2003, 2005). Novak (1997) hypothesized that Western intellectuals in the mid 1950s such as Aldous Huxley and Gerald Heard merely redefined the subjective effects resulting from hallucinogen administration as a spiritual experience, thereby popularizing such an association in western culture. However, the observation that indigenous cultures that ingest classical hallucinogens almost invariably do so under sacramental contexts (Schultes, *et al*., 2001), along with the findings from double-blind clinical studies demonstrating that under supportive conditions, hallucinogens occasion mystical-type experiences with high frequency (Pahnke, 1963; Griffiths, *et al*., 2006) suggests that the association of hallucinogens with spiritual experience relates to the pharmacology of these agents rather than being based entirely on cultural suggestion.

Early clinical research

In the 1950s and 1960s, thousands of research participants were administered hallucinogens in the context of basic clinical research or therapeutic clinical research, resulting in hundreds of publications (Grinspoon and Bakalar, 1979; Grob, *et al*., 1998; Strassman, 2001; Nichols, 2004). During this time, the United States Army investigated classical hallucinogens as incapacitating agents in soldiers, and the United States Central Intelligence Agency conducted clandestine research investigating classical hallucinogens as interrogation agents in which civilians were administered hallucinogens without knowledge or consent. Eventually, both groups ceased to focus on classical hallucinogens in favour of non-classical 'hallucinogens' such as the synthetic anticholinergic compound quinuclidinyl benzilate (BZ), which showed greater promise as a warfare agent than LSD because its effects were marked by greater immobility, delirium, amnesia and duration (Lee and Shlain, 1992). Very early academic research on classical hallucinogens was designed without considering the powerful influences of set (psychological state) and setting (environment) (Malitz, *et al*., 1960; Rinkel, *et al*., 1960; Hollister, 1961; Rümmele and Gnirss, 1961; Leuner, 1962). Subsequent research, which included more preparation and interpersonal support during the period of drug action, found fewer adverse psychological reactions, such as panic reactions and paranoid episodes, and increased reports of positively valued experiences (Chwelos, *et al*., 1959; Leary, 1964; Leary, *et al*., 1963, 1964; Metzner, *et al*., 1965; Pahnke, 1969).

One major area of early research focused on the comparison of hallucinogen effects with the symptoms of psychosis (e.g. Stockings, 1940; Hoch, *et al*., 1953; Hoffer and Callbeck, 1960; Leuner, 1962; Kuramochi and Takahashi, 1964). Although the study of hallucinogens as models for the psychosis observed in schizophrenia eventually fell out of favour in psychiatry (Grinspoon and Bakalar, 1979; Snyder, 1988; Strassman, 2001), a renewed interest in this area is emerging, in part due to modern brain imaging techniques and neuropharmacological findings that have supported hallucinogens as a model of at least certain aspects of acute psychosis (Vollenweider, *et al*., 1997; Gouzoulis-Mayfrank, *et al*., 1998a; Vollenweider and Geyer, 2001; Gouzoulis-Mayfrank, *et al*., 2005, 2006).

Other areas of early human research included investigations of therapeutic applications of hallucinogens in treatment of psychological suffering associated with cancer and in the treatment of substance dependence. Anecdotal observations and non-blind studies in cancer patients suffering from anxiety and depression suggested that LSD administration resulted in an ability to openly discuss existential fears and be at peace with approaching death, and that this reorientation often outlasted the acute drug effects (Kast and Collins, 1964; Cohen, 1965; Kast, 1967). Follow-up investigations involved the administration of a high dose of a hallucinogen to carefully prepared patients under highly supportive interpersonal conditions, with the patient wearing eyeshades and listening to classical music through headphones during the course of pharmacological action, a model known as 'psychedelic peak therapy' or 'psychedelic therapy' (Kurland, *et al.*, 1969; Pahnke, *et al.*, 1969; Richards, et al, 1972; Grof, *et al.*, 1973; Kurland, *et al.*, 1973; Grof and Halifax, 1977; Richards, *et al.*, 1977, 1979; Grof, 1980; Richards, 1980; Kurland, 1985). Unfortunately, these early studies did not include the stringent control conditions or groups that now have become standard in modern clinical psychopharmacology research. The results suggest, however, that these compounds may have improved psychological well-being in the face of anxiety and depression secondary to cancer.

Another focus of study was hallucinogen-facilitated therapy in the treatment of alcoholism and other forms of substance dependence (e.g. Smart, *et al.*, 1966; Hollister, *et al.*, 1969; Ludwig, *et al.*, 1969; Kurland, *et al.*, 1971; Savage and McCabe, 1973). While some studies prepared patients and utilized supportive conditions (e.g. Kurland, *et al.*, 1971; Savage and McCabe, 1973), others drastically departed from the 'psychedelic therapy' model (and from the guidelines herein), and involved the administration of high doses to unprepared, restrained patients (e.g. Smart, *et al.*, 1966). Results across studies were ultimately inconclusive due to such variations in methods and a lack of modern controls and experimental rigour (Abuzzahab and Anderson, 1971; McGlothlin and Arnold, 1971; Halpern, 1996; Mangini, 1998). Similarly, some therapists reported that hallucinogens administered under supportive contexts could accelerate psychotherapy for a variety of psychological disorders (e.g. Abramson, 1960, 1963; Crochet, *et al.*, 1963; Mogar and Aldrich, 1969; Rhead, 1977). However, these reports were largely based on anecdotal clinical accounts rather than controlled studies.

Escalation in recreational hallucinogen use, primarily LSD, in the 1960s, led to considerable sensationalism concerning these drugs in media coverage. Adding to the controversy was the publicized departure and termination of Timothy Leary and Richard Alpert from Harvard University in 1963 following charges of unorthodox methods in hallucinogen research (Grinspoon and Bakalar, 1979; Lee and Shlain, 1992; Novak, 1997; Strassman, 2001). Leary's subsequent irresponsible advocacy of hallucinogen use by youth further undermined an objective scientific approach to studying these compounds. The growing controversy and sensationalism resulted in increasing restrictions on access to hallucinogens throughout the 1960s (ultimately resulting in the placement of the most popular hallucinogens into Schedule I of the 1970 Controlled Substances Act in the United States), creating substantially greater regulatory barriers for researchers to conduct human trials. The negative publicity also resulted in withdrawal of federal research funds, which had previously supported much of the human research, and in the professional marginalization of clinical investigators interested in pursuing research with hallucinogens. Human research with hallucinogens in the USA became virtually dormant when the last trials were published in the early 1970s. Commenting on the unusual evolution of psychiatric research with hallucinogens, Strassman (2001) mused, "They began as 'wonder drugs,' turned into 'horror drugs,' then became nothing" (p. 28).

Unique risks of human hallucinogen research

Hallucinogen administration in humans results in a unique profile of effects and potential adverse reactions that need to be appropriately addressed to maximize safety. Different risks are associated with different drug classes, and human research with each class requires procedures to be in place to address those particular risks. For example, because high doses of certain opioids and sedative/hypnotics can cause respiratory depression (Gutstein and Akil, 2006; Charney, *et al.*, 2006), when conducting research with high doses of these drugs, respiration rate and/or blood oxygen are monitored, and mechanical breathing assistance and appropriate rescue medications are readily available. As another example, administration of high doses of psychomotor stimulants, such as cocaine, can cause cardiac stress (O'Brien, 2006). Therefore, electrocardiogram (ECG) readings taken at screening are scrutinized carefully, pulse and blood pressure are monitored during sessions, and rescue medication for acute hypertension is immediately available. Similarly, human hallucinogen administration entails its own unique risk profile. Unlike opioids, sedative/hypnotics or psychomotor stimulants, the primary safety concerns with hallucinogens are largely psychological rather than physiological in nature.

Physiological toxicity

Hallucinogens generally possess relatively low physiological toxicity, and have not been shown to result in organ damage or neuropsychological deficits (Strassman, 1984; Gable, 1993, 2004; Halpern and Pope, 1999; Hasler, *et al.*, 2004; Nichols, 2004; Halpern, *et al.*, 2005). Nonhuman animal studies have shown MDMA (structurally similar to some classical hallucinogens, but with a substantially different pharmacological mechanism of action) to have neurotoxic effects at high doses, although MDMA has been judged to be safe for human administration in the context of several therapeutic and basic human research studies. In contrast, there is no evidence of such potential neurotoxic effects with the prototypical classical hallucinogens (i.e. LSD, mescaline and psilocybin). Some physiological symptoms may occur during hallucinogen action, such as dizziness, weakness, tremors, nausea, drowsiness, paraesthesia, blurred vision, dilated pupils and increased tendon reflexes (Isbell, 1959; Hollister, 1961; Nichols, 2004). In addition, hallucinogens can moderately increase pulse and both systolic and diastolic blood pressure (Isbell, 1959; Wolbach, *et al.*, 1962b; Strassman and Qualls, 1994; Gouzoulis-Mayfrank, *et al.*, 1999; Passie, *et al.*, 2000; Griffiths, *et al.*, 2006). However, these somatic effects vary and are relatively unimpressive even at doses yielding powerful psychological effects (perceptual, cognitive and affective) (Metzner, *et al.*, 1965; Passie, *et al.*, 2000; Metzner, 2004).

Although a full discussion of special physiological toxicity concerns for medical patient populations is beyond the scope of this manuscript, a few observations are worthy of note. The early literature examining hallucinogens in the treatment of anxiety and depression secondary to cancer indicated that the classical hallucinogens LSD and *N,N*-dipropyltryptamine (DPT) were physiologically well-tolerated. The physical adverse effects of these agents observed in cancer patients were manageable and similar to effects observed in physically healthy individuals. These researchers noted that any other symptoms experienced during sessions with cancer patients were symptoms already associated with their existing illness (Richards, *et al.*, 1972; Kurland, *et al.*, 1973; Kurland, 1985). Early clinical research also safely administered LSD to chronic alcoholics and cancer patients with 'considerable liver damage', suggesting hepatic concerns are 'negligible unless the dysfunction is of a critical degree' (Grof, 1980, p. 164).

Participants and review committees may be concerned that LSD or other hallucinogens are associated with chromosomal damage. These concerns stem from an anti-LSD media campaign by the USA government in the late 1960s that was based on and followed soon after initial reports (Cohen, *et al.*, 1967a,b; Irwin and Egozcue, 1967), suggesting that LSD caused chromosomal damage in human leukocytes (Ott, 1996; Weil, 2004). This campaign included pictures of deformed children (Grinspoon and Bakalar, 1979) at a time when the thalidomide tragedies of a decade earlier were relatively fresh in the public's memory (Ott, 1996). However, many follow-up investigations soon squarely refuted the hypothesis that LSD use in humans was a significant risk for chromosomal damage or carcinogenic, mutagenic or teratogenic effects (e.g. Bender and Siva Sankar, 1968; Tjio, *et al.*, 1969; Dishotsky, *et al.*, 1971; Long, 1972).

Abuse and dependence

Like many classes of psychoactive drugs, hallucinogens are sometimes used in a manner that jeopardizes the safety or well-being of the individual or others (e.g. driving while impaired; a pattern of use that interferes with work, school or relationships). Under such circumstances, hallucinogens are said to be 'abused'. However, hallucinogens are not typically considered drugs of dependence in that they do not engender compulsive drug seeking (National Institute on Drug Abuse, 2001, 2006; O'Brien, 2006), consistent with the observation that they are not reliably self-administered in nonhuman animals (Poling and Bryceland, 1979; Griffiths, *et al.*, 1980; Fantegrossi, *et al.*, 2004). Furthermore, they are not associated with a known withdrawal syndrome (O'Brien, 2006). Therefore, there is little risk that exposing human volunteers to hallucinogens will leave participants physically or psychologically dependent on these compounds. This low dependence potential allows for the possibility of administering these compounds to hallucinogen-naïve volunteers when blinding issues are critical (e.g. Griffiths, *et al.*, 2006). However, in certain situations it may be advantageous to study hallucinogen-experienced participants (e.g. brain imaging studies requiring the participant to remain immobile).

Acute psychological distress and dangerous behaviour during hallucinogen action

Although hallucinogens have relatively low physiological toxicity and are not associated with compulsive drug seeking, there is still concern that they may pose other psychological risks. The most likely risk associated with hallucinogen administration is commonly known as a 'bad trip' and is characterized by anxiety, fear/panic, dysphoria, and/or paranoia. Distressing effects may be experienced in a variety of modalities: sensory (e.g. frightening illusions), somatic (e.g. disturbing hyperawareness of physiological processes), personal psychological (e.g. troubling thoughts or feelings concerning one's life) and metaphysical (e.g. troubling thoughts or feelings about ultimate evil forces) (McCabe, 1977; Grinspoon and Bakalar, 1979; Strassman, 1984). Because emotional experience is often intensified when under the influence of a hallucinogen, in unprepared individuals or uncontrolled situations any of these effects may potentially escalate to dangerous behaviour. For example, fear and paranoid delusions may lead to erratic and potentially dangerous behaviours, including aggression against self or others (Strassman, 1984). Although very rare, in hazardous and unsupervised conditions, individuals under the influence of hallucinogens have ended their lives by such acts as jumping from buildings (Keeler and Reifler, 1967; Reynolds and Jindrich, 1985; Reitman and Vasilakis, 2004; O'Brien, 2006). We recognize that even under unsupervised and unprepared conditions, reactions to hallucinogens involving violence and self-destructive behaviour are rare, and our intention is not to create an unrealistic account of the dangers of hallucinogens. Nonetheless, even infrequent reports of such dangers require that investigators take seriously such risks and take steps to avoid their occurrence.

Prolonged psychosis

Another potential risk of hallucinogen administration is provoking the onset of prolonged psychosis, lasting days or even months (Strassman, 1984). Although determining causation is difficult, it appears that individuals who experience such reactions have premorbid mental illness before taking hallucinogens. However, it is unknown whether the precipitation of psychosis in such susceptible individuals represents a psychotic reaction that would have never occurred in the absence of hallucinogen use, or whether it represents an earlier onset of a psychotic break that would have inevitably occurred (Grinspoon and Bakalar, 1979; Strassman, 1984). Unlike acute psychological distress, these cases will be extremely rare in well-selected and well-prepared participants. In a survey of investigators who had administered LSD or mescaline, Cohen (1960) reported that only a single case of a psychotic reaction lasting more than 48 h occurred in 1200 experimental (non-patient) research participants (a rate of 0.8 per 1000). Notably, the individual was an identical twin of a schizophrenic patient and thus would have been excluded under the proposed guidelines. Prolonged reactions over 48 h were slightly more frequent in patients undergoing psychotherapy than in experimental non-patient participants, but still relatively rare, occurring at a rate of 1.8 prolonged reactions per 1000 patients. Cohen (1960) also reported that suicide attempts and completed suicides occurred at a rate of 1.2 and 0.4, respectively, per 1000 patients. The causal link between hallucinogen exposure and suicide or suicide attempt was only clear for a portion of these cases in patients, and no suicides or suicide attempts were noted for the 1200 non-patient, experimental participants. However, it is important when evaluating these data to consider that only 44 of the 62 researchers queried by Cohen returned survey results (Cohen, 1960; Novak, 1997). Although Cohen and Ditman (1962) subsequently expressed misgivings over the increased incidence of adverse effects due to the increasing recreational use of LSD and some questionable clinical practices, they maintained that when used under the proper guidelines, LSD was an important tool for use in human research (cf. Novak, 1997). McGlothlin and Arnold (1971) reported one case out of 247 individuals who received LSD in either experimental or psychotherapeutic studies in which an LSD-related psychotic reaction lasting more than 48 h occurred. That single case was a patient who received repeated LSD administrations in a psychotherapeutic context. Although very rare, care must be taken to minimize the risks of such an episode. The volunteer selection guidelines, addressed in a later section, will be the key factor in minimizing the risk of prolonged psychosis in human hallucinogen research studies.

Some clinical observations suggest the possibility that unconscious psychological material may be activated during hallucinogen sessions, and that such material, if not properly worked through and psychologically integrated, may lead to psychological difficulties of a non-psychotic nature, such as negative emotions and psychosomatic symptoms, lasting beyond the session (e.g. McCabe, 1977; Grof, 1980). Although these observations have not been examined experimentally, they deserve consideration. As suggested in our subsequent discussion of volunteer-monitor interactions, we believe that the strong interpersonal support from session monitors before, during and following sessions will minimize any enduring untoward psychological effects.

Lasting perceptual abnormalities

Another potential risk of hallucinogen administration is hallucinogen persisting perception disorder (HPPD). In order to meet DSM-IV-TR criteria for this disorder, a hallucinogen user must re-experience perceptual effects similar to those experienced under acute hallucinogen action after cessation of hallucinogen use, these effects must be clinically distressing or impair functioning, and the effects must not be caused by a medical condition or be better explained by another psychiatric disorder or hypnopompic hallucinations (American Psychiatric Association, 2000). The incidence of HPPD is unknown, although it is thought to be very uncommon given the relatively few cases reported out of the millions of hallucinogen doses consumed since the 1960s (Halpern and Pope, 2003). Although the term 'flashback' is sometimes used interchangeably with HPPD, the former term is often used to describe any brief perceptual effects reminiscent of acute hallucinogen effects but occurring beyond acute hallucinogen use, usually in the absence of clinical distress or impairment (Lerner, *et al.*, 2002). Indeed, many illicit hallucinogen users report some brief visual abnormalities occurring after acute hallucinogen effects, but only for a small minority of users are these effects troubling or impairing enough to be considered clinically significant or warrant the diagnosis of HPPD (Lerner, *et al.*, 2002; Baggott, *et al.*, 2006). Many illicit users regard such sub-clinical effects as benign and pleasurable (Strassman, 1984; Lerner, *et al.*, 2002; Frecska and Luna, 2006). Importantly, the incidence of HPPD or other perceptual abnormalities appears to be much lower in therapeutic or research contexts with careful screening and preparation than in the context of illicit recreational use, which may include the confounds of polydrug use and unscreened psychiatric disorders (Cohen, 1960; McGlothlin and Arnold, 1971; Strassman, 1984; Halpern and Pope, 2003). Because such perceptual abnormalities are poorly understood, researchers administering hallucinogens to human volunteers should probe for perceptual disturbances in follow-up contact.

Guidelines for safety

The guidelines that follow are intended to support the safe administration of high doses of hallucinogens to human volunteers while minimizing potential adverse reactions. Although a previous paper outlined methodological issues relevant to the study of hallucinogens in humans (Gouzoulis-Mayfrank, *et al.*, 1998b), safety issues were not the primary focus of that paper. The present paper substantially complements this previous work by providing a more detailed discussion of safety concerns. Issues relevant to the conduct of human research with drugs of abuse in general have been well described (Fischman and Johanson, 1998). The present guidelines extend and complement the recommendations of Fischman and Johanson (1998) for high-dose hallucinogen research. For some domains, such as volunteer selection, volunteer preparation, and the interactions between the volunteer and study personnel, the proposed criteria are substantially more extensive than those presented by Fischman and Johanson (1998) and those routinely used in human behavioural pharmacology because these domains appear to require even greater attention for hallucinogens than for other classes of psychoactive drugs. Although particular aspects of the proposed guidelines may be debatable, it is hoped that this paper will encourage such discussion while conveying the general themes and major domains of concern in human hallucinogen research. The proposed guidelines may serve as a helpful starting point for investigators planning to conduct human hallucinogen research.

Selection of volunteers

There are two main domains of consideration for volunteer selection. First, selection criteria may be methodological in nature and involve the specific research questions being explored. Second, which is the focus of this manuscript, is safety-related selection criteria. In our studies at Johns Hopkins, participants must be in good general health as assessed by detailed medical history, physical examination, 12-lead ECG, blood chemistry profile, haematology and urinalysis. Pregnant women or those not practicing effective means of birth control are excluded. Relevant to general medical screening, classical hallucinogens moderately increase pulse and both systolic and diastolic blood pressure (Isbell, 1959; Wolbach, *et al.*, 1962b; Strassman and

Qualls, 1994; Gouzoulis-Mayfrank, *et al.*, 1999; Passie, *et al.*, 2000; Griffiths, *et al.*, 2006). Therefore in our studies of psilocybin to date, volunteers have been excluded if resting blood pressure exceeded 140 systolic and 90 diastolic (mmHg), averaged across four assessments on at least two separate days. Using these screening parameters with 54 participants to date, no psilocybin session has resulted in blood pressure increases considered medically dangerous, and we have never needed to administer an anti-hypertensive medication in response to psilocybin effects. Modification of these limits may be considered in future studies if safety continues to be observed under these parameters.

Certain medications may alter the effects of a hallucinogen and, therefore, individuals taking these medications should be excluded from participation. Specifically, chronic administration of tricyclic antidepressants and lithium (Bonson and Murphy, 1996), and acute administration of serotonin reuptake inhibitors (Fiorella, *et al.*, 1996) and the antipsychotic medication haloperidol (Vollenweider, *et al.*, 1998) have been shown to potentiate hallucinogen effects, and therefore participants' use of these represents a safety concern. Chronic administration of serotonin reuptake inhibitors (Stolz, *et al.*, 1983; Strassman, 1992; Bonson, *et al.*, 1996) and monoamine oxidase inhibitors (Bonson and Murphy, 1996) have been shown to decrease sensitivity to hallucinogens, and therefore participants' use of these represents a scientific concern. We also advise investigators to include questions concerning over-the-counter dietary supplements in addition to prescription medications when probing medication history, and to exclude those taking potentially problematic substances (e.g. 5-hydroxytryptophan and St John's Wort may affect serotonergic function, and, therefore, it is appropriate to exclude individuals currently or recently taking these products). It should also be noted that administration of *ayahuasca* (which contains monoamine oxidase inhibitors in addition to DMT) to individuals taking serotonin reuptake inhibitors may lead to a severe serotonin syndrome reaction (Callaway and Grob, 1998).

Psychiatric screening criteria are important for minimizing the already low chances of precipitating a longer term psychotic reaction by hallucinogen administration. Thorough psychiatric interviews (e.g. SCID; First, *et al.*, 2001) should be conducted to identify contraindicated psychological functioning or history. In our research, individuals are excluded who have a current or past history of meeting DSM-IV criteria for schizophrenia or other psychotic disorders (unless substance-induced or due to a medical condition), or bipolar I or II disorder, which are the most important conditions to exclude for ensuring safety. We also exclude those with a first or second-degree relative with these disorders. There is considerable evidence from family, twin and adoptive studies that genetic factors make a robust contribution to the aetiology of schizophrenia, with genetic factors established as relevant to some, perhaps all cases (Buchanan and Carpenter, 2005). In fact, data indicate that there is approximately a six-fold greater chance of developing schizophrenia in second-degree relatives of individuals with schizophrenia (Patel, *et al.*, 2003). Other investigators have also excluded individuals scoring high on the personality traits of rigidity and emotional lability on the grounds that these have been significantly associated with negative experiences during hallucinogen action and during non-pharmacologically induced altered states of consciousness (Dittrich, 1993; Hasler, *et al.*, 2004).

Depending on the nature of the study, it may be appropriate to exclude those with other psychiatric disorders as well. Unless the research study is designed to specifically address a question relevant to a specific psychiatric disorder, our advice is to select a population that is psychiatrically healthy. This strategy is warranted because the effects of hallucinogens may potentially interact with various psychiatric disorders. Furthermore, including volunteers with psychiatric disorders may increase the chances that symptoms from such disorders may inadvertently be misattributed to hallucinogen action. For example, our recent studies with healthy volunteers have excluded volunteers with a current or a recent past history (e.g. within the last 5 years) of alcohol or drug dependence (excluding caffeine and nicotine) or major depression, and volunteers with current obsessive-compulsive disorder, dysthymic disorder, panic disorder, dissociative disorder, anorexia nervosa or bulimia nervosa.

Recent and current studies have investigated therapeutic applications of psilocybin for psychiatric disorders (Grob, 2005; Moreno, *et al.*, 2006). Because preliminary reports have suggested safety, studies examining therapeutic indications are likely to continue. These studies target for participation volunteers with disorders that would normally be excluded from non-treatment studies. Therefore, additional considerations are appropriate for such studies. For example, in a study of hallucinogen-assisted therapy for depression or anxiety, individuals should be excluded whose symptoms of depression or anxiety are sufficiently severe to warrant immediate treatment with medication (e.g. due to suicidal ideation). In addition, clinical treatment studies may choose to lift restrictions on relatively minor non-target psychiatric disorders that would be excluded in studies with healthy volunteers. For example, a study of hallucinogens in the treatment of anxiety related to cancer might choose to allow the inclusion those with comorbid dysthymic disorder or mild obsessive-compulsive disorder. Investigators should examine the relevant evidence when considering lifting specific exclusions, proceed cautiously, and implement any supplemental safeguards that might be appropriate for such exceptions.

Study personnel

It is difficult to overemphasize the importance of the interpersonal atmosphere created by study staff in influencing a volunteer's response to a hallucinogen. Most critically, this applies to the interpersonal environment created by the actual session monitors (Leary, *et al*., 1964; Masters and Houston, 1966). We use the term 'monitor' to refer to the staff members, who will be with the participant in the session room during the course of hallucinogen action. The monitors should be knowledgeable about the medical and psychological markers of potential adverse reactions to the drug. Furthermore, monitors should have significant human relation skills and be familiar with descriptions of altered states of consciousness induced by hallucinogens. Personal experience with techniques such as meditation, yoga or breathing exercises may also prove to be helpful in facilitating empathy for volunteers who experience altered states of consciousness during hallucinogen action. The lead monitor for each participant in the Johns Hopkins studies to date has been a clinical psychologist or a clinical social worker. However, we believe that clinical sensitivity (e.g. empathy, respect) is likely more important than formal degrees when considering monitor qualifications.

We recommend the presence of at least two monitors during hallucinogen administration sessions so that the volunteer will never be alone should one monitor need to briefly leave the session room (e.g. to the restroom). For each participant in the Johns Hopkins studies, we have specified a primary monitor (who takes the lead in participant interactions) and an assistant monitor, with differing required levels of involvement for the two monitors during volunteer preparation (see Preparation of volunteers section below). In prior research into potential treatment applications of hallucinogens, the presence of both genders in the monitoring team has been recommended (Grof and Halifax, 1977; Grof, 1980; Kurland, 1985). Having both genders present may foster feelings of security. In the Johns Hopkins studies, we have followed this recommendation when possible, but also have conducted sessions in which the primary and assistant monitors were of the same gender as the volunteer. We would counsel against both members of the monitoring team being the opposite gender of a volunteer, unless there is a staff member of volunteer's gender who has established some rapport with the volunteer in advance, and who can quickly be summoned to assist should support be needed in the restroom. For studies that are intended to maximize the potential for mystical-type experience during hallucinogen administration, an additional valuable monitor characteristic may be her or his ability to interact with and relate to the participant concerning spiritual issues (e.g. Moss and Dobson, 2006; Council on Spiritual Practices, 2001).

Although the volunteer's interactions with the monitors are of paramount importance, all individuals at the study site having contact with the volunteer on or before the session day may influence a volunteer's reaction to a hallucinogen. Pre-session negative mood consisting of anxiety or depression has been shown to significantly predict anxious or other negative experiences during the session (Metzner, *et al*., 1965). Strassman (2001) reported that a visiting medical student's unexpected interaction with a volunteer before the session may have contributed to an adverse event resulting in the volunteer leaving the study site under the influence of psilocybin. To the degree possible, investigators should work with all personnel that the volunteer may encounter (e.g. receptionist, building security, nurses) to ensure that volunteers are treated with courtesy and respect. For example, in the Johns Hopkins studies, a research staff member other than the study monitors meets with the volunteer in the morning and administers a few pre-session questionnaires and manages other logistics. This staff member should be friendly, welcoming and compassionate, as he or she inquires as to the volunteer's current emotional and physical well-being (e.g. recent sleeping history, interpersonal or work stressors, anticipation of session, adherence to study dietary and medication/drug restrictions). The staff member should maintain a positive social rapport with the volunteer to reduce the likelihood of adverse psychological reactions during the session and to gain accurate information on the volunteer's condition so that other study staff may be notified if there is any potential reason to postpone or cancel the session (e.g. if the volunteer is experiencing a particularly stressful life event or is feeling ill). If any staff member treats the volunteer disrespectfully or coldly (i.e. 'like a guinea pig'), this may negatively influence the volunteer's psychological state and subsequent hallucinogen experience. We recognize that treating volunteers respectfully is an ethical imperative for all human research. However, with hallucinogen administration research, the importance of this mandate is even more compelling given the powerful influence of set and setting on hallucinogen effects. Therefore, we recommend providing additional attention to volunteer rapport beyond what is customary in general human behavioural pharmacology practice.

Physical environment

The physical environment during hallucinogen sessions is extremely important for ensuring safety for volunteers in two respects. First, an aesthetically pleasing environment may decrease the probability of acute psychological distress. The Johns Hopkins hallucinogen research projects use a living room-like setting (Figure 1). The furniture is comfortable and is atypical for a research laboratory or medical office setting. An overly 'clinical' environment with an 'antiseptic' look (e.g. white walls, extraneous medical equipment, personnel in white lab coats) may increase anxious reactions. Strassman (2001) noted that the medically oriented environment in which his DMT studies were conducted may have contributed to volunteers having unpleasant subjective experiences. For example, some volunteers reported vivid and realistic experiences of being medically examined by extraterrestrials. It has also been noted that many of the potentially unpleasant physical reactions to hallucinogens (e.g. subjective changes in temperature, difficulty in breathing, various bodily sensations) might be in part psychosomatic in nature (Blewett and Chwelos, 1959), and therefore possibly more likely in settings evocative of medical conditions (Masters and Houston, 1966). Some protocols may require videotaping of sessions for scientific purposes. Although there might be concern that videotaping could increase self-consciousness or paranoia, we have no evidence that this has occurred in the Johns Hopkins studies, in which videotaping of sessions is routine.

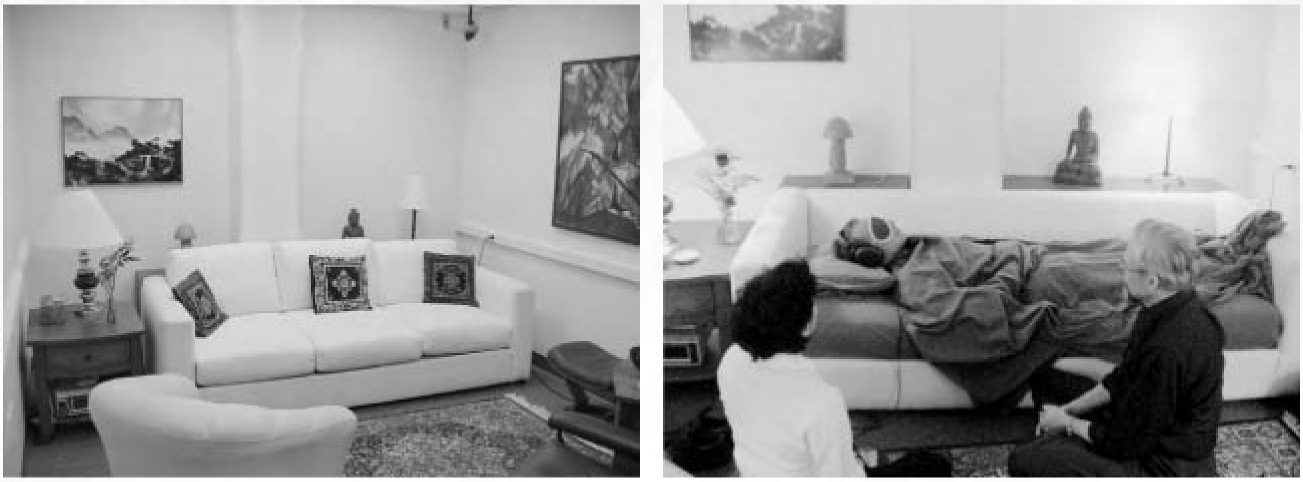

Figure 1. The living room-like session room used in the Johns Hopkins hallucinogen research studies. Aesthetically pleasing environments such as this, free of extraneous medical or research equipment, in combination with careful volunteer screening, volunteer preparation and interpersonal support from two or more trained monitors, may help to minimize the probability of acute psychological distress during hallucinogen studies. For studies that investigate potential therapeutic effects or the phenomenology of introspective hallucinogen experiences, the use of eyeshades and headphones (through which supportive music is played) may contribute to safety by reducing the distractions of environmental stimuli and social pressures to verbally interact with research personnel.

Beyond the psychological importance of a comfortable, relaxing environment, attention must be paid to the physical safety of the environment. The environment should be designed keeping in mind the perceptual changes and disorientation that can occur under the influence of hallucinogens. Thus, any potentially dangerous objects (e.g. furniture with sharp corners; glass lamps) should be avoided. If there is a window in the room, the investigators need to be confident that the volunteer could not exit the window if in a delusional state. Additionally, the session room should not have a telephone, and the participant should surrender her or his cellular telephone before the session. Not only may an incoming telephone call be distracting or alarming while under the influence of a hallucinogen, but it may also represent a safety risk, as Strassman (2001) has reported a case in which a participant used a session room telephone to call a companion, which culminated in the two fleeing the study site. Having a private restroom located near the session room would be ideal for volunteer use during the session. A shared restroom may be used if the monitors ensure that the volunteer does not interact with non-study personnel while going to the restroom (more details under the section: *Conduct of hallucinogen administration sessions*). Of course, most research laboratories do not provide the ideal physical environment. Thus, resourcefulness and ingenuity may be necessary to convert a less than ideal location into a relaxing and secure environment.

Preparation of volunteers

As with any human research with psychoactive drugs, volunteer preparation at the earliest stages must include a thorough review of the consent form, which should include in plain language the range of experiences that may result from hallucinogen administration, including changes in perception, sense of time and space, and emotion (possibly including anxiety, fear, panic and paranoia). Relative to other drug classes, the subjective effects of hallucinogens are likely more difficult to describe to a naïve volunteer; therefore, additional time may be necessary to fully discuss these potential effects with volunteers. The consent form should also include the approximate timecourse of the drug, the state of knowledge concerning its toxicity profile, and its status as an experimental drug. In addition, the consent form should state that there is a relatively small risk of adverse effects that last for hours to days after the hallucinogen session. These include mood disorders (such as depression), psychotic disorders and anxiety disorders. It should also state that there are rare reports in which hallucinogen exposure appears to cause, accelerate or precipitate the onset of significant or lasting psychiatric illnesses such as psychoses and intermittent or persisting visual perceptual abnormalities ('flashbacks', HPPD).

The next step in volunteer preparation is to conduct a series of meetings between the monitors and volunteer to build rapport and trust. The relationship between the monitors and the volunteers should be well established by the time of the first session (Masters and Houston, 1966). In the Johns Hopkins studies, there are at least eight contact hours over the course of at least four meetings, usually over a 1-month period. One of these preparatory meetings should be conducted in the room in which the hallucinogen is to be administered, to familiarize the participant with the physical environment. The primary monitor meets with the volunteer during all of these meetings, while the assistant monitor is required to be present on at least one occasion. It is important that the assistant monitor, in addition to the primary monitor, has developed a trusting relationship with the volunteer because this assistant monitor will be the only person in the session room with the volunteer if the primary monitor needs to leave briefly.

During these preparatory meetings, the monitors discuss meaningful aspects of the volunteer's life. The main purpose of the participant-monitor meetings is to develop rapport and trust, which we believe helps minimize the risk of fear or anxiety reactions during the hallucinogen session. This typically includes discussions of the volunteer's childhood, romantic life, current relationships with family and friends, and the volunteer's philosophical and/or spiritual beliefs. Reviewing personal history and feelings may be important for two reasons. First, this discussion helps establish a significant level of trust. The interaction should convey that all aspects of the person are welcome, from the petty to the noble, from embarrassments to achievements and from sorrow to joy. By the time of the hallucinogen session day, the volunteer will ideally feel completely comfortable with the monitors, reducing the likelihood of paranoia (e.g. feeling that the monitors are trying to control her or his mind, or have deceived the volunteer about the nature of the study). Second, related personal material may 'emerge' under the effects of the hallucinogen. That is, the volunteer may experience intense thoughts, feelings and visions related to his or her personal history or world-view. Knowing about the volunteer's life will allow the monitors to better understand her or his session experience and help the monitors in providing interpersonal support should strong emotions arise. If it is felt that sufficient rapport and trust have not developed during these monitor meetings, then either additional contact hours should be provided, or the volunteer's participation should be cancelled. A high dose of a hallucinogen should not be administered to a volunteer if sufficient trust has not been established. As with other forms of human research involving the development of rapport and trust (e.g. clinical trials involving psychotherapy), investigators should be careful that this rapport and trust does not create a situation in which the volunteer feels obligated to remain in the study. Volunteers and monitors should be clear that participation is voluntary, and that the participant will be fully supported if her or his decision is to quit the study.

At some point during preparatory meetings, time must be devoted to explain the study logistics. These should include the timing of the session (e.g. what time to arrive at the laboratory if an outpatient study, what time the session is likely to end), any restrictions on diet or contraindicated medicines, drugs or nutritional supplements (e.g. if fasting or a low-fat diet is required the morning before session), and any requirements of other people (e.g. if a family member or friend is to pick up the participant at the end of the session).

This discussion should also include thorough descriptions of study procedures, to the degree allowable by blinding issues. For example, if cognitive or memory tests are to be performed, or questionnaires are to be answered, the participants should be aware of these requirements. If physiological measures, such as blood pressure, are to be taken during the time of drug action, this also should be explained. The activities during hallucinogen action will naturally depend on the scientific questions under investigation. Whatever the nature of the experiment after hallucinogen administration, the scenario should be thoroughly discussed with the volunteer in preparation. In some cases, such as with brain imaging research, it may be helpful for volunteers to be run through a preliminary research session to familiarize them with the equipment and procedures. Some studies have conducted an initial non-blind hallucinogen administration session in which safety measures are assessed before subsequent blinded sessions to, among other reasons, acquaint volunteers with the effects of the drug before the introduction of additional, potentially anxiety provoking measures (e.g. blood draws) (Strassman and Qualls, 1994; Strassman, *et al.*, 1994, 1996).

The preparation of the volunteer should involve a detailed discussion of the possible range of experiences that may be encountered after hallucinogen administration. This includes the typical onset and duration of the drug(s) under investigation. Preparation involves discussion of the various potential physical sensations, such as nausea or heightened awareness of physiological processes, such as breathing and heartbeat. Volunteers are encouraged to trust that their bodies will continue to function properly regardless of such sensations, and that these bodily processes will continue without the volunteers' volitional control.

The major categories of potential psychological experiences during hallucinogen action should be discussed with the participant. The range of subjective experience under hallucinogens can be remarkably broad (Blewett and Chwelos, 1959; Richards, 1980; Masters and Houston, 1966; Strassman, 2001; Nichols, 2004; Stolaroff, 2004). This range of experiences includes perceptual changes, such as visual illusions, intensification of colours, proprioceptive changes (e.g. one's body may feel gigantic or tiny), and synesthesia (e.g. seeing sounds or hearing colours). Another type of possible experience is the alteration of emotions, such that emotions of either a positive or negative nature may be greatly intensified, yielding experiences that may range from euphoria to despair. Another category of possible effects involves changes in the sense of time and space. At the extremes, time and/or space may be experienced as infinite or nonexistent. Other experiences may include thoughts, feelings or insights concerning one's personal history (e.g. revisiting childhood memories) or current life circumstances (e.g. relations with loved ones), highly symbolic experiences (e.g. involving religious symbols, animals, etc.), and experiences described by some to be of a mystical or spiritual nature. Importantly, it should be emphasized that these experiences may consist of much more than the participant subjectively observing internal and external events. Rather, the effects may involve a profound change in one's sense of self, such that one feels as if he or she is merging into the surrounding environment or the entire universe (Schultes, *et al.*, 2001). The individual may temporarily experience a complete loss of subjective self-identity, a phenomenon sometimes referred to as 'ego loss' or 'ego death' (e.g. Leary, *et al.*, 1964; Grof and Halifax, 1977; Grof, 1980). While a detailed discussion concerning the range of possible hallucinogen effects will enhance safety by psychologically preparing the participant for the unique and often intense effects of a hallucinogen, it may also serve to undermine the blind. That is, such preparation may train the participant on how to identify a hallucinogen by its effects. Nonetheless, the primary concern must be the participant's safety. Therefore, researchers must minimize the potential for unblinding by manipulating other aspects of the experimental design, such using hallucinogen-naïve participants or the use of an active placebo (e.g. Griffiths, *et al.*, 2006).

The volunteers should be given guidance on how to handle difficult hallucinogen experiences. Whether the disturbance consists of frightening illusions or internal imagery, difficult thoughts and feelings about some past or present personal issue, or anxiety related to a radical change in sense of self (e.g. temporary loss of self-identity), the volunteer is encouraged to mentally surrender to the experience, trusting that her or his usual state of consciousness will return when the drug effects resolve (Blewett and Chwelos, 1959; Masters and Houston, 1966; McCabe, 1977). For example, if the participant experiences disturbing internal imagery of a demon or monster, he or she is encouraged to mentally approach the figure and interact with it (e.g. imagine asking the figure why it has appeared), rather than attempt to flee from the disturbing imagery. The participant should be alerted that sometimes people experience extremely convincing sensations of dissolving, melting, exploding and so forth, and that the best way to deal with all such situations is to surrender to the experience, subjectively allowing oneself to dissolve, melt or explode. Similar advice applies to physical symptoms such as nausea; for example, participants may be encouraged to 'dive in' to their stomachs, which may alleviate the nausea, as it has been suggested anecdotally that nausea and other somatic discomforts may in part be of a psychosomatic nature (Blewett and Chwelos, 1959; Masters and Houston, 1966).

The preparation of volunteers for hallucinogen administration will require balancing the ethical requirements to prepare the volunteer for the potentially powerful psychological effects of hallucinogens, with the scientific concern not to bias the volunteer with respect to the dependent variables. This is especially true because classical hallucinogens have been shown to increase suggestibility in an experimental model involving body sway (Sjoberg and Hollister, 1965; Middlefell, 1967), and suggestibility has been proposed as a potential mechanism of the possible therapeutic efficacy of hallucinogens (Dobkin de Rios, *et al*., 2002; Barbosa, *et al*., 2005). That is, one could argue that examples conveyed during preparation are then experienced during the session only due to an increased level of suggestibility during hallucinogen action. Increased suggestibility would seem to be of greatest concern as a confound when investigating the phenomenology of subjective hallucinogen-occasioned experience (e.g. the study by Griffiths, *et al*. (2006), demonstrating that psilocybin can occasion mystical-type experiences under supportive conditions). In the study by Griffiths, *et al*. (2006), although experiences of a spiritual variety were included among the range of possible effects conveyed in preparation, the monitors emphasized that these experiences were not the only variety of interesting or valuable effects that might occur. Specific categories of mystical-type experience to be assessed in measures were not discussed. In the Johns Hopkins studies, we have not encouraged participants to read the diverse and widely varying published accounts of hallucinogen effects as part of their preparation, because this may introduce compelling idiosyncratic expectations. Our research has proceeded safely by delivering all such preparatory information to participants verbally during presession meetings with monitors. Researchers will need to design studies such that a maximum amount of preparation is provided for safety reasons, while not confounding the particular hypotheses being studied. Furthermore, controlled studies should ensure that the unique preparation methods and research environment qualities described herein are in place, under double-blind conditions, for both hallucinogen and placebo groups (or conditions). For example, in the study by Griffiths, *et al*. (2006), the use of identical procedures under double-blind conditions for psilocybin sessions and the active placebo (a high dose of methylphenidate) sessions permitted a reasonable degree of control over suggestibility.

Conduct of hallucinogen administration sessions

As with research with many other psychoactive drugs, a physician should be available during hallucinogen sessions, should any untoward medical complications arise. Furthermore, medication for the treatment of acute hypertension (e.g. intravenous labetalol) should be immediately available in the event that blood pressure exceeds predetermined safety parameters.

Adverse psychological reactions to hallucinogens will be minimized when studies are conducted under conditions that provide strong interpersonal support to the participants (Blewett and Chwelos, 1959; Chwelos, *et al*., 1959; Pahnke, 1969; Masters and Houston, 1966). The monitors should carefully observe the participant and be vigilant for signs of psychological distress. If the volunteer needs to walk to complete study tasks or to go to the rest room, the monitors should stand close by to assist by gently holding an arm or shoulder. Even with high doses of hallucinogens, individuals do not typically show substantial motor impairment, and will likely be able to ambulate without considerable difficulty (with the exception of hallucinogens such as parenteral DMT with abrupt effects and short duration of action). However, perceptual and proprioceptive effects may make walking disorienting, which is why gentle guidance may be helpful. One of the monitors should always be present in the session room with the participant. Because the session monitors will have developed rapport and trust with the participant, they should be the only people to interact with the volunteer during the course of hallucinogen action, barring any non-routine event (e.g. fire alarm, medical intervention by a specialist). Individuals who are anticipated to have contact with the volunteer during the course of hallucinogen action (e.g. nurse, physician) should have at least met with the volunteer once prior to session to develop some degree of rapport and trust.

For all but the shortest acting hallucinogens (e.g. parenteral DMT), the participant is likely to need to use the restroom at some point while experiencing hallucinogen effects. If a private restroom is not available, then study staff should escort the volunteer to assure that no one is in the restroom. Either the restroom door needs to have no lock, or study staff should have a key readily available if needed. Cohen (1960) reported a case in which a depressed patient who had been administered LSD barricaded himself into a room to attempt suicide. In the Johns Hopkins studies, sessions are conducted in a room located on the third floor of a research facility. The session room itself has a private restroom just outside of the session room. During sessions, the volunteer is closely escorted to the restroom and a session monitor waits just outside the restroom to be available if the volunteer should encounter any difficulties. Furthermore, waiting in this area outside the restroom allows the monitors to ensure that the volunteer does not exit the research site. Any attempt by a disoriented volunteer to leave the session area would be met with compassionate but firm direction to return to the session room.

Serious attention must be devoted to the possibility of volunteers trying to leave the study site under the influence of a hallucinogen. Walter Pahnke's (1963) dissertation study (known as the 'Good Friday Experiment') examined the ability of a high dose of psilocybin to occasion mystical experiences by administering either psilocybin or placebo (randomly assigned) to seminary students in a small, basement chapel into which a Good Friday service from the main sanctuary was broadcast. A retrospective investigation conducted over 25 years after the original experiment revealed that two volunteers left the chapel under the influence of psilocybin (Doblin, 1991). One of these volunteers reported feeling imprisoned in the chapel and left the chapel during a portion of the experiment. The other volunteer abruptly left the chapel believing that God had chosen him to immediately announce to the world the dawning of an age of peace (Roberts and Jesse, 1997; Smith, 2000). This volunteer was apprehended by the research staff and administered the antipsychotic agent chlorpromazine after efforts to calm him were unsuccessful (Doblin, 1991; Roberts and Jesse, 1997; Smith, 2000). Strassman (2001) also reported an incident in which a participant experiencing the full effects of a high dose of psilocybin evaded the research staff and left the research site. Fortunately, the participant's spouse monitored the participant and no one was injured.

The risks of allowing a research volunteer experiencing the effects of a hallucinogen to leave the study site are significant. For example, in a bewildered or delusional state, the person might walk into traffic or attempt to drive. Although many hallucinogen users maintain reasonable control while under the influence of hallucinogens, panic or delusional reactions to hallucinogens have in rare circumstances resulted in tragic consequences, such as jumping out of windows (Keeler and Reifler, 1967; Reynolds and Jindrich, 1985; Reitman and Vasilakis, 2004; O'Brien, 2006). Interestingly, the volunteer who fled Strassman's (2001) study site on psilocybin was a carefully screened, experienced LSD user. Therefore, it is imperative for safety reasons that the study site environment, session procedures and participant preparation all minimize the chance of a volunteer leaving the study site.

Strategies for handling non-routine scenarios should be considered. For example, how are study monitors and the volunteer expected to respond in the event of a fire alarm or fire? On the single occasion at Johns Hopkins in which a fire alarm sounded during a session, the two study monitors closely escorted the volunteer outside, making sure to minimize contact with other individuals. The three of them walked to a nearby quiet area with an attractive landscape and enjoyed the scenery until the volunteer and monitors could return to the building. The monitors encouraged the participant to view the occasion as an opportunity to enjoy the natural world outdoors (something normally unavailable during sessions), rather than as an impediment to having a successful session. If any non-routine events occur, the monitors should maintain contact with the volunteer throughout.

If participants become anxious during the course of hallucinogen action, it is now widely recognized that the appropriate first response is to provide strong personal support and reassurance (O'Brien, 2006). This primarily includes interacting with the volunteer in a comforting and reassuring manner. If the volunteer is behaving anxiously and a negative psychological reaction seems to be escalating, the monitors should convey a solid sense of security and calm, while empathizing with what may be an incredibly intense and unpleasant experience. Attempts to 'talk down' the participant (i.e. the use of reality-defining techniques to distract the participant from or attenuate the altered state of consciousness) may be counterproductive and aggravate a difficult reaction (McCabe, 1977). Instead, participants should be reminded to surrender to the experience.

Appropriate forms of reassurance may include a supportive touch to the arm or shoulder with verbal reminders that the participant is in a research study, has taken the hallucinogen, and that he or she will return to normal consciousness in 'a few minutes' or 'a few hours' (or whatever the appropriate estimate may be, depending on the specific drug under study and when it was administered). During an intense hallucinogen-occasioned experience when verbal interactions may be of limited help, a powerful form of reassurance (sometimes called 'interpersonal grounding') is simply holding the hand of the participant (McCabe, 1977). Many volunteers report that during such experiences, a reassuring hand provides an incredible sense of stability and connection. Monitors should demonstrate this practice during preparation to normalize hand holding during sessions.

If volunteers have been appropriately screened and the guidelines herein followed, reassurance should be sufficient to diffuse acute psychological distress in the vast majority of cases. For example, in recent studies in our laboratory, in which we have administered high doses of psilocybin to 54 volunteers, reassurance has been sufficient to handle all cases of acute psychological distress that have arisen. Although pharmacological intervention is a last resort and should rarely, if ever, be needed, medications should be readily available for use if the need arise. For cases in which acute psychological distress is insufficiently managed with reassurance alone, treatment with a benzodiazepine anxiolytic is the pharmacological intervention of choice (Abraham and Aldridge, 1993; Frecska and Luna, 2006; O'Brien, 2006). In these cases, we recommend a 10 mg oral dose of diazepam (Grinspoon and Bakalar, 1979), although oral doses of 15-30 mg per hour or every few hours as needed have been recommended for pharmacological treatment of 'bad trips' that do not respond to reassurance in emergency department settings (Ungerleider and Frank, 1976). Because of its high lipid solubility, diazepam has a more rapid onset, a shorter time until peak plasma concentration and a shorter duration of therapeutic action than many other benzodiazepines including lorazepam, despite the fact that lorazepam has a shorter elimination half-life (Greenblatt and Shader, 1985; Funderburk, *et al.*, 1988). Although the intravenous route may be considered, the oral route is preferable because intravenous injection procedures may further exacerbate the participant's anxiety. Moreover, antipsychotic medications (e.g. risperidone, olanzapine) should be available in the event that an adverse reaction escalates to unmanageable psychosis. However, experienced clinicians have suggested that although antipsychotic medications may reduce psychotic behaviour through sedation, their use may be problematic because the effects may be abrupt, unpleasant and intense and their use may result in subsequent psychological problems (McCabe, 1977; Grinspoon and Bakalar, 1979; Grof, 1980). Furthermore, pretreatment with the antipsychotic haloperidol has been shown to exacerbate the psychosis-like effects of psilocybin (Vollenweider, *et al.*, 1998), suggesting that haloperidol should not be used as a rescue medication. Although not approved for use in the USA, ketanserin (a 5-HT$_{2A}$ antagonist) pretreatment has been shown to attenuate psilocybin effects (Vollenweider, *et al.*, 1998), suggesting possible use as a rescue medication for hallucinogen administration. Ultimately the decision to medicate will depend on whether the monitors and responsible physician judge that they are capable of maintaining the safety of the volunteer and others without medical intervention. Bringing the participant to the emergency department represents an ultimate 'last resort' in the treatment of a very difficult (i.e. psychotic) reaction. However, medical evaluation by well-meaning emergency department personnel, who are inexperienced with hallucinogen effects can readily escalate and prolong an adverse reaction. Therefore, all possible efforts should be made to treat a difficult experience in the session context, even if pharmacological intervention is required.

The conduct of the session will largely be based on the particular research topics being studied. The research requirements of many types of studies will require the participants to adhere to regimented testing conditions (e.g. cognitive tests, memory tests, brain scans). In such investigations, interference with procedures may be minimized by judiciously selecting dose and the hallucinogen experience level required of volunteers. Adverse reactions will generally be more likely at higher hallucinogen doses; however, adverse reactions can potentially occur at any dose level. Experienced hallucinogen users may be particularly appropriate participants for studies involving challenging conditions, such as remaining immobile for long periods in a confining brain imaging scanner. Regardless of experience level and dose, however, the possibility of psychological adverse reactions exists whenever a hallucinogen is administered. To the degree possible, investigators should attempt to implement their scientific protocols as planned. However, monitors should always be vigilant for potential adverse psychological reactions. In the event of a significant adverse psychological reaction, interpersonal support should be provided even if it interferes with data collection. Clearly, volunteer safety must take priority over scientific procedures. In studies such as ours, in which participants are encouraged to focus their attention inward by wearing eyeshades and listening to music through headphones, our advice is for monitors to occasionally probe the volunteer's psychological well-being (e.g. ask the volunteer, 'Would you like to describe where you find yourself?') to ensure that the volunteer is not experiencing significant anxiety and is in need of support.

For studies that investigate potential therapeutic effects or the phenomenology of hallucinogen experiences (i.e. studies that do not require participants to engage in research tasks during the session), the employment of eyeshades and headphones (through which supportive music is played) may contribute to safety by reducing the distractions of environmental stimuli and social pressures to verbally interact with research personnel. This may be especially important for volunteers who are experiencing the effects of a hallucinogen for the first time. Typically, we have kept eyeshades and headphones in place for most of the session. In the latter hours of the session some time is spent with the volunteer sitting on the couch, interacting without eyeshades and headphones, although music may still be played through speakers to provide nonverbal structure and continuity. As a whole, we encourage our participants to 'collect experiences' to discuss after the drug effects have abated, and discourage attempts to analyse material or communicate excessively while the atypical states of consciousness are still occurring.

After the effects of the hallucinogen have resolved, the participant should either be released into the care of a friend or family member or required to stay overnight at the research site for monitoring. If participants are released from the study site after the session, they should be instructed not to drive an automobile or engage in any other potentially dangerous activity for the remainder of the day. At Johns Hopkins, volunteers are released into the care of a friend or family member, who has been appropriately oriented by our staff to be available to emotionally support the participant, but also to provide space (i.e. be in another room) if the participant feels the need to be alone. We have also given the participant the primary monitor's pager number to call if he or she feels the need for support that evening. Of the 54 volunteers tested at a high psilocybin dose to date, no one has paged the monitor, although volunteers do seem to appreciate this opportunity for additional support.

Post-session procedures

After the session, safety monitoring should continue in the form of one or more post-session meetings (typically the next day) between the primary monitor and participant to ensure psychological stability and provide an opportunity for the volunteer to discuss thoughts or feelings from the session. As with any acute, intense positive or negative emotional experience, participants often feel the need for, and seem to benefit from, additional time for reflecting on the novel thoughts and feelings that may have arisen in the session. Given the potentially intense and unusual psychological nature of hallucinogen effects, the volunteer may have difficulty discussing the experience with others in her or his life. Because the monitors were present during the session when the hallucinogen effects were experienced and have knowledge of a broad range of reported phenomena during drug action, the volunteer may feel more comfortable discussing her or his experience with the monitors than with others. This follow-up contact also allows the assessment of any potentially persisting adverse effects, including perceptual abnormalities. More than one post-session meeting may be necessary if the volunteer is experiencing psychological difficulty concerning thoughts and feelings encountered during the session. Of the 54 volunteers tested with a high dose of psilocybin at Johns Hopkins to date, none has shown evidence of persisting psychosis or psychological problems related to their sessions, and all have returned to their normal daily activities. If the primary session monitor is not a clinically trained psychologist or psychiatrist, it is prudent for research teams to have available for consultation a clinically trained psychologist or psychiatrist familiar with altered states of consciousness, who can work with patients who appear to have developed psychological difficulties stemming from hallucinogen administration.

Concluding remarks

After a decades-long period of dormancy in response to the sensationalism surrounding the nonmedical use of hallucinogens during the 1960s, human hallucinogen research has resumed in the USA and Europe, and is now beginning to address a variety of important basic research questions as well as potential therapeutic applications (Nichols, 2004). In light of the unusual history of restriction on human research with this class of compounds, it is critical for investigators to implement appropriate and conservative safeguards. With such safeguards this class of compounds can be studied safely in humans. Careless research that lacks attention to the unique risk profile of hallucinogens may not only endanger the safety and well-being of the research participants, but may also jeopardize future human research with these scientifically fascinating compounds. On the other hand, carefully conducted research that respects hallucinogens' unique and often powerful psychological effects may potentially inform the treatment of various psychiatric disorders, as well as lead to significant advances in our understanding of perception, cognition, behaviour, the psychology of religion and the biological underpinnings of consciousness.

Acknowledgements

Support for preparation of this manuscript was provided by grants from NIH (R01 DA03889), the Council on Spiritual Practices and the Heffter Research Institute. We thank George Greer, MD, Charles Grob, MD, Robert Jesse, Annie Umbricht, MD and Franz Vollenweider, MD for helpful comments on previous versions of this manuscript. We also thank the staff of the Johns Hopkins psilocybin research studies, whose insights have contributed to these guidelines, including Mary P. Cosimano, MSW and Brian D. Richards, Psy.D. for their roles in screening volunteers and monitoring sessions, and Lawrence P. Carter, PhD, Ryan K. Lanier, PhD, Benjamin McKay, Chad J. Reissig, PhD, and Ryan G. Vandrey, PhD for their assistance in monitoring sessions.
